Machinery.

ENGINEERING EDITION.

Index to Vol. X.

September, 1903, to August, 1904.

LIBRARY
IVERSITY OF ILLINOIS

1904.

THE INDUSTRIAL PRESS.
66 WEST BROADWAY.
NEW YORK.

Index to Volume X.

- Alloys of High Tensile Strength. Herbert E. Field 315
- Alloys Suitable for Bearing Purposes, A Study of..... 66
- Alloys, Zinc Aluminum 514
- Alternating-current Motors for Railway Work—American Developments. Wm. Baxter, Jr. 304
- American Blower Co.'s New Office Building 14
- A. S. M. E., Dec., 1903, Meeting 227
- A. S. M. E. Meeting in Chicago, May 31 417
- A. S. M. E., Twenty-fourth Annual Meeting of the... 251
- Automobiling, Early 402

- *Baltic*, The New White Star Steamer 662
- Bauer Propeller-blade Shaping Machine 132
- Baxter, Wm., Jr.:
  - Variable Speed Motors, 395, 452, 512, 573, 636
- Beams and Planes Severally Supported and Eccentrically Loaded, Problems in. C. F. Blake 571
- Beams, Flexure of (Flexure Simplified) 194
- Bell, A. R.:
  - Centenary of the Locomotive, 1803-1904 257
  - Early Steam Engines.... 509
- Betts Machine Co., The Reconstructed Shop of the.. 22
- Bicycle Two-Speed Gear, The Columbia 531
- Birnstock, W. W.:
  - Table for Computing the Cost of Castings 536
- Blake, C. F.:
  - Notes on Design 362-397
  - Problems in Beams and Planes Severally Supported and Eccentrically Loaded 572
- Blowing Engines with Mechanically Operated Piston Valves for Air Cylinders 187
- Boiler Bracing. Charles L. Hubbard (1) 18
  - (2) Calculations for Through Stays 82
- Boring Mill, The "Betts" Worm-driven 25
- Boring Mill, The Poole Worm-driven 81
- Bridge, New Williamsburg, Opened to Pedestrians, Dec. 19 228
- Brown, Walter:
  - High Speed Tool Steels.. 534
- Bullock Electric Mfg. Co., Shop No. 3 of the 283

- Cams, Making Master 603
- Camming the Brown & Sharpe Automatic Screw Machine, Directions for. Ralph E. Flanders 6
- Card Index in the Drafting Room, The 152
- Cast Iron, Process for Hardening 578
- Castings, Table for Computing the Cost of. W. W. Birnstock 536
- Centenary of the Locomotive, 1803-1904. A. R. Bell... 457
- Chain, Notable Installation of the Renold Silent..... 456
- Cincinnati Shaper Co., New Shop of the 116
- Clutch, A New Form of Friction 100
- Cole, Arthur W.:
  - An Air Lubricated Journal 468
- Colvin, Fred H.:
  - Cutting Fractional Screw Threads 143
  - Injector Troubles and Repairs 337
- Compressed Air as an Insulator 518
- Coolidge, C. E.:
  - Spiral Gears 30
  - Comments on Drives for High Speed Cutting Tools 507
- Coupling, The Storz System of Pipe 307
- Crane Motors, Alternating Current 467
- Crane, Niles 40-ton Traveling Yard 195
- Cranes, The Use of Magnets in Connection with. Dr. Alfred Gradenwitz 590
- Curtis Steam Turbine and Its Manufacture, The 1
- Cutter Working on a New Principle, A Milling 354
- Cutting Fractional Screw Threads. Fred H. Colvin. 143

- Death of Robert H. Thurston, Sudden 134
- Deep Drilling. Frank B. Kleinhans 244
- Design of Punch and Riveter Frames. John S. Myers.. 127
- Design, Notes on. C. F. Blake:
  - (1) Machinery Shafting.. 362
  - (2) Machinery Shafting, (concluded) 397
- Designation of Standard Machine Parts 215
- Die Head, Adjustable, and Method for Making Threaders for Use in same. Jos. M. Stabel 207
- Die Making, Notes on. Frank E. Shailor 649
- Differentiation of Engineering, The 27
- Drawing, Mechanical, and the Shop 20
- Drilling Machine, Le Blond Automatic Index Plate... 346
- Drives for High-Speed Cutting Tools, Comments on. C. E. Coolidge 507
- Dynamos, Humming of..... 666

- Eccentrolinead, The. M. S. Smith 535
- Electricity from Fuel, The Reid Process of Producing 254
- Emerson, F.:
  - Talk on Lathe Spindles... 485
- Engine with Corliss Gear, A Marine 181
- Engineering Knowledge, Indication of the Advance of. 509
- Engineering, The Differentiation of 27
- Engines, Early Steam 509
- Estimating Time for Lathe Work. Henry Hess 449
- Explosions, Compressed Air. 402
- Exposition, Question of Power at the St. Louis.. 352
- Exposition, The Louisiana Purchase 68
- Exposition, The St. Louis.. 77
- Editorial:
  - Alcohol for Industrial Purposes 350
  - Allis-Chalmers Co., New Ventures of the 419
  - A New Old Engine...... 16
  - Are the Claims for Education Made Good?...... 76
  - Are We Eager to Learn? 472
  - Asked to Ante-up....... 654
  - Automatic Sprinklers on Shipboard 655
  - Automobile, The Dangerous 299
  - Compressed Air and Machine Tools 530
  - Cunard Company Leads off 473
  - Data, Suppressed 472
  - Electricity as a Motive Power for Machine Shops 16
  - Engineers, Examination for Stationary 182
  - Genius, Mis-Directed Inventive 594
  - Government Experiments. 76
  - Haswell, Chas H........ 594
  - Improving the Steam Engine 182
  - Indicator, Regarding the. 418
  - Inventions and What Constitutes Abandonment.. 594
  - Is this General English Practice? 299
  - It Pays To Keep Informed 350
  - Machine Shop Equipment. 419
  - Mill Type of Construction, The 654
  - Motor, Hitching the..... 183
  - One Way to Keep Up the Demand 126
  - Planing Machine, Completion and Exhibition of Sellers 530
  - President Dodge's Address 246
  - "Standard," Use of the Word 417
  - Suggestions That Help... 298
  - Superheated Steam 351
  - Systematic Presentation of Papers 16
  - The Question of Power Transmission 655
  - The Useful Elephant..... 654
  - "Thermit," Lecture Upon. 183
  - To Europe in Sixty Hours 655
  - Turbine Developments, Other 419
  - Where Interchangeability Pays 418

- "Factor of Safety"........ 181
- Fair of '46, Anecdotes of the 40
- Fairfield, Howard P.:
  - Spindle Construction (1). 523
  - (2) 584
- Field, Herbert E.:
  - Alloys of High Tensile Strength 315
- Fireproof Paints, Value of.. 509
- Fitch, Charles H.:
  - Accurate Machine Description 28
- Flanders, Ralph E.:
  - Camming, Directions for, the B. & Sharpe Automatic Screw Machine.. 6
  - Making Master Cams..... 603
- Flexure Simplified. John S. Myers 194
- Floorplate and Concrete Foundation, Long........ 651
- Fore River Ship and Engine Company's Plant, Improvements at the. E. L. C.... 462
- Forming Tools, Straight and Circular, Jos. M. Stabel.. 515
- Foundry and Pattern Departments of the B. F. Sturtevant Co. 121

- Gardner, F. N.:
  - A Talk on the Disk Grinder 547
- Gas Distribution by Gas Power, High Pressure ... 367
- Gas Turbine, The 17
- Gear, The Columbia Bicycle Two-Speed 531
- Gear Cutter, Old: History John Steptoe Shaper Co.. 217
- Gearing, Use of Diagrams and Tables for the Solution of Problems in. Frank B. Kleinhans 357
- Gears, Spiral. C. E. Coolidge 30
- Gordon, J. R.:
  - Some Tools Used in the Manufacture of Globe Valves 427
- Gradenwitz, Dr. Alfred:
  - The Single-phase Motor in Europe 305
  - Use of Magnets in Connection with Cranes.... 590
  - Electrically-driven Portable Tools............ 652
- Grimshaw, Robert:
  - Koehler's Profile Lathe... 528
- Grinder, A Talk on the Disk. F. N. Gardner... 547
- Gun, Breech Mechanism of the 16-inch Coast Defense 176

- Hamilton Corliss Engine Works, The New 231
- Hardening Cast Iron, Process for................. 578
- Heating and Ventilating Plant, Unique 21
- Hess, Henry:
  - Estimating Time for Lathe Work 449
- High-Speed Cutting Tools, Comments on Drives for. C. E. Coolidge 507
- High-Speed Steel 17
- High Speed Steel. E. R. Markham 355
- High-Speed Tool Steels. Walter Brown 534
- High-Speed Tool Steel Tests 300
- Hollow Bloom Tube-making in England............ 666
- Hubbard, Chas. L.:
  - Boiler Bracing 18, 82
- Hydraulic Installations 196

- Index, The Card, in the Drafting Room 152
- Index Plate Drilling Machine, The Le Blond Automatic 346
- Injector Troubles and Repairs. Fred H. Colvin .. 337
- Installation of the Renold Silent Chain, Notable ... 456
- Insulator, Compressed Air as An 518

- Jig Making. Frank E. Shailor 603
- Joint For Propeller Shaft, Universal 428
- Journal, An Air Lubricated. Arthur W. Cole 468
- Jump Drill or Trepan, Extraordinary Shaft Sinking with the 464

- Kaup, W. J.:
  - Metal Coloring 179
- Kleinhans, Frank B.
  - Deep Drilling 244
  - Use of Diagrams and Tables for the Solution of Problems in Gearing .. 357

- Latent Heat Question, The. 453
- Lathe, Hydraulic-Feed 14-inch Boring 335
- Lathe, Koehler's Profile, Robert Grimshaw 528
- Lathe Spindles, Talk on. F. Emerson 485
- Lathe Work, Estimating Time for, Henry Hess ... 449
- Le Blond Automatic Index-Plate Drilling Machine .. 346
- Le Blond Machine Tool Co.'s Shop, R. K. 403

THE CURTIS STEAM TURBINE AND ITS MANUFACTURE.

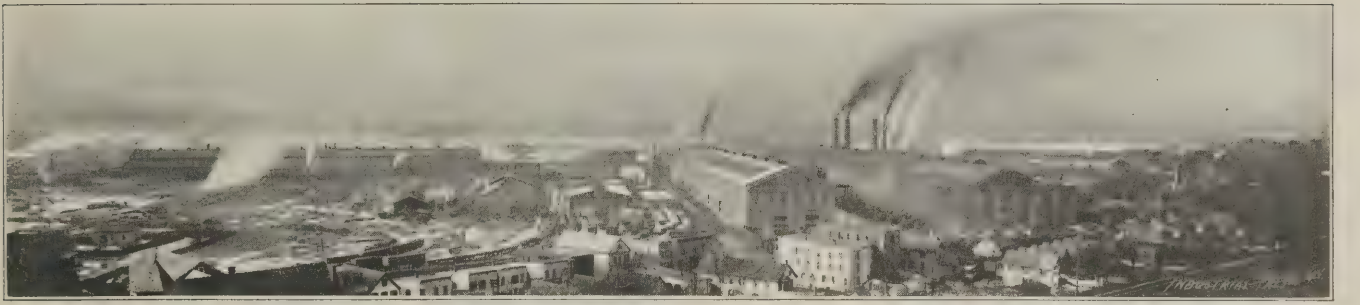

Fig. 1. General View of General Electric Works, Schenectady, from Mount Pleasant.

THE most important development in steam engine work since the time of George H. Corliss has been the advance in steam turbine building during the past ten years; and probably the most interesting step in this development has been the advent of the General Electric Co. in the steam turbine field. De Laval and Parsons had both experimented extensively in their native lands before their products were introduced into this country and when the Westinghouse Machine Company began to build Parsons turbines it was not looked upon as out of the ordinary, for that wheel was well known and the Westinghouse Company had manufactured steam engines for many years.

The General Electric Company, however, have confined themselves almost entirely to electrical machinery and the fact that they have prepared for the manufacture of a steam turbine, as yet but little tried and almost unknown, on a more extensive scale, if we are not mistaken, than any of their competitors, here or abroad, has aroused no little interest and speculation.

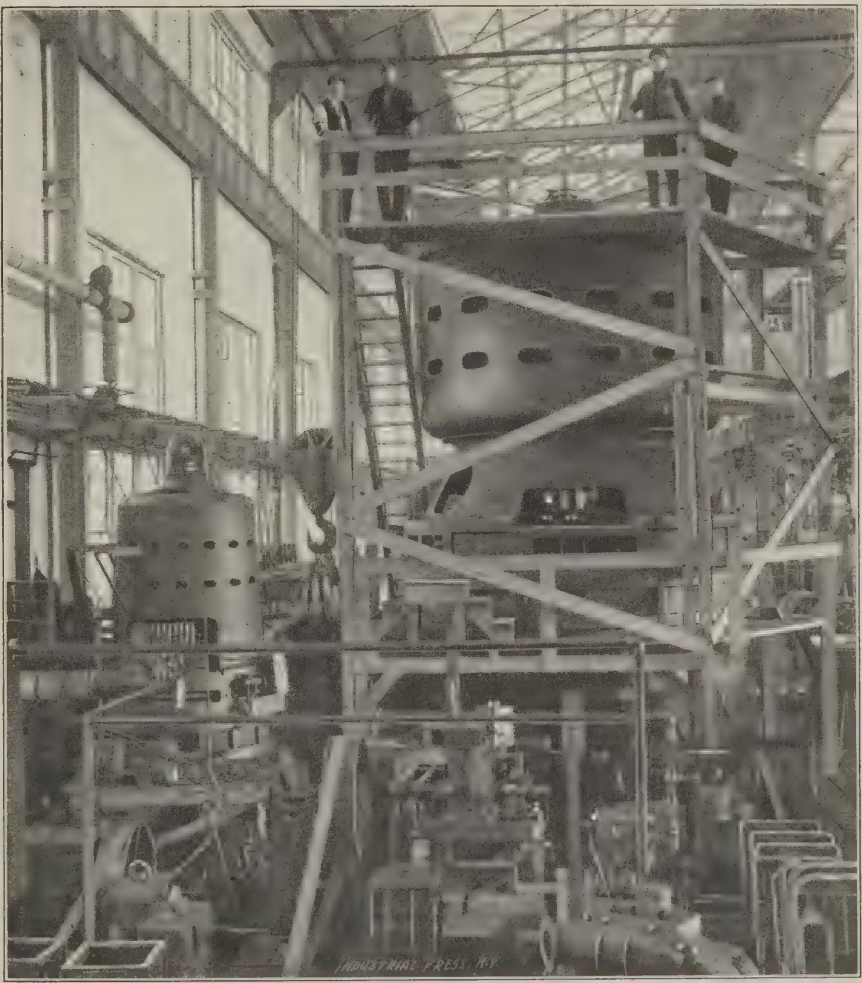

Fig. 2. Erecting the first 5000 K. W. Turbine and Generator. At the left is a 500 K. W. Turbine set under Test.

The first illustration on this page is a view of the General Electric Company's works, Schenectady, N. Y., taken from Mt. Pleasant, an elevation some distance to the rear of the plant. Most of the buildings are situated at the right of the center of the engraving. The largest one, near the center, is the main machine shop, which is one of the largest in the country, and the one at the center, a building 750 feet long by 150 feet wide, is a new structure devoted entirely to turbine manufacture. At the left, where the ground is seen to be broken, a new and larger building is now going up, which will be used for the manufacture of turbines, and as orders are ahead for 240,000 kilowatts of turbine units, it is anticipated that both structures may be needed to accommodate this remarkable business.

The second illustration shows the first 5,000-kilowatt turbine (6,700 horse power), direct-connected to its generator, in process of erection, and beside it a 500-kilowatt machine. The larger turbine was shipped to Chicago, and is one of several to be installed at the Commonwealth Electric station in that city. Compared with the vertical reciprocating engines of like capacity in the station of the Manhattan Railway Company, New York City, the turbine is, of course, very much smaller. It weighs about one-eighth as much, and one of this size can ordinarily be erected, ready to run, in four or five weeks, while the reciprocating engine is liable to require more than that number of months.

The turbine is designed to operate at 500 revolutions per minute and the vertical engine at 75 revolutions per minute. In point of economy the turbine will undoubtedly be greatly superior with fluctuating loads, since one important advantage of steam turbines is that the steam passing through them is not subject to alternate heating and cooling, as in the engine cylinder, and so it makes little difference in the slight loss from condensation whether much or little steam is passing through. It is expected that the variation in efficiency in this machine will not be more than three per cent. from half load to 50 per cent. overload. It is also expected that its regular economy will be better than that of its big competitor, for, granted that the passages through the turbine are correctly proportioned, expansion can be carried much further than in the steam engine. Steam at condenser pressure occupies a great deal of space and to provide for complete expansion in a steam engine the low-pressure cylinder must be impracticably large. There is also the great and irrecoverable loss due to condensation and re-evaporation in the steam engine which is entirely absent in the turbine.

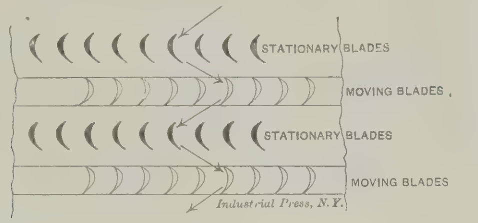

Fig. 3. Diagram of Parsons Turbine.

In Fig. 5 is a reproduction from a photograph of the 5,000 kilowatt machine. It is of vertical type with generator mounted above the turbine, the axis of each being vertical. One of the compound turbine wheels of this machine is shown in Fig. 6 and in Fig. 7 is shown one of the first Curtis turbines built, a 500 kilowatt horizontal machine, which has been running successfully for two years in the power house of the General Electric Company's works. The turbine wheels are arranged in two sets in casings, one on each side of the exhaust pipe appearing prominently in the illustration, and the generator is located at the right.

Before proceeding with further explanation of the Curtis turbine, it will be advisable to outline the general principles of the steam turbine in general, as a type of machine, and then explain the Curtis method of solving the problem. In any steam motor, provision must be made to expand the steam from boiler pressure down to atmospheric or condenser pressure, as the case may be, in order to utilize the full power of the steam. The method of doing this in the steam engine is too well known to need explanation; but in the turbine, where the steam flows in a continuous or nearly continuous current, it must be accomplished by making the passages through which the steam flows with sides diverging and cross-sectional areas gradually increasing. It is only by this means that the potential energy of the steam can be fully converted into kinetic energy, and the steam have its highest possible velocity, which velocity is to be transmitted to the buckets of the wheel and cause the turbine wheel to rotate. Theoretically these passages should increase in area directly as the specific volume of steam at the successive points and inversely as its velocity.

Steam issuing from a nozzle under these conditions will have a velocity of from 3,000 to 4,000 feet a second and if it impinges against the blades of a wheel the latter should have a peripheral velocity of about half this to utilize completely the total energy of the steam. In the De Laval turbine, which operates on this principle, the peripheral velocity is frequently as high as 1,200 feet a second, or as high as safety will permit with the strongest materials for its rotating member.

It is desirable, and in fact necessary, to secure a slower speed of rotation than this for best results, provided there is no sacrifice of economy in consequence, and this is brought about in several other types of turbines through compounding. A compound turbine may be built either for water or steam, and it is entirely possible for a water jet to flow at such great velocity as to make compounding desirable for a water turbine. The principle of compounding is very simple and is thus explained in Bodmer's textbook "Hydraulic Motors:"

"If a turbine is allowed to run at a much lower speed than at the best, the water leaves the buckets with a very considerable absolute velocity, and there is consequent loss from unutilized energy. This energy might, however, be usefully employed in driving a second turbine, the water, after leaving the first, being deflected by a set of stationary guide vanes to cause it to enter the second wheel at the proper angle. Both turbines could be keyed to the same shaft and their speed would be much lower than that of a single turbine driven by the same head of water and utilizing it to the same extent. This arrangement would constitute a compound turbine and it is clear that, instead of two wheels only, three or more might be employed in the same way, the speed being lower the greater the number of wheels. The only object in using a compound turbine in preference to a single one would be to reduce the speed in cases where the head was great and high velocity of rotation inconvenient or impracticable."

There are different methods of taking advantage of this principle of compounding, the first one to attract attention being that of the Parsons turbine, in which the steam flows through the wheel in a direction parallel to the axis and expands continuously from boiler pressure to vacuum. There are alternate rows of guides and vanes as in Fig. 3. The steam flows through a fixed ring of directing blades onto a revolving ring of similar blades, and so on, its pressure being reduced a few pounds, say two or three, at each step. Assume, for illustration, that the steam expands from 100 pounds pressure to zero in its passage and that there are 40 rows of guides and vanes. Assuming the coefficient of expansion to be the same throughout, the pressure would drop 2½ pounds at each step and the velocity of flow corresponding to this difference of pressures would be only about 400 feet per second, as against a velocity of some 3,000 feet per second, such as would occur if complete expansion were to take place in a nozzle at the start, before the steam came in contact with the blades. The theoretically correct peripheral velocity of the turbine wheel, therefore, would be one-half of 400, or 200 feet a second, as against 1,500 feet a second where complete initial expansion takes place.

The Curtis method of applying the compound principle is different from this and enables the wheel to be constructed with a fraction of the number of blades of the Parsons wheel, although it has the disadvantage of possible erosion of the passages, through the use of steam at much higher velocities. This action is much reduced, however, with superheated steam, and we are informed that it is not marked in the machine that has been under test at the works the past two years. In the Curtis turbine a steam nozzle is employed to expand the steam, and give it a high velocity before it comes in contact with the blades, but the expansion is not entirely complete in the nozzle, Mr. Curtis preferring to have a certain amount occur in passing through the wheel to overcome any retardation that may take place through friction between the blades and the steam. The nozzle is a modified form of the De Laval nozzle. The wheel is designed to run at a much lower speed than half the velocity of the impinging steam, so that when the steam issues from the first set of blades it has a high residual velocity; and this, in turn, is taken up in part by a second set of rotating blades, and so on.

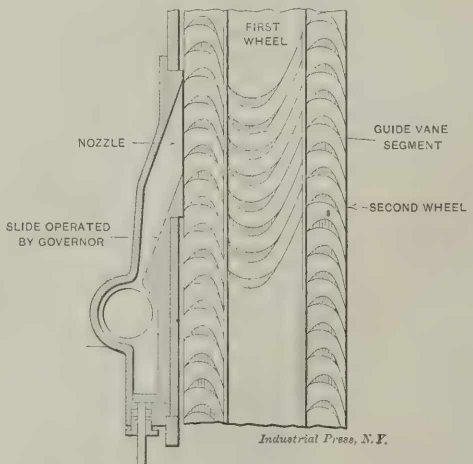

Fig. 4. Diagram of the Curtis Turbine in its Simplest Form.

For illustration, suppose the steam to start with a velocity of 3,000 feet per second; once compounding would reduce the required velocity of the wheel by two, or to 750 feet per second, instead of 1,500 feet, as with a single wheel; and

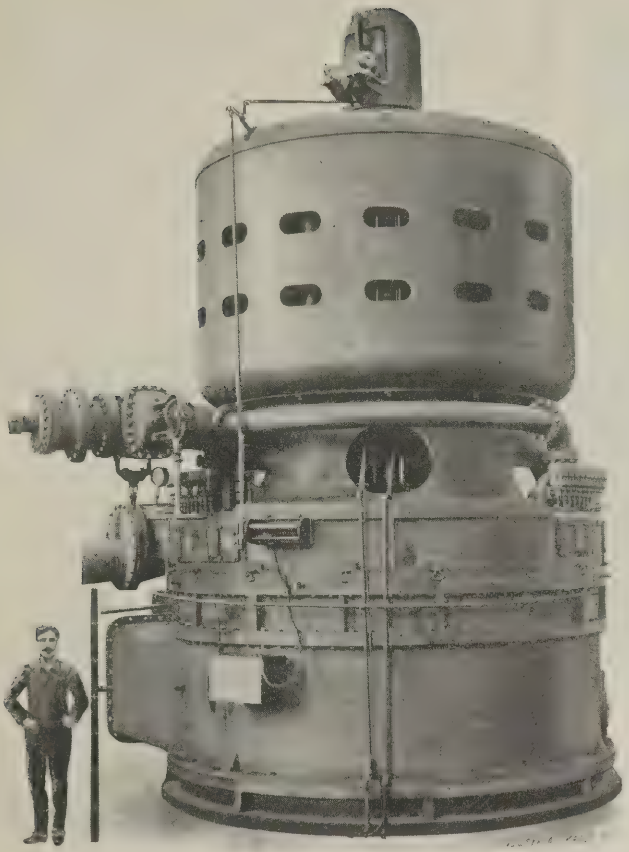

Fig. 5. 5,000 K. W. Curtis Turbine Direct-connected to Generator.

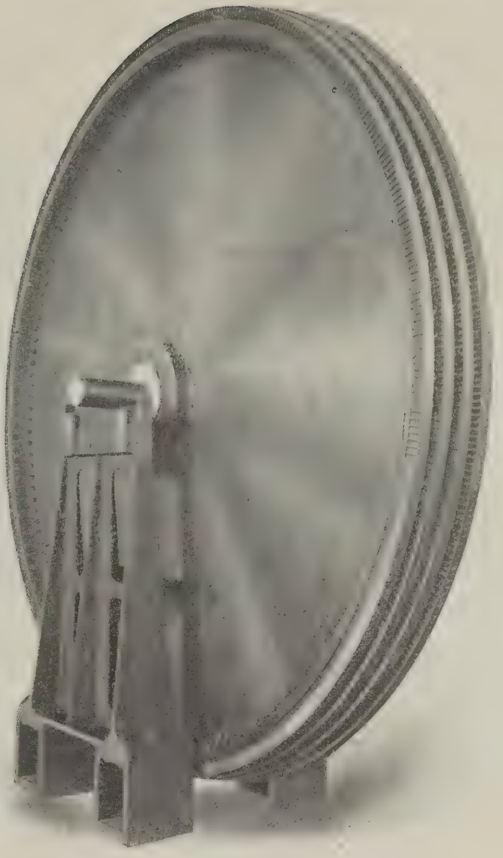

Fig. 6. 5,000 K. W. Turbine Wheel with Buckets Attached.

twice compounding would reduce the velocity to 500 feet per second. This simple illustration shows why the speed reduction under the Curtis system can be attained with so small a multiplicity of parts.

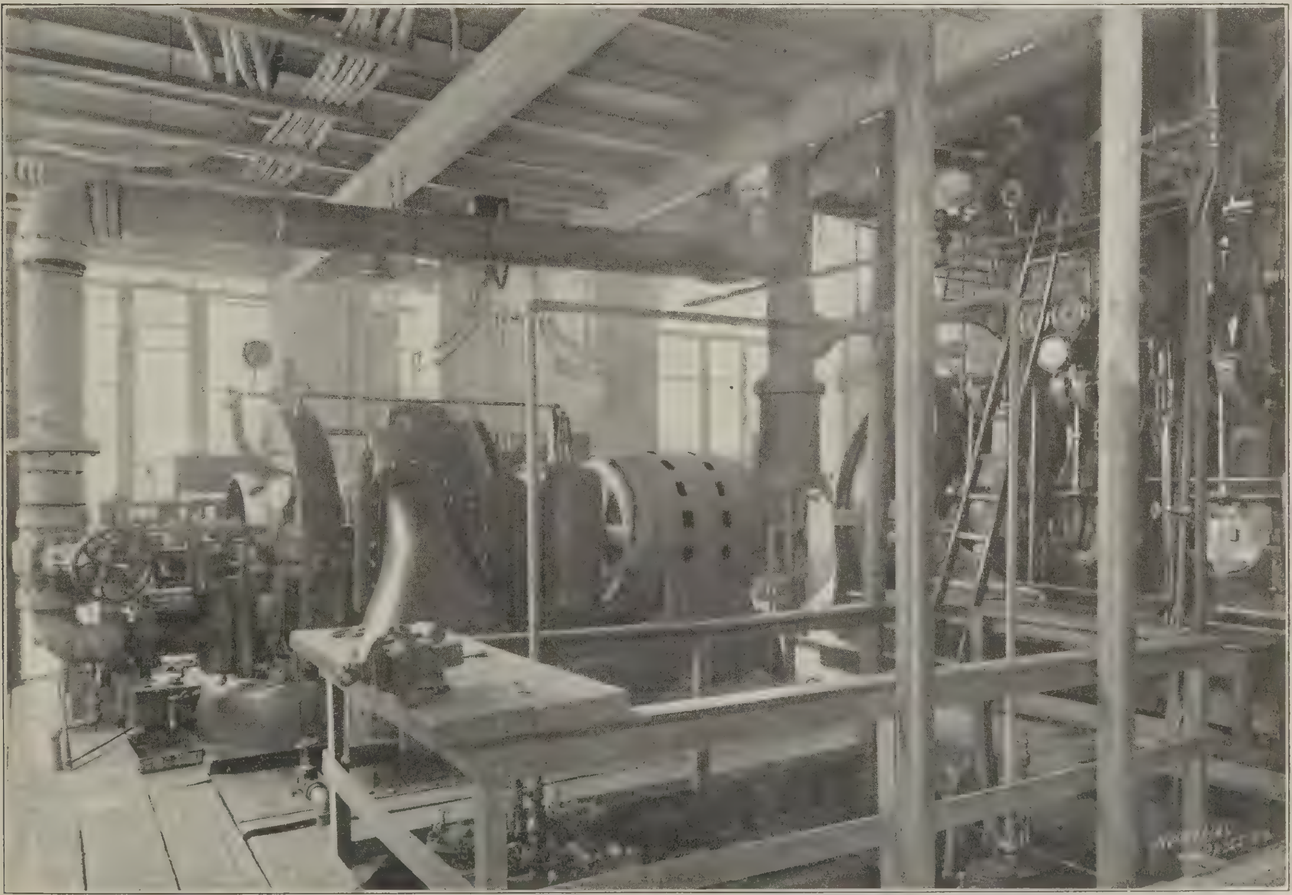

Fig. 7. 500 K. W. Horizontal Turbine, Direct-connected to Generator, operating in Power plant of General Electric Company's Works.

In its simplest form the Curtis turbine consists of two rings of curved buckets, as in Fig. 4, mounted upon disks revolving with the shaft. Between the two revolving rings is a group of curved blades in the form of a short segment fixed to the interior of the turbine case. The nozzle is of rectangular cross section, so designed that one side of it can slide under the action of the governor without altering the ratio between the inlet and outlet area of the nozzle, by which means the quantity of steam delivered is adjusted to suit the load.

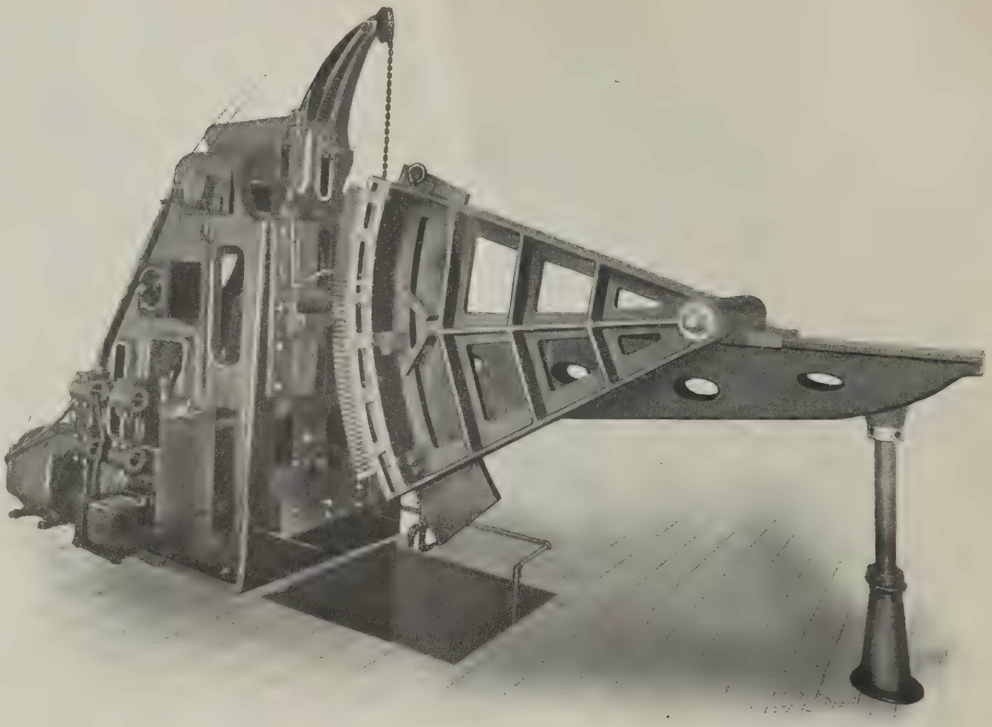

Fig. 8. Riddell Bucket Cutter at work on a Steel Segment, Cutting Buckets out of Solid Stock.

In its practical form, instead of there being a single nozzle, there are several ranged in a row, and instead of two sets of blades there is provision for several stages of expansion. The arrangement is shown in diagrammatic form in Fig. 12. Steam enters through the series of nozzles, forming a broad belt of steam, and the quantity admitted is regulated by a series of poppet valves, one for each nozzle. Regulation is effected by opening or closing these valves automatically, and for fine regulation, involving a less quantity of steam than flows through any one nozzle, throttling in one nozzle is resorted to. In the 5,000 kilowatt turbine there are three sets of these nozzles, spaced at 60-degree angles, and the steam passes through three sets of blades into an intermediate receiver, in which the pressure is approximately that of the atmosphere. From thence it passes through a second set of guide passages, or nozzles, which expand the steam nearly to the vacuum pressure and the velocity of steam is abstracted by three more sets of blades. The second row of nozzles occupies the whole circumference of the wheel, to allow for the great volume of the low-pressure steam. The turbine shaft is supported by a step bearing in which the thrust is taken by oil under pressure. The generator shaft is axially in line with the turbine shaft, and flexibly connected with it.

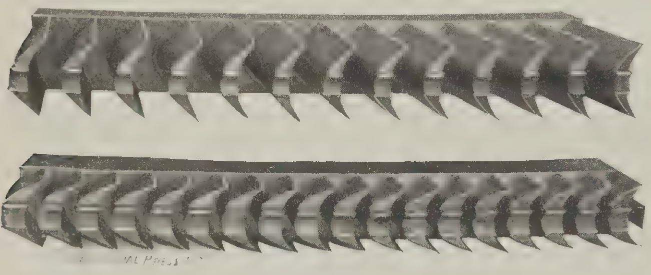

Fig. 9. Bucket Segments: The lower one for High-pressure Steam and the upper one for the Steam after it has expanded to a lower pressure.

Referring to the illustration of the turbine in Fig. 5, steam enters through the main steam pipe, which is shown connecting with two of the series of nozzles, and below is the casing surrounding the two turbine chambers and space for the intermediate receiver between. The governing mechanism is controlled by electrical connection with the governor, the latter being at the extreme top of the machine. In Fig. 13 is a diagram showing the principle of the device. The governor at G connects with a cylinder R on the surface of which is a series of contact points arranged spirally, so that, as the cylinder turns one way or the other, these points will come in contact successively with corresponding points from which the vertical wires extend and close the circuit through these wires in succession.

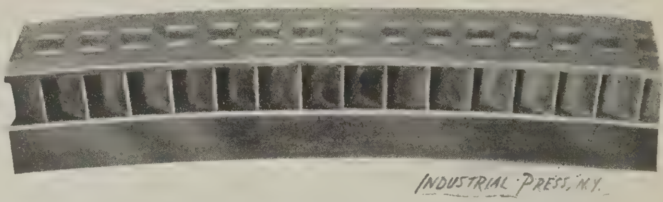

Fig. 10. Bucket Segment after Enclosing Ring has been Riveted on.

Referring to Fig. 13, A is the supply wire for the current, and B the return. The current passes through the switch S, which ordinarily is closed, and thence to the wire x and to the cylinder. The vertical wires at the left connect with the solenoids belonging to the various sets of nozzles, but in this diagram the horizontal wires leading to one set of nozzles only are indicated, which accounts for several of the vertical wires having no apparent connections. When the cylinder R is so rotated by the governor as to bring two contact points together, the current energizes the corresponding solenoid at T, and thence passes to the return wire B. Should the turbine speed up above normal, the governor arm drops and breaks the current at the switch S and all of the solenoids are thrown out of action and their valves close, shutting off steam.

The nozzle valves are not operated directly by the solenoids, but through the medium of small auxiliary valves which the solenoids control and which serve to create a balanced or unbalanced steam pressure, upon the faces of pistons attached to the nozzle valve spindles. One face of each of the pistons is

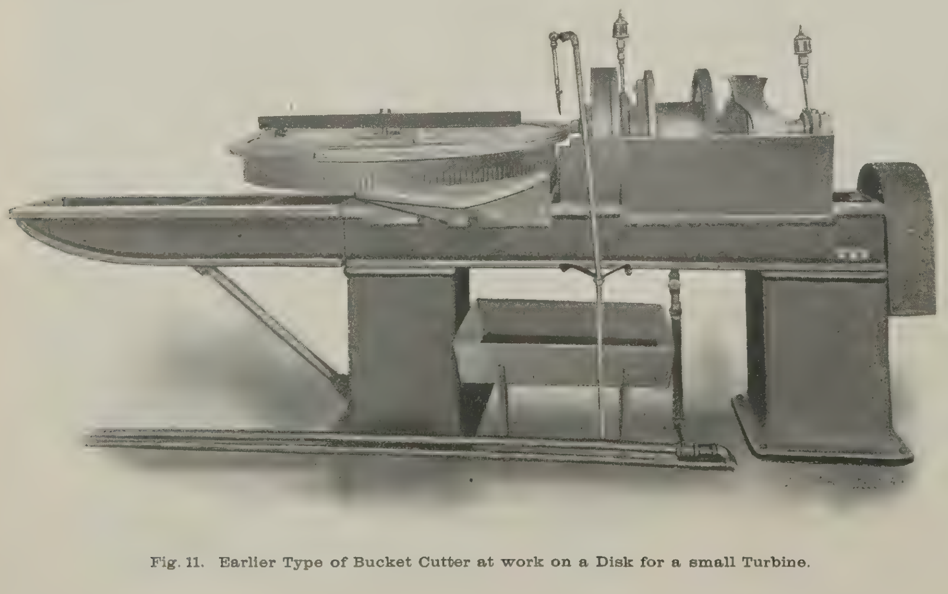

Fig. 11. Earlier Type of Bucket Cutter at work on a Disk for a small Turbine.

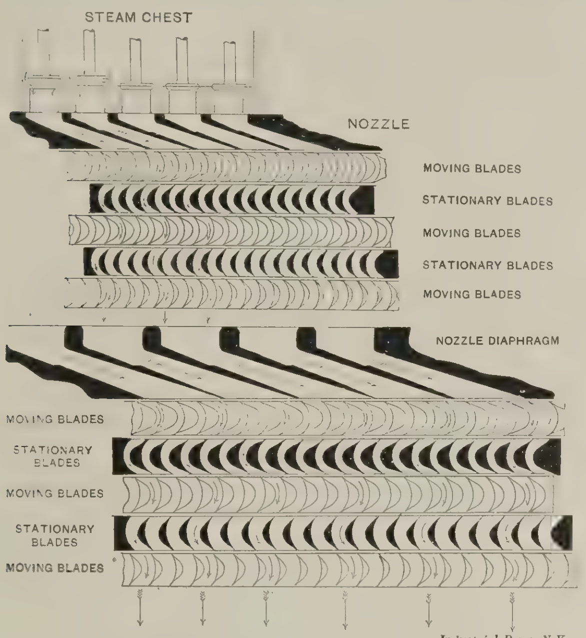
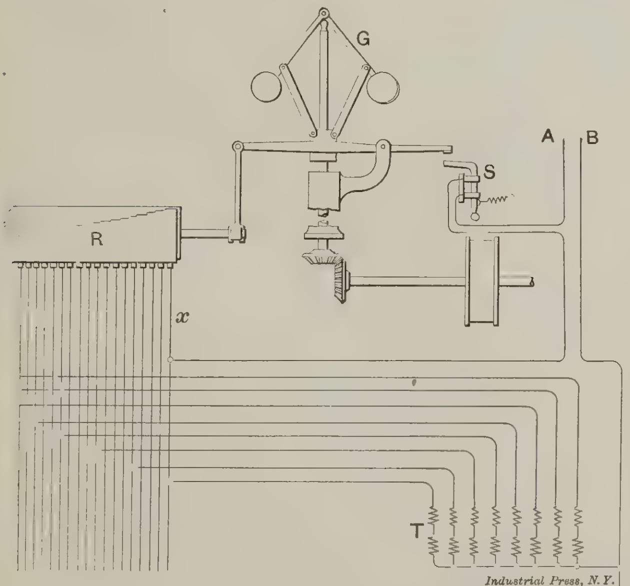
always exposed to the pressure within the steam chest and the auxiliary valve in one position admits steam to the opposite side of the piston. When this happens the pressure is balanced and the nozzle valve closes, the action being assisted by a small spring. When the cylinder space back of a piston or on the side away from the steam chest, is opened to the exhaust by its auxiliary valve, the piston is unbalanced and the valve will open, from the fact that the area of the piston is greater than that of the nozzle valve.



Industrial Press, N.Y.

Fig. 12. Diagram of Curtis Turbine in its Latest Form.

The most vital points in a steam turbine are the buckets, since they, and the spaces between them, must be shaped exactly right to give the correct direction of flow and highest mechanical efficiency, and also to provide for the progressive expansion of the steam. The buckets of the Curtis turbine are cut out of the solid metal by special bucket cutting machines. For the smaller sizes of wheels the blades are cut from the disks comprising the wheels, and for the larger sizes the buckets are cut from segments of steel and then bolted around the periphery of the disks. In Figs. 9 and 10 are shown bucket segments, in the first instance as they appear after machining and in the second with a rim of steel riveted on, closing the outer openings of the curved passages between the buckets. The view in Fig. 4, already referred to, shows the completed wheel of the 5,000 kilowatt turbine.



Industrial Press, N.Y.

Fig. 13. Diagram of Governing Apparatus.

While this process of making the buckets produces very nicely finished work, it is at best an expensive process, calling for special and expensive machines, which have taken a long time to design and develop. There are about twenty machines now in use. In all of them a single-pointed cutting tool is employed, the tool being so guided by the mechanism that its cutting edge will be in correct position for cutting effectively at all points of the curve. In the older machines the tool was given a motion of rotation around the circumference of a circle (approximately, depending on the shape of the buckets), and as it passed the bucket segment would remove a chip. The tool was gradually fed into the work as the cutting advanced. In the latest type the tool is given an oscillating motion, back and forth across the face of the segment. On the forward stroke the tool advances for the cut and on the return withdraws for clearance. The machine of this type is partly pneumatic in its action, and is an exceedingly interesting piece of mechanism. After the patents, now pending, are issued we hope to publish more about it.

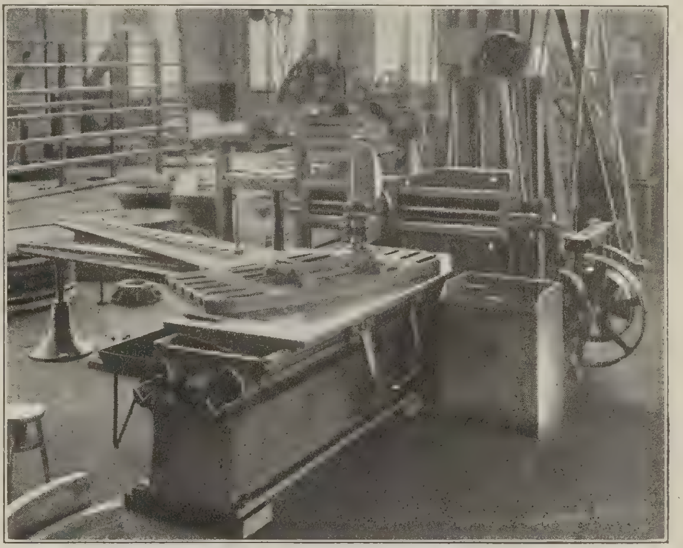


Fig. 14. Rig for Planing Bucket Segments.

* * *

I very vividly remember, while serving my apprenticeship as a machinist in a railroad shop that the temperature in the shop often dropped below 40 degrees and frequently to freezing if the outside weather was within 15 degrees of zero. With a temperature of 40 degrees a workman's hands become numb, and it is almost impossible to do good work with hand tools. This shop was considered by those in charge as being amply heated with an overhead direct steam system. The employees, instead of working to keep warm, as a rule chose to loaf to keep warm, and I do not believe that the amount of work produced on such cold days, when estimated very conservatively, amounted to more than 75 to 80 per cent. of the normal output. In this building there were about 150 employees earning approximately $2.50 per day; considering, however, the output to be 85 per cent. the loss on cold days amounted to something like $37.50.

An efficient heating plant for this shop would cost about $3,750 complete. Without considering the cost of steam, of which there was plenty of exhaust going to waste; allowing for depreciation, etc., making liberal total of 12 per cent. or $450 per year as the amount that the cost of the heating plant should earn, it would take only twelve days with the thermometer below 15 degrees above zero to make the expenditure a paying investment.—J. I. Lyle, in a paper before the New York Railroad Club.

* * *

What is called a triple typewriter is being manufactured by a concern in Cincinnati. The machines are built principally for use in large shoe manufacturing concerns in making out their order tickets for the factory. Nearly all such factories are divided into three departments, each of which requires separate tickets, and as these tickets are made of heavy cardboard carbon paper cannot be used to make duplicates. The triple typewriters are made from three single typewriters so joined together that they operate with one keyboard. The operator finds it no more difficult to operate one machine of this kind than a single machine.

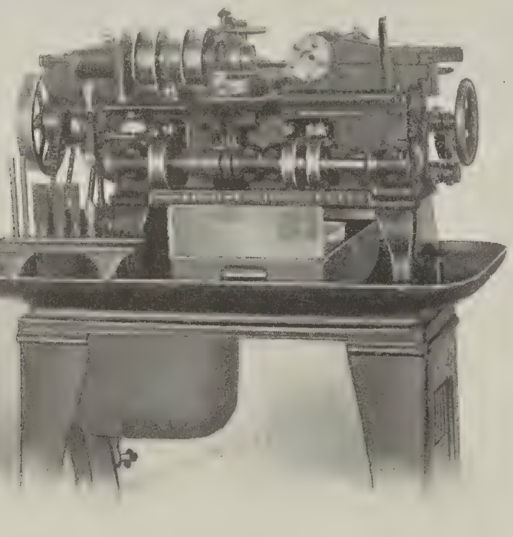
DIRECTIONS FOR CAMMING THE BROWN & SHARPE AUTOMATIC SCREW MACHINE.

RALPH E. FLANDERS.

The Brown & Sharpe automatic screw machine, as now made, has three tool carrying slides—a front cross slide, a back cross slide, and a turret slide. The back cross slide is controlled by a cam fast to shaft *A* (Fig. 1) through the medium of levers *B* and *C*, and the front slide is controlled by a similar cam through lever *D*. The turret slide is controlled by a cam on shaft *E* (Fig. 2) rotating in unison with the cross slide cams, and acting through lever *F*. The motion for feeding the stock, revolving the turret, and reversing the spindle, is taken from a driving shaft which runs at constant speed. Through change gears and a worm and worm wheel this shaft also rotates the cross slide and turret cams at a speed suitable for the piece being made. Bearing these essential points in mind, we will proceed to draw out the cams for making a model piece.

Laying Out Operations.

Fig. 3 shows a screw which was made of gun iron for a foreign rifle works. The particular dimensions on this piece are the diameter .1573, the length .630, and the thread .126 diameter x 42 threads per inch, or nearly No. 5-42. For these dimensions gages had been provided. The operations were laid out as shown; 1st, box-tool, to rough turn body size, and finish turn thread diameter; 2d, box-tool to finish turn body; 3d, die and pull out die holder for threading; 4th, form tool for finish around and under head; 5th, cut-off tool to sever finished piece, and neck and bevel unfinished piece for threading; 6th, feeding stock to stop in turret and revolving turret. The thread diameter is finished by a second blade in the first box tool, thus allowing the finishing box tool blade to clear this portion of the cut and shorten the throw required. The work is fed to a stop to bring dimension .630 correct.



Brown & Sharpe No. 00 Automatic Screw Machine.

Spindle Speeds.

In laying out a set of cams, the first point to determine is the rate of spindle speed. Gun screw iron can be readily turned and formed with a surface speed of 60 feet per minute. It has been formed at 90 feet per minute with fine feed, while with coarse feed it sometimes has to drop to 45 or 50 feet. Sixty feet per minute is, however, a conservative rate of speed for this job.

For threading on this fine pitch and soft material the rate may run anywhere from 25 to 40 feet per minute. It is well to remember that we can scarcely get the threading speed too low in an automatic screw machine, so the slower it can be done without sacrificing the production on the other operations, the better.

Now, consulting the spindle speed chart furnished with the No. 00 size machine, into which we will put this job, we find that 1,080 revolutions per minute appears to be the most suitable speed. This will give about 67 feet per minute for turning and forming, and about 35 for threading. To obtain the surface speed, multiply the diameter of the work in inches or fractions thereof by 3.1416 to find the circumference; multiply this by the revolutions per minute, and divide by 12 to get the answer in feet. Better yet, look up diameter and revolutions in one of the numerous tables to be found in catalogues and reference books.

Feeds.

For feeds, with this surface speed, .006 would be about right for rough turning, with .008 for the finishing cut. For forming this width, we could not safely take much more than .0004, with .0013 for cutting off. These feeds are given in Fig. 3, and refer in all cases to the thickness of the chip, or the distance the tool advances for each revolution.

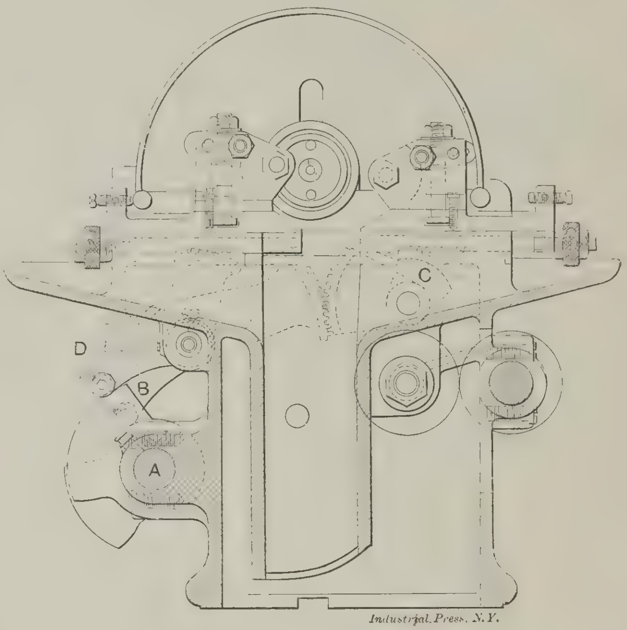


Fig. 1. Section showing Operation of Cross-slides.

Number of Revolutions to Make One Piece.

We next want to know about how many revolutions of the spindle it will take to make one piece. For rough turning we have a length of .630 to turn at .006 per revolution; this will give about 105 revolutions for this operation. (Note that the threaded diameter was rough turned by form tool, so that the first blade passes freely over this part without cutting.) It takes ½ second to revolve the turret on this machine. If the spindle goes 1,080 revolutions per minute; in ½ second it will go 1,080 ÷ 60 × ½ = 9 revolutions. Better add on a few revolutions here and make it 13 for good luck. Finish turning .630 in length with a feed of .008 will take .630 ÷ .008 = 79 revolutions. Revolving turret, as before, 13 revolutions.

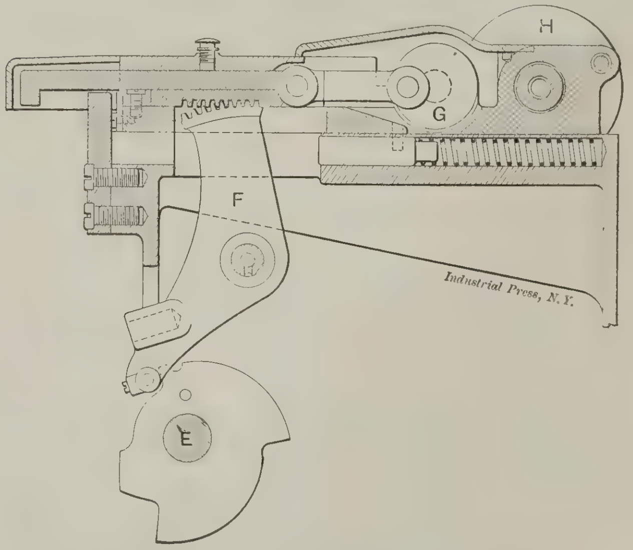

Fig. 2. Section showing Operation of Turret-slide.

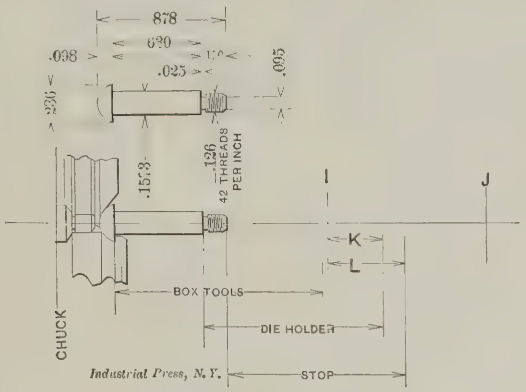
To find the number of revolutions required for threading, we find the number of threads on the piece by multiplying the pitch, which is 42, by the threaded length .15; this gives us about 6. Add, say, 2 revolutions for clearance and multiplying by 2, gives 8 revolutions on and 8 revolutions off, or 16 revolutions for threading.

The next time the turret is revolved, the form tool is in action, so we need not reckon in the revolutions. We form from stock .236 in diameter down to .157, which gives a difference of .079 in diameter, or about .040 difference in radius. Add .003 for clearance, and call the throw of the form tool .043. With, say, .00043 feed, this will give 100 revolutions for this operation. To save time, we will overlap the movements of the front and back slides, timing the cams in such fashion that when the form tool has completed its cut, the parting tool will have cut into the neck between the screwhead and the chuck, as far as can be done safely and still support the work for the form tool to finish. In the present instance the back cut-off tool cuts down to a diameter of about .110 before the form tool was withdrawn. This gives us a throw of about .055. Now it will be noticed in Fig. 3 that the face of the cutting off tool is made on an angle. This is done, as shown in Fig. 4, to get rid of the teat which is always left on work parted by a dull, straight faced tool. This angular cutting edge causes the piece, in breaking off, to leave the major portion of the teat on the unfinished stock still in the machine, where the further advance of the tool shaves it off. Fifteen degrees has proved to be a suitable angle for steel and iron, while a somewhat greater angle, say from 20 to 25 degrees works better with brass or bronze. It is evident that we must add to the throw already found an amount equal to *S* in Fig. 4, which equals the width of the blade multiplied by the tangent of the angle. These values have been worked out in the table shown, for different widths of tool, and angles suitable for steel and brass respectively. With a blade .035 wide and an angle of 15 degrees, the by-travel amounts to .010. Besides this last allowance we should add on about .005 to provide clearance at each end of the movement of the tool. This gives us in all .055 + .010 + .005 = .070 for the throw of the cutting off tool to be used in estimating the number of revolutions of the spindle to make the piece. At .0013 feed this will give us .070 ÷ .0013 = 54 revolutions. Revolving turret as before, 13 revolutions. Feeding stock, same as revolving turret, about 13 revolutions. The total number of revolutions needed to make one piece, will be as follows:



Industrial Press, N. Y.

FRONT SLIDE.	TURRET SLIDE.	BACK SLIDE.
	Rough Turn—Box Tool .006.	
	Revolve Turret	
	Finish Turn—Box Tool .008.	
	Dwell.	
	Revolve Turret.	
	Thread—Die Holder and Die.	
Form—Circular Tool .0004.	Revolve Turret twice.	Cut-off Circular Tool .0013
	Feed Stock to Stop.	
	Revolve Turret.	

Fig. 3. Screw made on Turret Lathe and Operation of Slides.

Rough turn	105	revolutions.
Revolve Turret	13	revolutions.
Finish turn	79	revolutions.
Revolve turret	13	revolutions.
Thread	16	revolutions.
Form	100	revolutions.
Cut-off	54	revolutions.
Feed stock	13	revolutions.
Revolve turret	13	revolutions.
Total	406	revolutions.

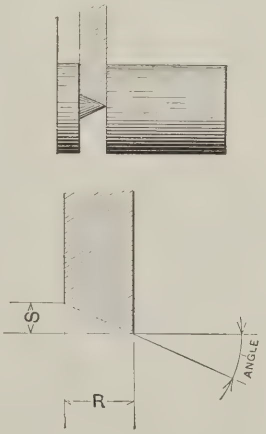
Our spindle speed is 1,080 revolutions per minute, or 1,080 ÷ 60 = 18 revolutions per second. Then it will take 406 ÷ 18 = 23 seconds, about, to make this piece. This will give a net production, after deducting 10 per cent. for sharpening tools, etc., of about 1,400 per day.

Laying Out the Cams.

Proceeding now to lay out the cams we will first lay out the lead cam by which the turret is operated. After we have drawn a circle to represent the diameter of the blank from which the cam is made, we will lay out on the circumference a distance sufficient for the first operation. It is best, in doing this work, to consider the circle as divided into hundredths instead of degrees and minutes and to facilitate this, it will be found convenient to use a piece of bristol board, cut out to fit the diameter of the cam blank, spaced off with the dividers, and graduated as shown in Fig. 5. This will save spacing off each circle separately.

The first operation, rough turning, took about 105 revolutions. If the spindle revolves 18 times per second; in the 23 seconds it takes to make one piece it will revolve 414 times, agreeing closely with our approximate estimate. If the spindle revolves 414 times in making one piece, or in other words, to one revolution of the cam shaft, each 1-100 of the cam periphery represents 414 ÷ 100 = 4.14 revolutions of the spindle. Then, if it takes 105 revolutions for the first operation, this portion of the cam will extend over 105 ÷ 4.14 = 26 spaces. Having found this division with our improvised protractor, draw a line through it and mark it 26, as shown on the lead cam in Fig. 6.

The next point to determine is the height of the cam lobe for this operation. Referring now to Fig. 3; lay off on the center line the nearest and furthest positions of the face of the turret in relation to the face of the spindle chuck, and draw vertical lines *I* and *J* through these two points. Now find on the box tool it is proposed to use, the working length, or the distance from the cutting edge of the first blade to the face of the turret when the tool is shoved in to the shoulder. After adding ⅛ to the dimension to allow for clearance and adjustment; lay off this distance from the point where the first box tool blade ceases action, toward the lines drawn to represent the position of the turret. As shown in Fig. 3, the dimension line marked "Box Tools" falls short of the advanced position of the turret, so we will bring this lobe up to its full height. Now lay off on the zero, or starting line, a distance *M-N* equal to the required throw for this tool = .630, and connect it by a spiral with the circumference at radial 26. This will be the first lobe of the cam.



R	15°	23°

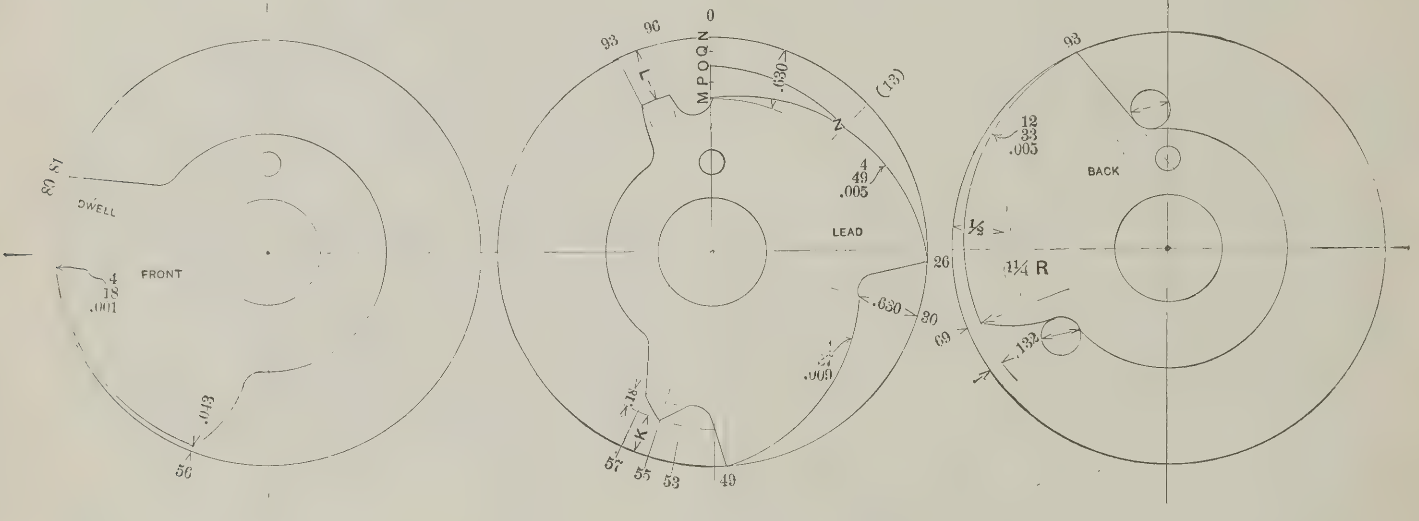
Fig. 4. Cutting-off Tool and Allowances for Angle of Face.

An approximate method of drawing this spiral is indicated. Owing to the length and steepness of this cam, we will have to draw it in two sections, so bisect the circumferential space of 26-100, at division No. 13; and there draw a radial line. Bisect the throw laid out (*M-N*) at *O*, and strike from this point an arc cutting radial No. 13 at *Z*. Again bisect *M-O* and *O-N* at *P* and *Q* respectively. With a radius equal to the distance between *P* and the center of the cam, connect points *M* and *Z*, and with a radius equal to the distance from *Q* to the center of the cam, connect point *Z* with the top of the lobe in the circumference at radial No. 26. This will be found a very close approximation to the theoretical spiral. Only one arc is usually needed to connect the starting and stopping points of the lobe, but sometimes it is necessary to draw a long spiral in as many as three or four sections.

It will be remembered that it takes ½ second to revolve the turret on this size machine. This makes 9 revolutions or 2-100 of the cam periphery. It will, however, ordinarily be found impracticable, when the diameter of the roll, and the angle of drop on the cam is taken into account, to get the roll down into position for a new cut in less than three spaces, and it is always well to add another space to give plenty of leeway, should it be found possible to speed the cams above the calculated rate of production. Our next radial will then be drawn four spaces beyond the last one, and will be numbered 30. Mark down on this line a distance equal to .630—the throw of the second box tool—as a starting point for the second cam lobe. We now wish to connect the top of the first lobe to the bottom of the second with a suitable drop. On the No. 00 machine, in anything from an 8-second to a 30-second cam, if the drop is drawn tangent to the 1¼-inch center hole it is about right. Cams faster than this will require an easier drop, while on slower cams it may be made a little steeper. Draw then a line tangent to the center hole from division No. 26 on the periphery and connect it with the starting point of the second lobe by an arc with a radius equal to that of the cam roll. The second lobe is drawn the same as the previous one—first find the number of spaces needed, here 19, draw a radial at division No. 49, and connect the two points with a spiral, substantially as before.



Front Cam. Lead Cam. Back Cam.

Fig. 6. Cams for making the Piece shown in Fig. 3.

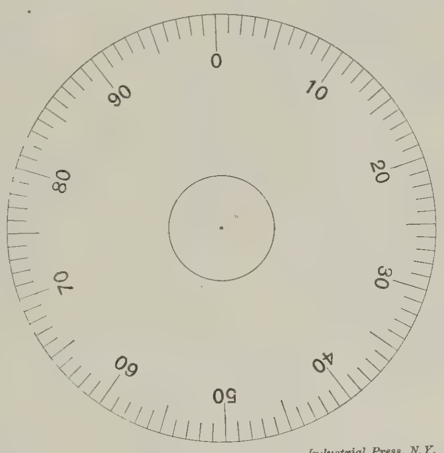
The pitch of the threaded portion of the sample is 42 per inch. As this part is .150 long, there will be 150 × 42 or 6.3 threads on one piece; adding 2 threads for good measure, we have 8.3 revolutions, or 2 spaces as the portion of cam periphery needed for threading on. Furthermore, if there are 8.28 revolutions actual, in the 2 spaces, and the pitch is 42, the throw of the die will be $\frac{8.28}{42} = .197$. Die holders for use in automatic screw machines should be made to pull out against a light spring, in order that the turret motion may merely start the die on. The pitch of the thread will feed it into the work, while the turret lags after at a slightly lower rate. To allow for this, we will subtract about 10 per cent. from the amount given, leaving .180 for the throw of this part of the cam. Allow 4 spaces for revolving the turret as before; 2 spaces, as calculated above, for threading on; and 2 more for threading off; drawing radials at 53, 55, and 57.

Now find the height of this lobe of the cam. In Fig. 3, set the dividers to a distance equal to the amount the face of the die in the holder we intend to use projects beyond the face of the turret, plus ⅜ for clearance. Lay off this distance from point where the thread ceased; and dimension *K*, the length by which it projects beyond the line of the turret *I*, will be the amount we must cut down from the circumference of the cam. Lay off this distance on radial No. 55, and it will give us the top of the threading lobe. Measure down .180, our calculated throw, from this point on radials Nos. 53 and 57, and connect the points thus found with an arc—a single one will do here—substantially as before described.

It will be noted that it is unnecessary in this machine to make provision on the cam for carrying the turret slide to its extreme backward limit before revolving the turret. We merely let the cam roll drop down a little below the starting point of the next lobe; the crank disk and connected mechanism, indicated at *G* in Fig. 2, disconnects the slide from cam lever *F*, draws it to the extreme rear, revolves the turret, and again brings it up and connects it with the lever, ready for the next operation. This makes the time necessary for revolving the turret much shorter than if we had to let the roll clear down to the bottom of the cam each time. While the cross slide tools are in action, there is nothing for the turret to do, so drop the cam down 1⅛ below the circumference, the limit of the backward movement of the turret in this machine.

The next operation is forming, done by a circular tool in the front slide. As the thread on our sample is so far back on the piece, the dieholder and form tool are clear of each other, and the front cam may commence work immediately after the spindle reverses. In the circle which we have drawn for our front cam blank draw radial 56, 1 space beyond where the spindle reversed at 55 on the lead cam. One hundred revolutions were appropriated for this cut. This will give 24 divisions for the spiral, which should have a rise of .043 to agree with the calculated throw for this operation. In order to allow the tool to clean out the chip and give a good finish, in all cases where a tool is fed onto a finished surface, whether it is a box tool, a hollow mill, or a cross slide tool, it is advisable to add a dwell of a few revolutions at the end of the spiral on the cam. Accordingly, we allow another space from 80 to 81, which is made concentric with the cam shaft center, so that the tool may rest on the finished diameter for 4 or 5 revolutions. The cross slide cams are, of course, brought up to the full diameter as a rule.

Our allowance for cutting off was 54 revolutions, but it will be remembered that this accounted only for that portion of the cutting off which was done after the forming was completed. As there is plenty of time for it, as a measure of precaution, and for convenience in setting up as well, the throw of this cam should be great enough to sever the piece from the stock diameter, instead of waiting to commence work on the reduced neck left by the form tool. Of course the blade will be cutting air the first part of its travel, but experience shows that this will not dull the cutting edge. The diameter of the stock is .236; allowance for bevel on cut-off blade .035 wide is .010; clearance is .004; this will give $\frac{.236}{2} + .010 + .004 = .132$ for cut-off throw. With a feed of .0013 this means 100 revolutions or 24 spaces. By referring to our list of operations it will be noted that after the cutting off is completed we have to provide for feeding stock and revolving turret. The turret is revolved in 4 spaces as before; although the feeding of the stock takes the same amount of time, in practice it is seldom found necessary to add an extra space to that absolutely needed, so the allowance for this will be 3 spaces. This makes 7 spaces in all, so our cutting off cam will end at 100 — 7 = 93, and begin at 93 — 24 = 69. Lay out the cam between radials 69 and 93, with a throw of .132, and draw a suitable rise and drop. These quick motion curves should be drawn about as dimensioned for cams on the No. 00 machine. The builders send with the outfit directions for laying out those curves for the different sizes of machines, but if these are not at hand, a little judicious experiment will suggest what is about right for the case in hand.



Industrial Press, N.Y.

Fig. 5. Protractor for Laying Out Cams.

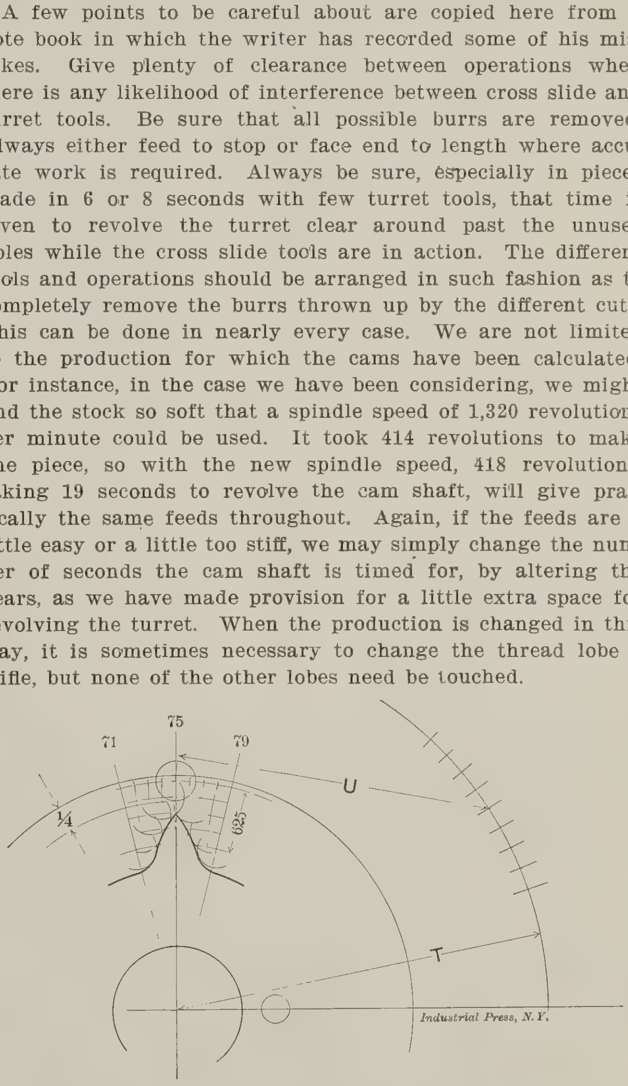
Returning again to complete the lead cam, we lay out a lobe for the stock stop in the space between radials 93 and 96, which was reserved for feeding stock. This lobe is made a "dwell," and its height is determined from the stop we propose to use, in the same way as was described for the other tools in connection with Fig. 3. After making a little drop for the cam roll between 96 and 0, while revolving the turret, and having run up to connect again with the starting point, the cam is completed. To finish the sample up in good style, a pointing tool should have been used in the turret to clean up the thread end of the screw while the forming was in progress. As the party for whom the work was done did not care to bother with this, it was omitted, but the method for laying out a lobe for such an operation would not differ from that for the rest of the cam.

The first time the cams are outlined, make the pencil lines soft, as it is often necessary to make slight changes in the cams after they have been laid out and compared with each other. The calculations should also be gone over a second time, to see that no mistake has been made. Let us prove our calculations in regard to the depth the cutting off tool has penetrated at the completion of the forming. The total throw is .132, and the total number of spaces occupied is 24; of these 12 are simultaneous with the forming, so that the depth of cut reached at radial No. 81 is $\frac{12}{24} \times .132 = .066$. Subtracting the clearance, we have about .064. The radius of the stock is $\frac{236}{2} = .118$. The diameter of the supporting teat is then 2 (.118 — .064) = .108. As the form tool cut extends only about 5-32 beyond this teat, the conditions are well within the limits of good practice, that the length of surface formed shall not exceed 2½ times the supporting diameter.

If the thread cam had been a little longer and steeper, it would have been found advantageous to lay it out in a more elaborate manner. Fig. 7 shows the method. It is required to draw a threading lobe to give a movement of .625 in 4 spaces on, and 4 spaces off, the lobe to be cut down ¼ inch from the circumference. Supposing the apex of the cam to be on radial No. 75; with center on this line draw a circle equal in diameter to the cam roll, with its bottom the required distance (¼ inch) from the periphery. Through the center of this cam roll draw an arc concentric with the cam and cutting radials 71 and 79. On radial 79 lay off from this arc, toward the center of the cam a distance, .625, equal to the required throw. Now divide this distance, and the arc on either side of radial 75, into any convenient number of parts, 4 in this case. With compass point at the center of the cam and a radius *T* equal to the distance between the center of the lead cam and the fulcrum of the lead lever, strike an arc. With centers in this arc, and a radius *U* equal to the distance from the fulcrum of the lead lever to the center of the roll, strike arcs through the center of the cam roll circle, and also each of the division points in its arc. Draw arcs also concentric with the cam through the division points on radial 79. Where each of these arcs intersects its mating arc drawn from the fulcrum of the lever, draw circles the diameter of the cam roll, as shown in the figure. If we now draw curves on each side of radial 75 tangent to the under side of these cam roll curves, we have our lobe. It will be noted that this lobe is narrower than the space between 71 and 79, that it is less than .625 high, and its apex is more than ¼ inch from the periphery, but if carefully laid out and made, it will give the required results with a pull out die holder.

General Remarks.

A few points to be careful about are copied here from a note book in which the writer has recorded some of his mistakes. Give plenty of clearance between operations when there is any likelihood of interference between cross slide and turret tools. Be sure that all possible burrs are removed. Always either feed to stop or face end to length where accurate work is required. Always be sure, especially in pieces made in 6 or 8 seconds with few turret tools, that time is given to revolve the turret clear around past the unused holes while the cross slide tools are in action. The different tools and operations should be arranged in such fashion as to completely remove the burrs thrown up by the different cuts. This can be done in nearly every case. We are not limited to the production for which the cams have been calculated. For instance, in the case we have been considering, we might find the stock so soft that a spindle speed of 1,320 revolutions per minute could be used. It took 414 revolutions to make one piece, so with the new spindle speed, 418 revolutions, taking 19 seconds to revolve the cam shaft, will give practically the same feeds throughout. Again, if the feeds are a little easy or a little too stiff, we may simply change the number of seconds the cam shaft is timed for, by altering the gears, as we have made provision for a little extra space for revolving the turret. When the production is changed in this way, it is sometimes necessary to change the thread lobe a trifle, but none of the other lobes need be touched.



Industrial Press, N.Y.

Fig. 7. Method of Laying Out Threading Lobe.

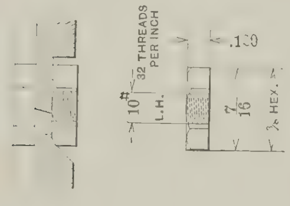
The cams are preferably made of mild sheet steel, of suitable thickness, finished on the periphery and casehardened. Plain forming and cut-off cams, and sometimes lead cams for the larger machines, when of strong design, are made of cast iron finished all over. The blanks should be turned to size and have the center hole bored and the driving hole drilled from a template. Make a copy of the cam drawings, with a hard, round ended pencil and a sheet of carbon paper, on a piece of tough manila. Include the center hole and the dowel hole in this copy, as it is by means of the small hole that the cams are timed together. Cut out the template thus drawn, locate it in position on the cam blanks, and carefully scribe the contour onto the metal. With drill and cold chisel remove the surplus stock and finish up the rises, drops, and idle periods with the emery wheel and file, leaving 1-16 inch or so for finish on the working surfaces. For the steep pitches, such as the thread lobes and possibly the two box tool lobes, the curve may be worked out with the file until it matches the drawing, but to get an even rise on such a slight pitch as that of our cross slide cams, it will be necessary to mill the spiral. To do this, place the cam on an arbor held in the index centers of a milling machine, drop a cutter onto the highest point of the cam, and alternately raise the knee and rotate the index head by suitable amounts until the entire surface is finished. "Millings," as they are termed, are given for the different lobes of the three cams, and they are read as follows: $\overset{4}{\underset{.001}{18}}$ on the front cam means that the index finger is to be moved 4 holes in the 18 circle, and the knee raised .001 for each cut; $\overset{12}{\underset{.005}{33}}$ on the back cam shows that we must index 12 holes in the 33 circle, and raise the knee .005; and so on.

To find the milling for the first box tool lobe on the lead cam, for instance, first find the lead, or the throw it would have if continued for a complete revolution; this will be equal to its present throw, divided by the per cent. of the circumference it occupies. $\frac{.630}{.26} = 2.423 =$ the lead of this lobe. Now divide this amount by any convenient quantity we may settle upon as the distance we will raise the knee for each cut. This quantity may be larger for a steep pitch, and smaller for a slight pitch. Suppose we settle upon .005; $\frac{2.423}{.005} = 485$. Four hundred and ninety is the nearest number of divisions we can get on or index head by plain indexing, and the table calls for 4 holes in the 49 circle. The amount the knee is raised being .005, the "milling" will be $\overset{4}{\underset{.005}{49}}$ read as explained above. To prove the millings, proceed as follows: $40 =$ number of teeth in index wheel; $.26 =$ per cent. of periphery occupied by lobe; $\overset{4}{\underset{.005}{49}} =$ the milling. $\frac{49}{4} \times .005 \times 40 \times .26 = .637$. This exceeds the calculated throw, but is near enough. If the two steep box tool lobes are milled, it would be advisable to use a convex cutter with a radius of cut about equal to the radius of the cam roll; this will lessen the stepped appearance the corner of a straight cutter would give to the rise. After the lobes are milled, the surfaces should be filed smooth and polished, and the cams tried in the machine before hardening. The lead cam should be stamped with the name of the piece it is to make, the spindle speed, the change gears used, and the name of the cam.

Examples of Layouts.

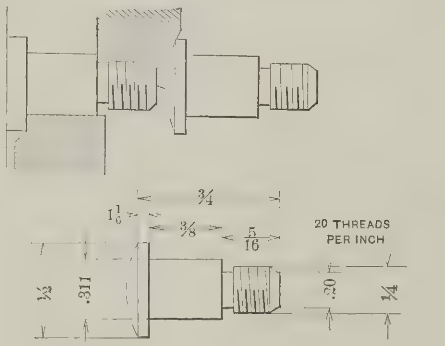
A few samples are here illustrated, showing the operations, feeds, speeds, and production. It is to be understood that, on rougher work, both the feeds and speeds might be greatly increased. Another factor which might tend to greater production is the use of some of the high speed steels for roughing tools. Turning our attention to the samples illustrated, it may be interesting to notice the important points in each one. The first column relates to the front cross slide, the second to the turret, and the third to the back cross slide, and the feeds are given for each operation. When two or more items are included in parentheses, it indicates that they are all done by the same tool.

The small brass nut, sample 1, is made from hexagon stock. Brass may be turned at the highest available speed of the machine, but it is seldom expedient to thread at over 1,500 to 1,800 revolutions per minute. In deep drilling in brass, one is more liable to get the feed too fine than too coarse. A fine, broken chip will quickly clog up the flutes of a twist drill, while a heavy stiff chip will push straight out. It will be found advantageous to use straight fluted drills on this metal. The centering and facing is done with one tool, and the feed is reduced when the facing blade commences its work. The cutting off tool is given a regular feed until the point has severed the completed piece, and then the feed is doubled while the tool cuts through the air in the hole. It is always advisable to cut to the center to avoid the trouble that would follow if the drill broke and the work was not severed from the stock.



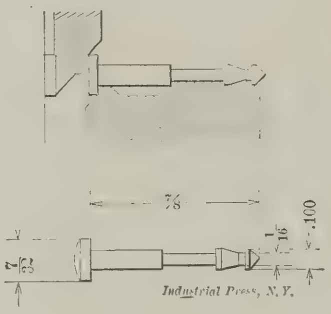
Sample 1.

Material—Brass.
Spindle, 1,440 R. P. M. Seconds each, 10.
Net production, 3,200 per day (10 hours).
(Center .0042, Face .0021, Dwell.)
Revolve Turret.
Drill .0058.
Revolve Turret.
Tap.
(Form .0012, Dwell.)
(1st cut-off .002, 2d cut-off .0042)
Feed Stock.



Sample 2.

Material—Steel
Spindle {Forward 300 R. P. M., Backward 600 R. P. M.} Seconds each 70
Net production 450 per day (10 hours).
(Form .00029, Dwell.)
(1st cut-off .0014, 2d cut-off .00064, Dwell.)
Thread.
Revolve Turret.
Feed to Stop



Sample 3.

Material—Steel.
Spindle, 1,320 R. P. M. Seconds each, 30.
Net production, 1,000 per day (10 hours.)
Rough Turn—Hollow Mill .0073
Revolve Turret.
(Finish Turn—Box Tool .009, Point. .001, Dwell.)
Revolve Turret.
(1st Form .0011, 2d Form .00016, Dwell.) Support.
Cut-off .0013
Feed Stock

Sample 2 is an example of the method of making commonly known as "cut-off and form." Wherever the turned portion is less than about 2½ times the supporting diameter, this method will usually give the greatest production. Much longer formed cuts can of course be taken if the work is supported by a back rest in the turret. In this piece, as well as in the others shown, note the means taken to remove all the burrs possible, and so leave the work nicely finished. The form tool cuts off the burr thrown up by the cutting-off tool in necking for the thread, and by means of the 45 degree angle, cleans up the under corner of the head. The cross slide tools are set to cut with the spindle running backwards at double speed, thus greatly increasing the production, while the threading speed is kept within limits.

Sample 3, a part of one of the standard typewriters, is an extreme example of long forming. It will be noted that two feeds are used for forming. The tool takes a chip of .0011 when finishing under the head, but is slowed down to .00016 when the wide cut starts in. The work is supported by a turret back-rest bearing on the two thin strips of body diameter at the end of the piece. These examples show some of the simpler forms of work done on these machines. This system of cams lends itself very readily to complicated combinations, and the cams, tools, and attachments for some of these operations are very elaborate.

MACHINE SHOP EQUIPMENT.*—1.

PLANNING THE DIFFERENT DEPARTMENTS.

OSCAR E. PERRIGO.

We will assume that our machine shop has been erected according to the methods suggested in the former articles on the subject, which discussed the plans and mode of construction of foundations, walls, roofs, and floors, and properly provided for the prime necessities of light, heat and power. Our next duty will be to describe and illustrate its equipment with the proper machinery, tools and appliances for accomplishing the contemplated work to be done. Machines should be so arranged in groups or departments as to best subserve the purpose intended, and to manufacture the product with the least cost for handling the materials in the various stages of their progress toward the completed product, and with the most efficient arrangement for supervising the work, and still to insure the desired standard of accuracy, finish and thoroughness of the completed output.

In considering the question of the proper equipment of a machine shop a great deal depends upon the character of the product which is to be turned out. It may be that of heavy machinery requiring little or no machining except of surfaces in contact, as is the case with such work as sugar mill machinery, rolling mill work and similar product which will necessitate heavy castings and consequently a large proportion of machines for heavy planing, boring, drilling, tapping and so on, as well as large erecting space and much use of the traveling crane and other forms of lifting devices. Again, it may be of a generally lighter kind of work, as for instance, steam engines of various sizes and similar work where much more finish as well as very accurate fitting is required. Or, it may be of machine tools, the larger of which will be similar to the engine work in many respects, while the smaller machines will require a large variety of machines both for general and special work and such as are capable of producing a large quantity of very accurate work even on rather large parts.

The design of these articles is not to arrange and specify such an equipment as may be required for any certain kind or class of manufacture, or for any special line of sizes of machines, for that is manifestly impractical, but rather to suggest the proper selection and arrangement of the machines for a medium kind of work, on a practical plan which may be useful to those having charge of this class of mechanical engineering and be helpful in pointing out such machines as will be most economical in the production of certain classes of work in the more modern and up-to-date methods, and so grouping and arranging them as to make their management easy, practical and profitable.

In this connection it will not only be proper to offer some suggestions as to the class or type of machines best adapted for certain kinds of work, but also as to the methods of testing such machines to ascertain their fitness for the work to be done on them. These requirements become all the more imperative since the demand is more and more pronounced for machines of higher speed, greater strength and consequently capable of a largely increased output, as well as for machines whose parts may be rapidly changed to adapt them to a large variety of work. To this is added the demand for greater accuracy, better fitting, a superior quality of stock in their make-up, more carefully considered design and a generally finer finish.

In all the operations of manufacturing, from the very conception of the idea that we *will* manufacture, to the final marketing of the product, if we are to expect success, either in the building, the equipping, or the management of the manufacturing operations of such a varied and complex nature, we must first of all have a well-conceived, well-matured, definite and comprehensive *plan*. If this is not so we shall find the various component parts of our fabric disproportioned to each other. One will be of too great capacity and another of too little; one portion will be an unnecessary expense which will absorb the profits of another; one will be pushed while another is neglected; and so on until the whole establishment is in such a disjointed, disproportioned and inefficient condition that success either mechanically or financially is impossible. This is very forcibly shown in cases where a business that "ought to pay" seems to drift along from year to year with scarcely any advance in methods or profits to its owners. Another man takes charge and perhaps astonishes everyone by his seeming extravagance, but gradually order comes out of chaos, the expenses which at first staggered the good old conservative directors begins to tell and in due time everything is in proper condition, every portion of the concern does its allotted part, each in harmony with the others, everybody is cheerful and satisfied, better work is produced and the stockholders are getting their dividends. Why? Simply that the man is master of the business and works with a well-conceived plan. He knew from the beginning just what would be the result; he was not afraid to make radical changes; there was no patchwork about it. Every portion of his plan was carried out in its entirety. Two different parts do not make a complete whole, and to have several plans in mind and then attempt to carry out a portion of each is but to invite failure. And the invitation is usually accepted. This is also true even in regard to minor operations in the same line. We must get such a grasp of the complete idea and plan in all its details that "from the beginning we can see the end." One of our most successful designers of machinery always seemed to be a good deal of a laggard during the first stages of a new design and would draw and sketch and measure in what seemed a very desultory sort of a way. When remonstrated with for what "the boss" thought was wasting time, he used to say, "I don't wan't to make my drawing until I can shut my eyes and see the machine working." The complete conception of the design as it gradually forms in the mind is what is needed. And when a man had the ability to thus "see through" the whole design, the "working up" of the various component parts is to a great extent matters of mechanical detail only.

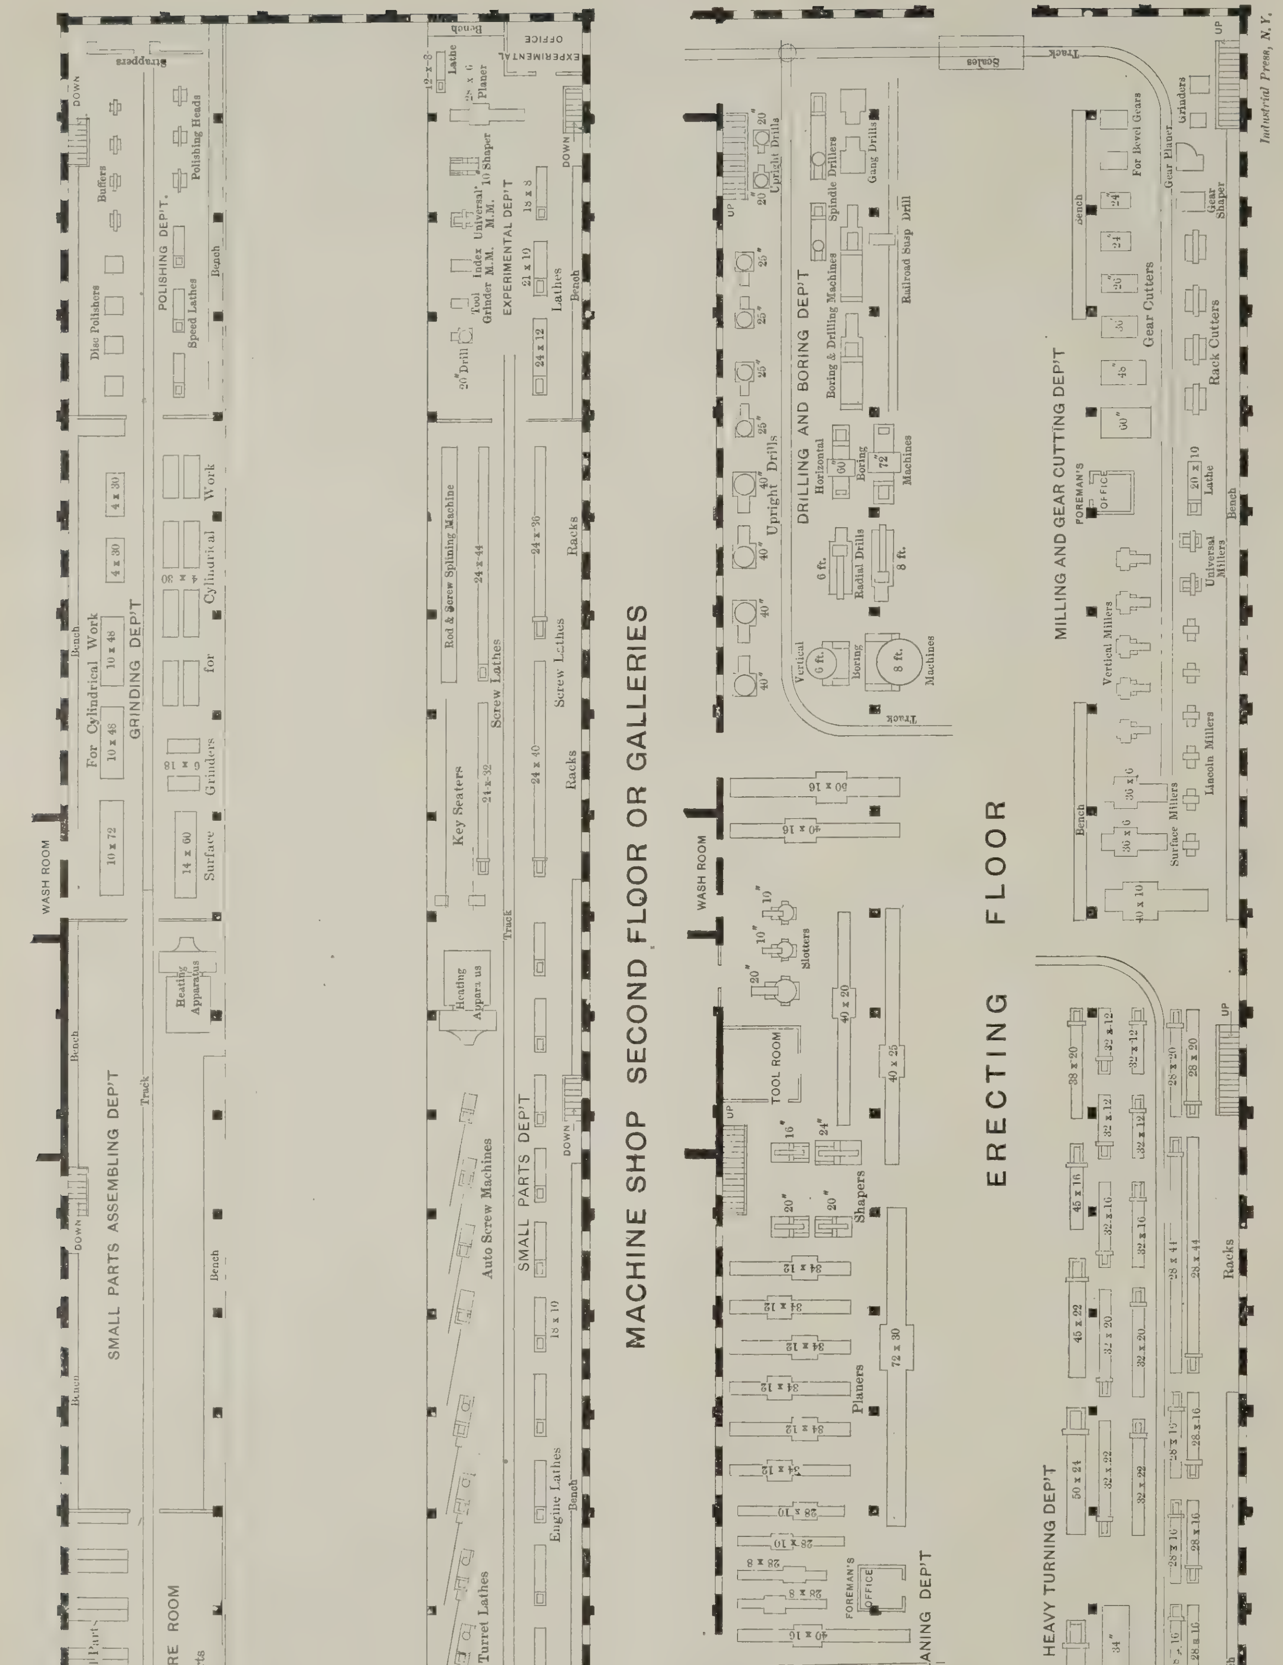
So it is, or should be, in planning manufacturing operations. We must see the end from the beginning. This applies with peculiar force in the alterations of or additions to plants already in existence, whether it be the changing on account of a different product to be manufactured, or of enlarging so as to increase the product. The plan should be comprehensive and provide for possible enlargements in the future, so that as each successive change is made we get nearer and nearer to the ideal of a completed structure that will be a credit and not a continual "eye-sore." Not only in appearance is this the proper method, but in the utility of the improvements made, and this again in proportion to the expense incurred. If any "piece-meal" plan is adopted from time to time the result will be not only a failure to get the greatest accommodation out of the improvement, but to do so at an expense which is frequently lost by subsequent alterations of such a nature as to compel us to tear down a portion of the former work. And this process is repeated again and again until the expense of successive changes, additions and alterations will have cost more than to have built the whole structure new. Beside this we have a mongrel structure in which "the last state is worse than the first." It is frequently better to make new things than to patch up old ones; ofttimes it is cheaper also. And this lesson may be followed through all the operations of manufacturing with good results to the reputation of the man who is responsible for the plans as well as the success of the establishment and the dividends to the stockholders.

It was from considerations such as these that in the first article (printed in the October number, 1902,) on Construction, it was pointed out how the capacity of our manufacturing plant might be economically increased and at the same time work along the same general lines so that the enlarged structure would be but an extension or expansion of the original plan.

In planning the relative location of the different departments of our machine shop in which are placed the several classes of machines it is necessary to so arrange them that when once the material, as iron castings or other heavy

---

* Supplementing the series upon Machine Shop Design, begun in the October, 1902, number, and ended in May, 1903.



Arrangement of Tools and Departments in Model Machine Shop, previously Described by the Author.

stock, comes into the shop, it shall pass in as nearly as may be a continuous line through the shop from its rough state to its place in the erection of the machines to be built with little or no "retrograde movement" or other unnecessary handling or similar expense. Light and easily handled stock is not subject to these conditions to such an extent, and may be handled on the upper floors as its transportation from place to place is easily effected by the tram cars, trucks, etc., on the level, and these run upon elevators, and carried to the various floors where they are needed for the different operations upon them, or to a finished parts storeroom, where they may be kept until they are wanted for the assembling of a complete machine. In our case, however, having but two floors, quantities of small work may be packed in trucks, cars or boxes and from the front gallery lowered to the ground floor by the traveling crane. In the same way stock or finished parts may be brought up to the gallery floors.

The plans accompanying this article show both the ground floor and the gallery floors, with the location of all the machines selected to equip the shop, arranged as is thought best for the easy handling of the stock and the convenient performance of all the necessary work of machining, erecting and shipping. The machines are all shown drawn to scale, and with sufficient space around them for readily handling the stock and the machined parts.

The main floor is divided into five departments, namely, the planing, drilling and boring, heavy turning, milling and gear cutting, and the erecting departments, all located as shown on the plan.

Usually the first operations on nearly all castings and on many forgings is that of planing, this being particularly so with the heavier stock. Consequently it is advisable to locate the planing department near where this class of stock can be the most readily received into the shop from the foundry or from the forge shop. As by far the larger amount comes from the foundry the point nearest that department is where the planers should be located, so as to save distance in conveying material, and consequent expense. Our tram track leading from the foundry to the machine shop brings castings to a point nearly under the traveling crane (by which they are readily placed upon the planers on each side of it), or directly under it, by which it conveniently serves the large planers located in the erecting space just inside the row of columns. An overhead trolley delivers castings to the other planers in the row arranged at right angles to the shop as they are taken from the foundry cars, or carries them, when planed, to the tram track and thence by the traveling crane to any part of the shop where they may be needed, generally to the tram track laid through the drilling and boring department, or to the large machines of this class located within the reach of the traveling crane inside of the columns. This overhead trolley may be operated by hand hoists, or by compressed air, but preferably it should be of the type carrying a small electric motor by which it is very quickly, efficiently and conveniently operated. There should be at least two of these hoists on the trolley track, which should extend from the front end of the shop down to and over the tram track in the drilling and boring department.

It should be explained that in laying out the positions of the planers the outline shown includes the extreme run of the planer table, hence there is more space at the ends than would appear at first glance. In locating the planers with reference to each other they are placed at equal distances of five feet between tables without regard to the front or back, so as to give free access to both sides when the operator is putting on, setting or removing work. Those of the larger planers are located parallel with the length of the shop. It will be best to drive these with electric motors. The other planers, of such sizes as will accommodate the usual variety of work, are located according to the space available. Much of the medium sized work may be done on long planers very economically by filling the table with as many parts as it will hold, and running through the lot with a long cut, as for instance, with lathe heads or carriages, which may be planed in lots of ten to fifteen much cheaper than a less number on a short planer. The two planers near the wash room are convenient for comparatively large work where a short table is required. The other planers are arranged in pairs facing each other so as to be convenient for one man to run two planers. One man can easily run the 60-inch and the 72-inch planers.

In connection with the planers are located the shapers and the slotters, as shown in the plan. These are also served by the overhead trolley as noted above, and work from them, or from the planers may be thus conveniently moved to the drilling and boring department unless the parts are so large as to make the traveling crane necessary.

Next in the order of work is usually that of boring, either in vertical boring mills, horizontal boring machines, radial drills, etc. Therefore this class of machines will naturally come next to the planers, and on the same side of the shop, in the drilling and boring department. The vertical boring machines are of the usual type in which much of the large work, such as pulleys, balance wheels and many other heavy parts are much more readily handled than upon a lathe. The horizontal boring machines are those with the low, traversing table, and elevating head and tail stocks, while the horizontal boring and drilling machines are those with a stationary head and an outer support for the boring bar, and a vertically adjustable table supported by two vertical screws. The first is adapted to heavy work, while the latter handles that of medium weight. The so-called railroad suspension drill is one provided with a perfectly level track upon which long beds, as lathe beds, may be supported on rollers and run to any desired point in their length for drilling and tapping. Assuming that there will be hollow spindles required, two spindle boring machines are provided. These may be of the horizontal cylinder type for the purpose of feeding, where only one tool is used, or with a heavy turret and slide when more than one tool is required. Two gang drills are provided for jig work where medium or small sized holes are needed. Next to the wall is a row of ordinary upright drills of the capacity indicated. Where necessary, small jib cranes should be attached to the columns for use at individual machines, or for a pair of machines.

The heavy turning department, on the opposite side of the shop and at the front end, contains all lathes of 28-inch swing and upwards. Also, the heavy turret lathes for cast iron work and the larger parts of steel or other material. Here are also the vertical chucking machines, which are in many cases to be preferred to those of horizontal type. The lathes of 38-inch swing and upwards are placed inside of the row of columns so as to be served by the traveling crane. Nevertheless, small jib cranes attached to the columns and operated by hand will be found very useful for a number of the other machines. The cone-turning machine should be arranged to turn and crown all the steps of a cone at once. This and the pulley-turning machine are located convenient to the vertical chucking machines. Two shafting lathes of 28-inch swing and 44-feet beds are provided. In locating the lathes a space of four feet is left between the ends so as to give free access to any part of the room. Material is brought in on the tram track, one end of which extends out under the traveling crane. The heavy turret lathes and the vertical chucking machines will handle much of the work frequently done in the engine lathes and do it much quicker, thereby saving the number of the latter to be set up.

Next in order is the Milling and Gear Cutting Department. Here surface milling machines are provided for large surfaces, while smaller surfaces are taken care of by the six plain, or Lincoln millers. Two universal millers do the more complicated work and a small lathe is put in as a convenient machine to save going to another department for small and simple jobs of turning. The five vertical millers will do a large quantity of work very accurately and a better advantage than planers could do it, and at the same time at a much less cost for labor, as is the usual result with milling machine work. Six gear cutters are provided for spur gears, and two for bevel gears, while a special gear shaper and a gear planer will do the work required to be particularly accurate. Four rack cutters will usually be a proper proportion to the above. While the cutters for these machines are made in the general tool room, two grinders are provided so as to keep them in order in the department where they are used.

A convenient extension of the rear tram track furnishes means to bring in and take out work.

The gallery floors are divided into six departments, namely, Small Parts, Grinding, Polishing, Small Parts Assembling, Small Parts Store, and Experimental Departments. A tram track connects them all, passing through the cross gallery at the front end, under a traveling crane, by which any machine, car, truck, or lot of stock may be quickly transferred to or from the main or ground floor.

The Small Parts Department is the largest of the six and contains six turret lathes for making steel work from the bar, and four automatic screw machines for smaller work and for such special screws as may be made in the shop more economically than they can be purchased. A line of engine lathes of the sizes given on the plan handle such small work as requires to be turned on centers. Long lathes for turning and threading leadscrews and similar work are provided, as is also a machine with a traveling head for milling the splines in long rods or screws, and two small key-seating machines for milling semi-circular key seats. Racks for bar stock are provided in the front gallery and near the screw lathes for stock and for finished work.

The Grinding Department and the Polishing Department are for obvious reasons placed as far from the other work as possible. Much of the cylindrical work is sent to the grinding room to be reduced to perfectly cylindrical form on wet grinders and does not require any polishing finish. For this work three large, two medium and eight small grinders are provided. One large and two small dry surface grinders are arranged to take such small parts as require this treatment.

The Polishing Department as now known in connection with a machine shop is somewhat new in this class of machine work, but its importance and efficiency is becoming more recognized as its usefulness is being demonstrated. Four disk grinders or polishers are provided for small or medium sized flat surfaces, and work direct from the planers is quickly polished to a fine finish and quite true. Three speed lathes are expected to do all the small cylindrical work that has not been ground. Work requiring a bright buffed finish is taken to the four buffers, while irregularly shaped parts are polished on the three polishing heads or on the two belt, or strapping machines. This room, of course, enclosed as tightly as possible to avoid the difficulty of floating particles or grinder's dust passing to the other departments. Nearly all of this trouble may be prevented by a small exhaust fan connected with hoods at each of the machines by a suitable main pipe and branches, by which the dust is discharged in the open air, or a proper receptacle. This has the additional advantage of saving the eyes of the workmen from much annoyance and discomfort.

Small parts when completed are taken to the Finished Parts Store Room, which is located in the front end of the shop and furnished with shelves arranged in alcoves on one side of the room, while the opposite side is reserved for somewhat larger parts or collections of parts as may be necessary. This space should be fitted up to suit the particular kind of work, and may be in broad shelves running lengthwise of the room, or in alcoves as on the opposite side.

Between this room and the grinding department is the Small Parts Assembling Department, in which it is intended to assemble groups of small parts, as for instance, the parts comprising the apron of a lathe, or similar work. If the parts are accurately made no machine work will be here needed, although a small engine lathe might be a convenience at times. Bench vises and the usual assembling "jacks" comprise most of the necessary fittings.

In the back end of the opposite gallery is located the Experimental Department, where small and medium sized experimental work is to be done. It contains, as will be seen in the plans, a variety of machines suitable for experimental work, so as to render it unnecessary to go to any of the other departments for anything except large turning, planing and gear cutting. Such a department is a necessity to a shop aiming at making progress and keeping up with the times, as work of this character costs too much if done in the regular tool room, and it is not only an awkward but expensive matter to place it in any other department.

Along the front of each gallery is an iron railing 32 inches high, that on the front end gallery having an easily removable section 12 feet in length, for convenience in passing work to and from the gallery by the traveling crane.

The Foremen's Offices, the Tool Distributing and the Finished Parts Store Room are sheathed up with ⅞-inch pine to the height of 44 inches, above which it is enclosed with wire netting of 1-inch mesh and 4 feet in width. This form of construction affords an ample enclosure and does not materially impede the light. The doors should be provided with spring locks, and workmen generally not allowed in these enclosures except by permission.

* * *

A MODERN OFFICE BUILDING.

The accompanying cuts show the new office building lately completed by the American Blower Co., Detroit, Mich. The building is devoted entirely to the company's offices and is a model of convenience and unusually attractive in appearance. It was intended that the building should represent the highest development in office construction, both architecturally and in its heating and ventilating and other equipment. It is from designs by Malcomson and Higginbotham, Detroit, in adapted Colonial style.

The building is faced with standard size paving brick in various shades of brown, laid in dark mortar and with Flemish bond. The trimmings are of buff Bedford limestone and plate glass windows give the best possible lighting effect, especially in the drafting room. The broad pilasters and heavy cornice in front give an imposing appearance.

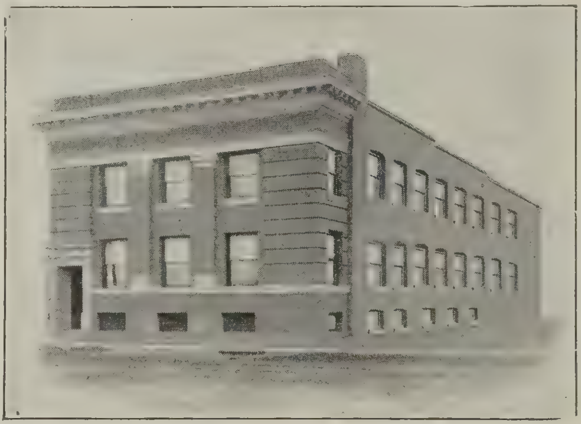


Fig. 1. Office Building of American Blower Co.

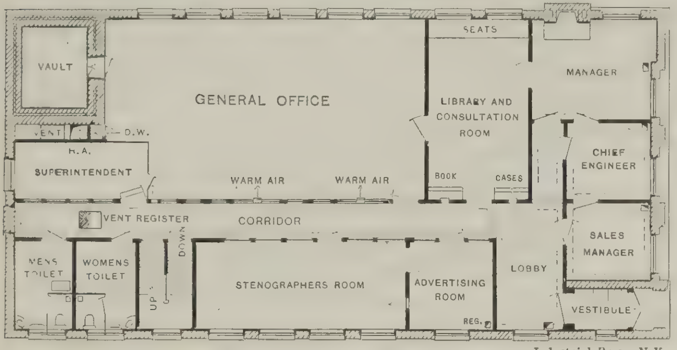
The first floor is occupied entirely by the different commercial departments, while the second floor is used by the engineering and drafting departments. The basement is used for the storage of catalogues, letter files, etc. A small building on the roof is used for blueprinting, and as a dark room.

The interior finish of the first story is Flemish oak with natural oak floor. The second story is finished in stained Louisiana cypress with maple floor, which affords a pleasing contrast. The decoration of the library and consultation room is more elaborate and includes a wainscoting, decorative frieze, and wood cornice, in harmony, however, with the general design of the building.

Every modern equipment is provided for the building, including electric lights, annunciator bells, dumb waiter, an outside telephone system, and an independent inside or house system connecting all departments in office and shops.

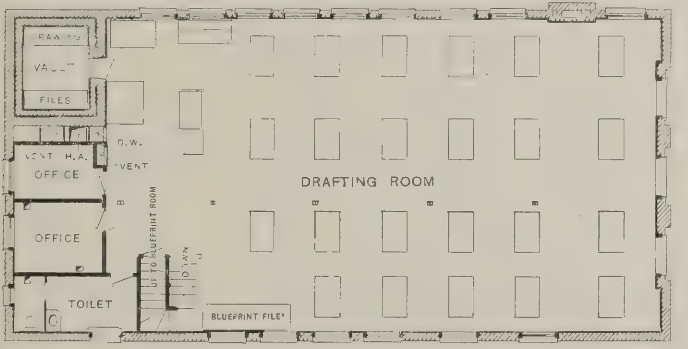
The main interest in the equipment, however, is in the mechanical system of heating and ventilation. As the manufacture of heating and ventilating apparatus forms a large part of the American Blower Company's business, this part of the office equipment naturally received due attention, and an even, pleasant temperature and thorough ventilation are secured without drafts.

The apparatus is located at one side of the basement, as shown in the accompanying plan. The fresh air enters the building through the basement window *F* and by means of the fan *A* is drawn over a coil of pipes *E*, called the tempering coil. The steam pipes of this tempering coil are just sufficient in number and length to heat the volume of entering air to a temperature of 65 or 70 degrees F. The fresh air is then drawn into the fan and forced over another heater *D*. This is the main heater and is designed to heat the air to about 140 degrees. Beyond the heater is located a large brick chamber *G* called the plenum chamber. This serves as a reservoir for the heated air and from this chamber the air is conveyed by galvanized iron pipes *H* to the various offices. Under the main heater *D* is a passage or by-pass as it is called, which permits a part of the air from the fan to pass under the main heater coil and into the plenum chamber. This passes into the lower section of the plenum chamber, which is separated from the upper part. Thus the plenum chamber is divided into two parts, the upper chamber containing hot air at approximately 140 degrees and the lower section tempered air at 70 degrees. As shown by this sectional view, each individual pipe leading off to the offices above, has two connections to this plenum chamber, one branch to the upper section and another to the lower. In each main where the pipe divides into these two sections, there is located a set of double swinging dampers, or mixing dampers. Each set of these dampers is controlled automatically by a diaphragm valve which is part of a system of automatic heat control furnished by the Johnson Electric Service Company of Milwaukee, Wis. These valves are operated by compressed air, which is supplied by a small air compressor, located in the basement, and operated by city water pressure. In each office is located a thermostat which can be set to control the room temperature at any desired point. These thermostats work upon the principle of the unequal expansion and contraction of brass and steel, and are all connected by head pipes, of about ⅜-inch bore, with their respective diaphragm valves. On the expansion or contraction of a piece of brass and steel in the thermostat, air pressure is admitted or cut off from the diaphragm valve and the mixing dampers are swung one way or the other as the case may be. It will be noted that these mixing dampers in swinging do not cut off the flow of air, but simply vary the proportion of hot and tempered air as controlled by the thermostat to maintain a constant temperature in the room. Thus a constant flow of pure air of the proper temperature is maintained at all times. Under the tempering coil there is also a by-pass similar to the one under the main heater. This by-pass is fitted with a swinging damper which is controlled by a thermostat placed in the upper part of the plenum chamber. Thus if the air in the plenum chamber becomes too hot, the thermostat opens the damper under the tempering coil and allows the entering air to pass under the tempering coil, instead of through it. The air is admitted to each room at a point about eight feet above the floor.



Industrial Press, N.Y.

Fig. 2. First Floor Plan.

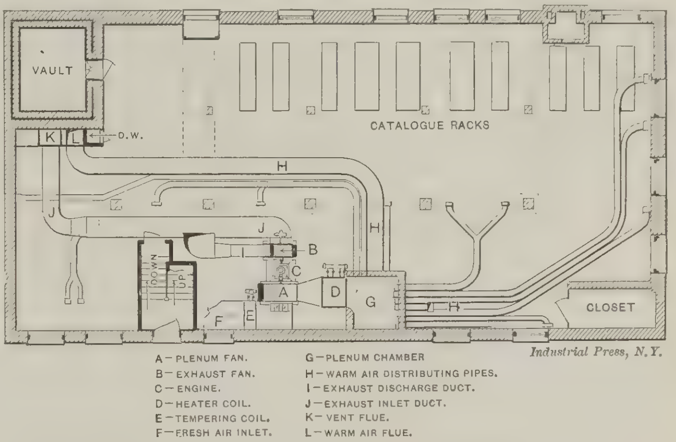


Industrial Press, N.Y.

Fig. 3. Second Floor Plan.

Another unique feature of this plant is the exhaust fan which is direct coupled to the same engine which runs the heating fan and which draws the impure or vitiated air out of the building. Thus while one fan is discharging pure warm air into the building, the other fan on the same shaft is drawing out the impure air. This is the main feature of mechanical ventilation which has brought it into such general favor during the last few years for use in public buildings.

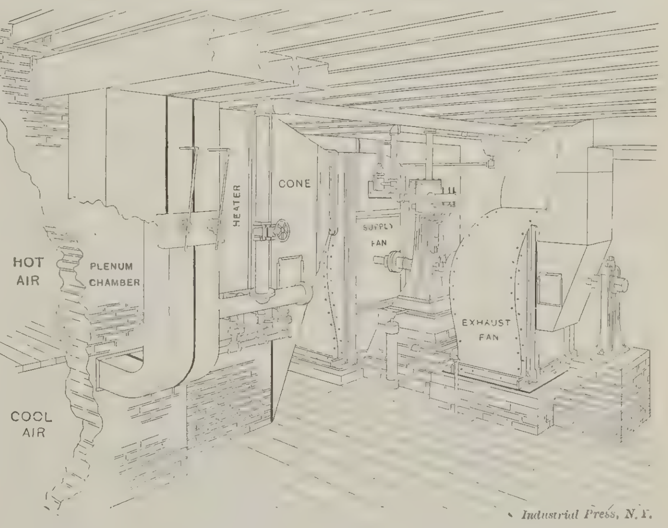
In each office on the first floor there is located an ornamental register face at the floor line, opening into the corridor which extends through the center of building. The air is thence drawn down through the large register in the floor at the rear of the corridor and after passing through the exhaust fan is forced outside the building. The air from the drawing room and second story offices is drawn through the flue at side of vault.



Industrial Press, N.Y.

Fig. 4. Basement Plan, showing Heating and Ventilating Apparatus.

The condensation from the heating apparatus is returned to a Webster feed-water heater located in the engine room of the factory, by means of the Webster vacuum system which was furnished by the American Engineering Specialty Co., of Chicago. This same system handles all the condensation from two other heating plants located in the factory. The advantage of this vacuum system is that it eliminates the back pressure from the factory engine, when using exhaust steam for heating and also removes the air from the heating coils and connecting pipes as fast as it accumulates, thus making the heating surface far more effective than it otherwise would be.



Industrial Press, N.Y.

Fig. 5. General View of Heating and Ventilating Apparatus.

Only one thing remains to be mentioned and that is the economy of this system. As the heating coils utilize the exhaust steam from the factory engine, which is brought into the basement through an underground conduit, and as the fan engine exhaust is also turned into the heater coil, the cost of operating is very small, and in fact practically nothing under the conditions, as the steam that is used for heating, would otherwise probably be wasted.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

SEPTEMBER, 1903.

NET CIRCULATION FOR AUGUST, 1903,—24,893 COPIES.

MACHINERY is issued in three editions—the Engineering Edition, printed on coated paper throughout, each volume comprising 650 reading pages and forty-eight 6 x 9 data sheets—price $2.00 a year; the Shop Edition, printed on super-calendered paper, comprising 430 reading pages, devoted to practical shop matter—price $1.00; and the Foreign Edition, which comprises the same matter as the Engineering but is printed on thin paper for transmission abroad—price $3.00 a year.

A NEW OLD ENGINE.

Several technical journals have recently published descriptions of an alleged new rotary steam engine, the principle of which, in its simplest form, involves the use of two revolving cylinders or wheels mounted on parallel shafts and working inside of a closely fitting case. One of the cylinders carries teeth, preferably two, which engage the same number of tooth depressions in the opposing cylinder. Both cylinders are geared so as to rotate in opposite directions and at the same peripheral speed, gears of the same diameter being keyed to the shafts outside the casing. This is necessary because the cylinders themselves are mutilated gears and can only transmit motion one from the other when the teeth are in engagement with the tooth spaces. Steam admitted into one side of the casing tends to rotate the cylinders, since the pressure on one tooth is unbalanced, the other tooth being shut away from the steam pressure by the periphery of the other cylinder. It is clearly obvious to anyone at all familiar with the construction of steam, air and water motors—especially the large class known as rotary engines—also with positive pressure blowers, that the principle is anything but new. The device in question is simply a modification of the well-known Roots blower used for iron foundries, etc. But we can go way back of this invention and find one very similar. Seth Boyden of malleable iron and patent leather fame, invented a steam rotary engine working on the same principle, although not employing mutilated gears, and was granted a patent for the same October 31, 1831. In the description of the invention the following appears:

"Two teeth wheels are placed with their axles in sockets or supporters parallel and horizontal to each other and close together as the teeth will play free. The whole is inclosed in a case of cylindrical form, which holds pieces termed packing against the ends and opposite sides of the wheels to prevent the steam from passing the wheels without acting on them. This packing is pressed to the wheels by screws to close the vacancy made by wear. The steam is applied to the under side of the wheels, pressing forward on the teeth of each wheel opposite to each other, causing a rapid rotary motion, while the teeth on the side next each other from the pressure of the steam. In this situation the steam presses outward on a surface equal to the depth and width of two teeth while the teeth come in behind each other, exposing the surface of only one, giving a power equal to the pressure of the steam on the tooth of one wheel. A connection is made to one of the axles through the case to communicate their motion to whatever it may be applied."

* * *

The application of electricity as a motive power for machine shops has been an evolution rather than a revolution, and, except in special instances, its use is steadily superseding that of steam, compressed air, hydraulics, rope drive, or combinations of these powers. In the past ten years the use of electric motors in shops has risen from a few incomplete and scattered cases to the present employment of about 600,000 H. P. regularly supplied by electricity.

A large manufacturing concern states that exclusive of those used for railways, automobiles, elevators, and fans, there are over 60,000 motors, ranging from 1/8 H. P. to 2,000 H. P., in daily operation in the United States, supplying over one million horse power, and representing an investment of about twelve million dollars.

It is recorded that in one instance where thirty steam engines of 1,375 total horse power were supplanted by fifty-seven motors of 1,065 total horse power, for machine shop driving, the average daily saving in steam was 41.6 per cent., of combustibles 32.2 per cent. (coal saved 20,000 pounds). In other cases electric driving has reduced by 50 per cent. the cost for engineer, coal, and water; the fuel account 20 per cent., the cost of power 44 per cent. The gross saving was 30 per cent. with direct connected motors, and 22 per cent. with belted or geared motors.

SYSTEMATIC PRESENTATION OF PAPERS.

In arranging for the recent meeting of the American Institute of Electrical Engineers at Niagara Falls a plan was adopted that was productive of good results and that we would commend to the American Society of Mechanical Engineers as a desirable means for enhancing the value of papers presented at its meetings. The plan consisted in placing in charge of a member who is a specialist in a given subject the preparation of a programme of papers on that subject. The result is a much more complete presentation of the topic under discussion than would be possible in any other way. It is of the greatest advantage to engineers to have complete data gathered in one place for convenient reference, and the subject treated from several different standpoints. It is seldom that an author can write comprehensively from his own experience alone, and a man seldom has time or opportunity to draw information from various sources and to present a paper giving a broad and general view of a subject. Such papers have been given at meetings of the A. S. M. E., notably by Prof. Thurston, on topics like superheating, steam turbines, etc. But as a general thing any single paper is more likely to either give the results of one man's experience or else to be more or less one-sided in its treatment. By having several related papers, however, written in accordance with a general plan outlined by a competent authority, they would be of greater value to all concerned, just as they have proven to be in the case of the Institute of Electrical Engineers.

Should it happen that a subject were to be treated on which there were very few available data, the plan would still work out well, for the person in charge could outline a series of tests which various colleges would doubtless be glad to carry out and the work would thus be conducted on a systematic basis. It is usual, under the present order of things, for a college laboratory to undertake a series of experiments so extensive that it is impossible to complete them in any reasonable time, and in consequence they do not bring out the points upon which information is desired in anything like a complete manner. It would be an improvement if some of these tests, at least, could be under the guidance of one central ruling hand.

* * *

This number of Machinery begins the tenth volume of the paper. A copy of the index for the past year will be sent free to any subscriber asking for it, and in writing kindly state whether the index for the Shop Edition or for the Engineering Edition is desired.

THE GAS TURBINE.

In connection with a discussion on the steam turbine at the Master Mechanics' convention at Saratoga, Prof. Hibbard of Cornell University announced that there were prospects of developments in the field of the gas turbine at the General Electric Company's works, Schenectady. A gentleman, who recently received an advanced degree at a Western university in virtue of a very thorough investigation on the subject of the gas turbine, is now in the employ of the General Electric Company, and the inference is that he will have at his disposal the extensive facilities of this company for conducting experiments that may eventually lead to a successful gas turbine. This gentleman is Mr. Sanford A. Moss, who has made a special study of the subject of gas turbines since 1898. He received the degree of Master of Science at the University of California and has also studied at Cornell University, specializing upon the same subject—that of the gas turbine.

The great thermodynamic advantage of the steam turbine over the steam reciprocating engine is that there is no condensation and re-evaporation through contact with metal surfaces which are alternately heated and cooled. The only condensation in a steam turbine to amount to anything comes from the conversion of the energy of the steam into work. In the gas turbine there is, of course, no condensation to enter into the question, but there is an opportunity for another and more important gain through the abolition of the water jacket. It is a singular fact that the turbine is theoretically and probably practically capable of effecting a saving over the reciprocating engine, whether used with steam or with heated air, but because of entirely different reasons in each case.

It is well known that the efficiency of the gas engine depends mainly upon the degree of compression pressure attained in the working fluid. When operating upon the Otto cycle the gas and air are compressed to as great a pressure as practicable and then are exploded, giving a still higher pressure. This same process can be employed in connection with a gas turbine and has been advocated for that purpose. Under this plan the air and gas would be compressed and exploded in a chamber lined with refractory material, and would then discharge through a diverting nozzle and impinge against the blades of a turbine wheel, as in the case of the De Laval steam turbine. The diverging nozzle would act as an expansion nozzle, to reduce the pressure of the gases to atmospheric pressure and convert their potential energy into kinetic energy before doing work upon the wheel. The discharge would occur in puffs, an impulse being given as often as an explosion occurred.

Another method of accomplishing the result would be to have the combustion element burn continuously in contact with compressed air in a refractory chamber from which the heated air would discharge continuously through the expansion nozzle. The pressure in the chamber would remain constant under such conditions and the question of efficiency of the apparatus would depend solely upon the pressure that was attained through compression, as the relative amount of work done in an engine working upon this cycle does not depend upon the temperature of combustion. The efficiency of this cycle is not as high as that of the Otto cycle, but for turbine purposes would have the merit of giving continuous discharge through the nozzle instead of intermittent discharge. This plan of compression and then heating under constant pressure was employed in the well-known Brayton petroleum engine, one of the pioneers in the gas engine field.

The perfection of the gas turbine will not be an easy proposition. It will either have to be accomplished by individuals, working in a hap-hazard way through a long period of years, or by the concentrated efforts of some large firm like the General Electric Company. The latter plan will undoubtedly result in the quicker solution of the problem. One of the problems will be that of the temperature of the gas and its effect upon the metal of the turbine wheel. While the hot air will not come in contact with any of the bearings of the wheel, it is evident that the blades might not stand up to their work if subjected to a very high temperature. The fact that all bearings and wearing surfaces, however, would be removed from contact with the hot gases, would undoubtedly make the water jacket unnecessary.

HIGH-SPEED STEEL.

Practically all the makers of tool steel in this country and in Europe appear to have brought out under some fancy name a so-called "high-speed steel." Most of these steels, if not all of them, depend upon the influence of tungsten, chromium, molybdenum, titanium, etc., together with the heat treatment to produce a peculiar steel alloy which is actually harder when hot up to, say, a low red with some brands, than when cold. In fact some makes of high-speed steel can be filed when cold after they have once been used. Almost any one of these steels seems to be able to accomplish wonders when manipulated by its friends, but in the hands of the average user there is a variety of experience—good, bad, and indifferent—which indicates a great degree of variation in the same brands of steel, and it also shows the want of adaptability in toolsmiths to handle them. This latter is often the prime cause for want of success. The whole training of most toolsmiths has been to give them a horror of overheating tool steel, but many of the high-speed steels must be forged at a white heat. In fact the attempt to forge at the heat ordinarily employed on tool steel will result in failure. One brand we know of must be heated until the steel drips at the point and is then dipped in oil—pretty severe treatment, but it must be followed to get the maximum efficiency. Again there is all the difference in the way a comparative test of different brands is made. Suppose that one maker has sent a sample of comparatively small section and another has sent a larger and heavier section. The small section is at a disadvantage for slow speed and a heavy cut, as it does not have the strength to resist vibration; but at high speeds and light cuts it will ordinarily show up better than the heavy section, as its temperature will rise to nearer the effective working degree. The point is that almost all the leading brands have a critical working temperature which lies within comparatively narrow limits. The best results with high-speed steels are obtained in those shops which have selected some one brand and have stuck to it. They have gotten their toolsmiths and machine men educated to the peculiar characteristics of the brand used and know how to handle it. A change to another brand is usually unsatisfactory all around.

* * *

LEAFLETS AS SUPPLEMENTS TO CATALOGUES.

A practice that is coming into vogue with some machine tool builders, is to have cuts and descriptions of their various machines printed on loose leaflets of the same size as their regular letter paper sheets, one machine and description appearing on a leaflet. Whenever an inquiry is received regarding a particular machine, the letter of reply is accompanied with a leaflet, in the same envelope, giving the cut and description. This practice insures that the party receiving the letter will also get the description which he often fails of in some offices, because of the careless treatment accorded catalogues and other advertising literature in general. The practice is one highly thought of by purchasing agents of railways and large concerns. It saves them much valuable time in wading through catalogues, and it puts the desired data in convenient form for filing along with the letter quoting price, date of delivery, etc. The leaflets may be perforated for filing in a loose-leaf binder, but this is not essential as they are not intended to take the place of the regular catalogues, but are only supplementary to them.

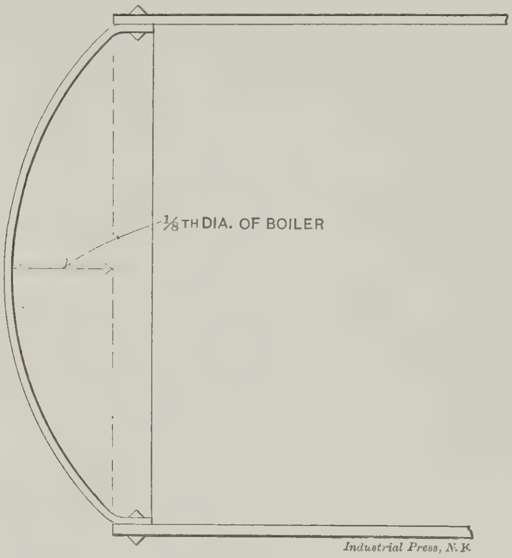
* * *

In a paper upon the gaseous fuel problem read by Mr. Henry G. Morris before the Engineers' Club of Philadelphia, a strong argument is made for the development of by-products coke ovens. Taking figures for the bee hive ovens between Altoona and Pittsburg, we find that 20,000 tons of coke are produced per day, from which about 100,000,000 cubic feet of gas discharge into the air. This gas, if converted into power through gas engines, would represent 5,000,000 horse power hours, or the effort of about 104 gas engines of 2,000 horse power each. Manufacturers of gas apparatus are now offering to guarantee the production of a horse power hour for one pound of fuel—a result not at present attainable through the medium of steam engines and boilers, except by the most complex type of engine.

BOILER BRACING.—1.

CHARLES L. HUBBARD.

In laying out the braces for any given boiler the first step, whatever the type of brace to be used, is to determine the bounding lines of the area to be supported. From tests made it has been found that a steel tube two inches in diameter and of standard thickness will resist a pull of from 15,000 to 20,000 pounds, so that in the case of a cylindrical boiler only that portion of the heads above the tubes need to be considered in laying out the braces. If a boiler head could be made convex or "bumped up" to the extent of one-eighth of its diameter, as shown in Fig. 1, it would be as strong as any portion of the shell, provided it was of the same material and thickness. It would be very difficult, however, to connect the tubes with such a head, so flat heads must be used and the pressure above the tube line must be carried by stays or braces.



Industrial Press, N.Y.

Fig. 1.

In determining the area to be supported it is customary to consider the lower edge as bounded by a line drawn through the upper row of tubes, at a distance equal to one-fourth their diameter below the upper edge (see *A C*, Fig. 2). The remaining boundry line is evidently that formed by the upper part of the boiler shell. It does not follow, however, that the whole of this enclosed area must be supported by the braces, because when the head is flanged and riveted to the shell a portion of it becomes stiff enough to carry the pressure independently of the braces. The distance from the shell that it becomes self-supporting may be determined by the following formula:

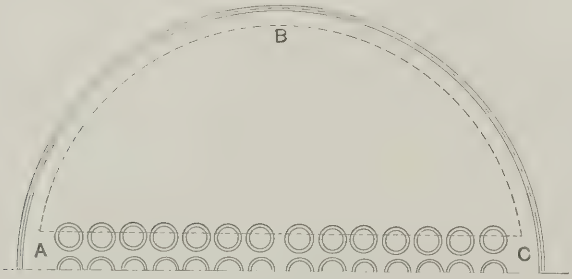


Fig. 2.

$$D = \frac{4484 \times T}{10 \times P} + .5, \text{ in which}$$

$D =$ the distance in inches.

$T =$ the thickness of the head in inches.

$P =$ the boiler pressure to be carried.

Refer to the diagram, Fig. 3.

Having determined the value of D for any given case the line *A B C* may be drawn in, giving us the area to be supported by the braces. If some form of diagonal brace is to be used, the number will be determined both by the size of the brace and the area to be supported. In case any of the solid steel braces like the McGregor or Huston are used the size of the brace will in general be fixed, and the number must be made such as will safely carry the total load upon the unsupported area. If crow-foot braces are used the size, and therefore the number may be varied somewhat. The actual supporting points are the rivets attaching the stays to the heads, and the spacing of these will depend upon the thickness of the plates and the pressure to be carried. The allowable maximum distance between the supported points may be computed by the formula

$$p = \sqrt{\frac{C\,t^2}{P}}, \text{ in which}$$

$p =$ the greatest allowable pitch in inches.

$t =$ the thickness of the plate in sixteenths of an inch.

$P =$ the working steam pressure carried on the boiler.

$C = 112$ for plates 7-16 inch and under.

$C = 120$ for plates over 7-16 inch.

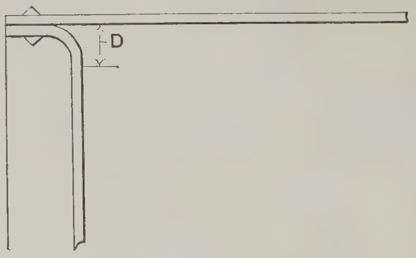

Fig. 3.

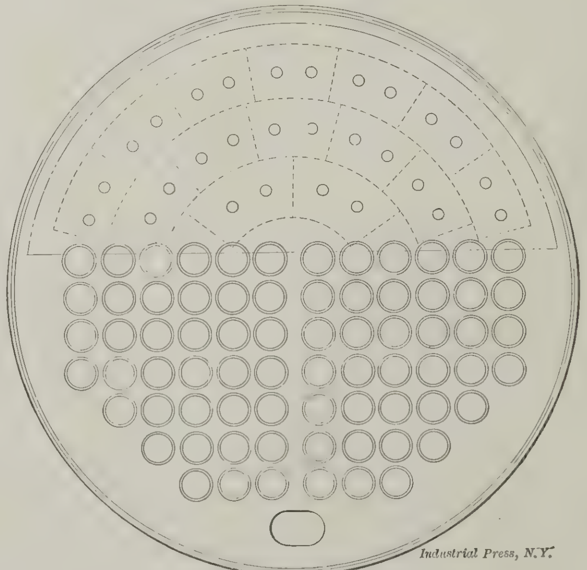
This applies only where the supported points are in equidistant rows, both vertically and horizontally. When the rows are not equally spaced, the greatest distance between supports may be taken for the value of "p," which will give a safe result in all cases.

In order to know the total load to be carried by the braces we must first compute the area of the supported portion and multiply it by the boiler pressure.

The area of this segment may be obtained from a table which can be found in almost any engineer's hand book, or may be computed in the following manner:

Carefully measure on your drawing by the means of a pair of dividers, the arc *A B C* (see Fig. 4), and multiply the same by one-half the radius of the circle. This will give the area of the sector *O A B C*; deduct the area of the triangle *O A C* and the result will be the area of the segment, *A B C*.



Industrial Press, N.Y.

Fig. 7.

In crow-foot bracing the supporting points are usually arranged in sets of four, and are fastened to forgings known as "crow-feet." A diagonal stay with a forked head and pin connects each crow-foot with the boiler shell, to which it is fastened with two or more rivets.

A crow-foot joined to the boiler head with four rivets is called a double crow-foot, while if only two rivets are used it is called a single crow-foot. Single and double crow-feet are shown in Figs. 5 and 6, respectively. In the design of crow-foot bracing that portion of the head enclosed within the segment is marked off in points to be supported, the distance between these being limited by the value of "p" as found by the preceding formula. The points are then taken in groups of two or four as desired and tied to a crow-foot by rivets. (See Figs. 7 and 8.)

The load to be supported by any one brace is that due to the steam pressure acting on an area bounded by lines drawn on the four sides of the chosen group of rivets, halfway between them and the adjacent groups or other points of support as the case may be. (See Fig. 7.) The rivets should be spaced so that the total load will be divided among the different braces as evenly as possible. It is customary to compute the size of the brace carrying the greatest load, and then make the others of the same size for uniformity.

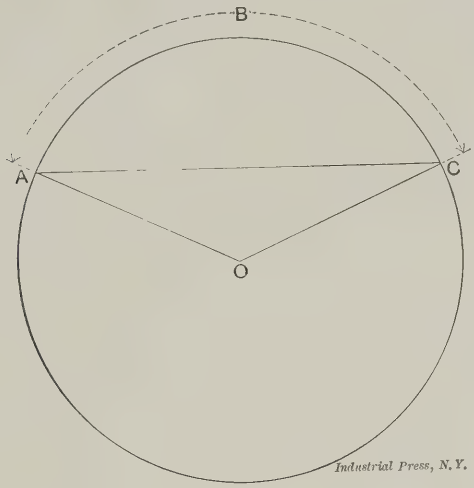


Fig. 4.

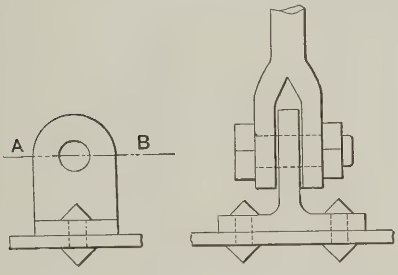

Fig. 5.

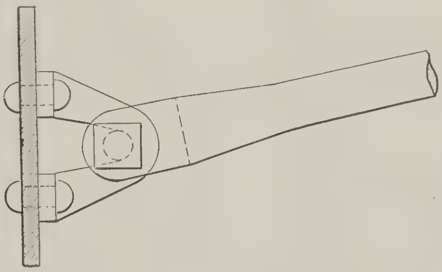

Fig. 6.

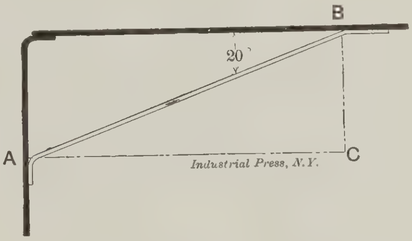

Fig. 10.

To find the size of rivets required divide the total load carried by the brace by the number of rivets in the crow-foot, to find the load on a single rivet and make the diameter such that the stress shall not exceed 6,000 pounds per square inch for steel. The diameter of these rivets should not in any case be less than three-quarter inch in diameter, owing to internal strains set up by riveting. The length of the bolt or pin between the supports is so short that the principal stress to be considered is that due to shearing; but for safety it may be checked for crushing effect and also treated as a uniformly loaded beam supported at both ends. Resistance to crushing may be taken as 15,000 pounds for steel, and 12,000 for wrought iron.

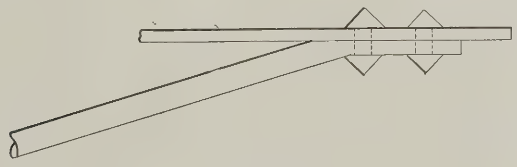

Fig. 9.

The pin being supported at both ends is in double shear, and we may assume a working stress of 14,000 pounds per square inch for mild steel, which is the material commonly used.

If it is treated as a beam the maximum bending moment, $M = \dfrac{WL}{8}$ in which W is the total load on the pin, in pounds, and L the distance between supports in inches.

The "section modulus" for a section of circular form is

$$\frac{\text{area} \times \text{diameter}}{8}$$

We know from "mechanics" that

$M = R f$ in which

M = maximum bending moment,

R = section modulus, or moment of resistance,

f = maximum stress in outer fiber of the bar.

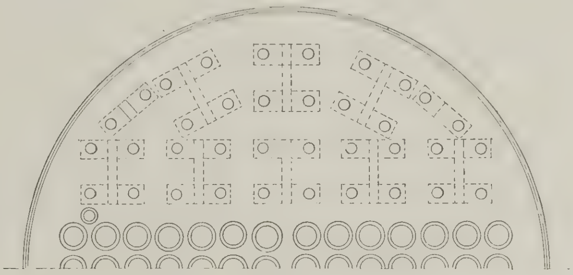

Fig. 8.

Substituting the values of M and R in the equations, and transposing we have

$$f = \frac{W L}{\text{area} \times \text{diameter}}$$

in which f should not exceed 12,000 pounds.

The crow-foot being a forging should not carry a load of much over 5,000 pounds per square inch of section at its weakest point.

The stays or braces are made of wrought-iron, as the fork which is attached to the crow-foot must be forged to shape. While wrought-iron should safely carry a load of from 7,000 to 8,000 pounds per square inch, the fact that the brace contains one or more welded joints makes its strength somewhat uncertain and it is well not to count on much over 5,000 pounds. The end which is attached to the shell is flattened, and riveted in place, usually with two rivets, which may be of the same diameter as the pin, though never less than ¾-inch (see Fig. 9). The angle which the brace makes with the boiler shell should not in general be greater than 20 deg. Referring to Fig. 10, it will be seen that the pull in the direction of the brace is greater than the load which it supports perpendicular to the boiler lead, in proportion to the lengths of the lines $A\,B$ and $A\,C$. If the brace makes an angle of 20 deg. with the shell, we must multiply the load to be supported at the head by 1.07 to obtain the pull on the brace, and the required diameter must be proportioned accordingly. For different angles multiply by the following factors:

Angle.	Factor.
14 deg.	1.03
16 deg.	1.04
18 deg.	1.05
20 deg.	1.07
22 deg.	1.08
24 deg.	1.10
26 deg.	1.11

The common form of crow-foot and forked brace is being quite largely superseded by the various forms of solid steel braces, two of which are shown in Figs. 11 and 12. As this type of brace is of steel and has no pin to shear or weld to prove defective, we can count on a much higher tensile strength. As these braces come in stock sizes, having usually one square inch of sectional area after deducting that cut away by rivet holes, the method of determining the number of braces is somewhat different from that already described. In this case we must first compute the area of the portion of the head to be supported and multiply it by the steam pressure, to get the total load. A solid steel brace should safely carry 10,000 pounds per square inch of section. From this it is evident that the total load divided by 10,000 will give the total cross section of the braces, and this divided by the sectional area of a single brace of the type to be used will give the number required. If the area to be held by the braces was in the form of a square it would be possible to locate them so that the exact number determined by a theoretical calculation could be used satisfactorily. But the space on the heads is in such form that this cannot be done, therefore it is necessary to put in enough braces to amply protect the whole, making the number actually required greater than the number determined by the calculation, as in some cases they must be nearer together than the area exposed to pressure calls for. As this adds to the strength of the boiler there can be no objection to it. After the braces are all located, the greatest distance between rivets should be measured and the strength of the head checked by the methods already given.

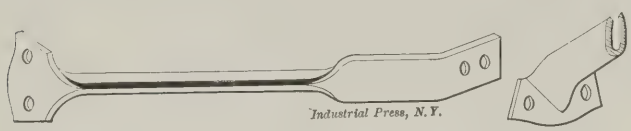

Fig. 11.

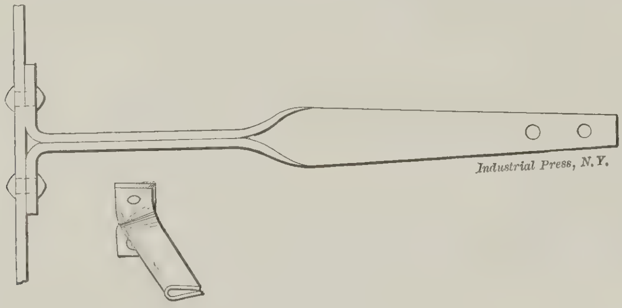

Fig. 12.

A future article will take up the design of "through bracing" and combinations of through and crow-foot bracing.

* * *

MECHANICAL DRAWING AND THE SHOP.

In an address before the Eastern Manual Training Association's convention, held at Boston in July, Mr. L. D. Burlingame chief draftsman of the Brown & Sharpe Mfg. Co., Providence, considered the subject of mechanical drawing and its relation to practical shop work. He said that the drafting office has three distinct functions to fulfill. First, it must be an interpreter *to* the shop; second, an interpreter *of* the shop; and third, a recorder *for* the shop. There was a time when the designer, who had a rough conception of what he wanted to build, stood over the patternmaker until some box-like patterns were produced. With these as a skeleton to build on, the inventor continued to work out his design from "hand to mouth," cutting, changing, discarding, until the desired end was attained or until it was found necessary to start again. Now all this is changed and every piece must be fully and separately detailed, in many shops each on a sheet by itself, all particulars of oiling and venting oil holes, must be shown, grinding limits given, the depths of tapped holes figured. There must be an indication of where stock is to be allowed for fitting, and of the special kinds of finish on machined surfaces. All special tools used in manufacturing the piece must be listed below its name, and perhaps a list of operations given either on the drawing or in a separate list, and so on until it would seem that little was left for the machinist to do but to follow the instructions on the drawings without thought, or the use of his judgment. This may seem so to the draftsman, indeed it seemed so to me at one time, but when, after having a number of year's experience as draftsman, I went into the shop to work, I soon learned otherwise and felt like changing Hamlet's words: "There are more things in heaven and earth, Horatio, than are dreamt of in our philosophy," to read, "There are more things in the machine shop and foundry to learn, than are dreamt of in our drafting room." I have since had a growing respect for the machinist and for the importance of the problems *he* is daily called upon to solve.

In this office of interpreter *to* the shop the best results can be obtained by thorough system, by uniformity of practice, by condensing, by avoiding repetition, by keeping clear of complicated systems and unintelligible symbols. The drawings should be made to as large a scale as practicable, with figures and lettering bold and well separted from the lines of the drawing. All lines should be heavy for satisfactory blue printing. Pattern figures should not appear on the drawing but be marked in a blue print specially for the pattern maker, or in some cases a separate pattern drawing made. Third angle projection should be used in all cases for the sake of uniformity and directness. Finish should be indicated by some method that will not allow of misunderstanding.

On standard machines, each piece should be fully detailed. If on a sheet by itself, so much the better, it can then accompany the work through the departments of the shop and other work need not be held waiting for the drawings to use for other pieces on the same sheet. Stock parts should be used whenever possible and when used should be called for by a simple numbering system requiring but little clerical work and reducing the chance of error to a minimum. The drawings should be mounted for the shop on some suitable form of board. A thin metal plate with edges rolled as in tin work, to stiffen, makes a cheap, light mount and prints so mounted can be stored compactly. Orders should not be verbal, but should be written on printed forms and officially signed, books being used that produce multiple copies in such numbers as are required. All orders for new machines or tools should go through the drafting room before work is started in the shop. On standard lines of machines where lot after lot is built, some changes at least are required and these are often radical. In these cases drawings must be changed, records made complete, pattern lists revised, patterns altered or made new, and when all is ready, the shop notified. If urgent, the work can go along piece-meal as fast as ready.

There is a difference in practice as to whether the drafting department or the shop foreman should order castings, forgings and stock. In either case complete lists should be made up and kept corrected by the drafting department.

Before leaving this part of my subject I would emphasize the fact that the drawing is a means to an end and not the end sought; a point sometimes lost sight of by draftsmen and often lost sight of by technical students, a misconception for which the instructors may be sometimes responsible. It is natural no doubt in schools where making drawings is the work in hand, to make the drawing as such seem of paramount importance.

Admitting what has previously been said regarding the important place occupied by the machinist, you will also note the importance of the drafting department, as the interpreter *of* the shop. A friend of mine, one whose work has been unusually practical and successful, makes a constant practice of consulting with the machinists in whose judgment he has confidence, sometimes stopping his work and making a trip to a distant part of the works to get the shop man's opinion. It is not only the helpful suggestion that may come from such a conference, but the very statement of the case so plainly that it can be understood by another, may show to the designer a better plan, or show up a hidden fallacy. It is much better to have the suggestions and criticisms of the shop at the beginning when some benefit may result. Such consultations should be of much more frequent occurrence.

The drafting room should be so located as to be in the midst of the shop work if need be, even at some sacrifice of quiet and other advantages. It should also be in close touch with the pattern shop and foundry.

When making special tools, such as jigs, milling fixtures, etc., for reducing the cost of the work, the foreman or workman should not only be consulted but should usually have a deciding voice as to what should be made. He, having the tools to use, generally knows better than the draftsman what is needed.

The machinist and shop foreman being constantly with the work, know which are the expensive operations, when there is difficulty in fitting, where the clearances are so small as to often become interferences. They have the machines to repair when they are worn or broken. Then why should their suggestions or opinions be disregarded or looked upon slightingly? Why should the spirit be bred of antagonism and distrust, until the shop man will not make suggestions for fear he will be snubbed or that his idea will be appropriated without credit? It certainly should not be so. I believe that it is not so in well-managed American shops to-day.

When I was abroad at the time of the Paris Exposition of 1900, I visited many shops in France and England. My observation at the time led me to believe, and my opinion was confirmed by the experiences of others with whom I compared notes, that the class distinction between the owner, the engineer (or designer) and the draftsman, on the one hand and the shop man on the other, is much greater abroad, especially on the Continent, than with us. It is there considered beneath the dignity of a technically-educated engineer, to listen to suggestions from machinists. The results of this feeling are sometimes very costly. In our American drafting rooms there is, in my judgment, a constant improvement in this respect, perhaps due to the increased percentage of American and Americanized draftsmen, thanks to the good work of our technical schools. At the best, enough attention is not paid this important function of the drafting department; that of conserving and making available the valuable information held by the shop.

A method I have known to be used with excellent results is for each foreman and responsible workman to have a blank stub book with suitable printed headings, paged and numbered. In this he writes all suggestions, taking out the perforated leaf and sending to the chief draftsman, keeping the stub as a memorandum for his own use. These are sorted when received, and those requiring immediate attention put into the hands of the proper parties to investigate, others are filed under the respective machines until time to build another lot, when they are considered collectively. The workmen are not only at liberty to use these books but are held accountable if they allow troubles to exist, lot after lot, on the machines they build, and do not report them. I would earnestly recommend that there be instilled into the minds of technical students the importance of taking advantage of the great mass of mechanical knowledge and the ideas stored up in the minds of the mechanics of the country, in the minds of the men who are actually doing the work, and that the students have it impressed upon them that if they become draftsmen, one of their important duties will be so to get in touch with the shop, as to make this knowledge available even though it may come to them in crude form from a mind not trained to analyze, to classify, and to put ideas upon paper. In other words, that they learn to be the *interpreters of the shop*.

In considering briefly the office of the drafting room as the *recorder for the shop*, we touch upon some of the more hum-drum, though not less important work, of tabulating, listing and classifying. Let me illustrate: Many thousand special tools accumulate in a large shop. Prominent among these are taps, reamers, drills and counterbores, cutters, gages, etc. When new designs are under way, it should be the draftsman's duty to adapt the design as far as possible to use such tools as are at hand. To accomplish this a complete record of all such tools should be kept and it is to the drafting department that we should look for dong it in a thorough manner, so that the record can be quickly referred to and depended on when used by either draftsman or shop man.

To again illustrate: A gear index of all spur gear patterns available to use under ordinary conditions arranged in order first by pitch, then face, then diameter will quickly tell whether a pattern for the required gear is made. These illustrations might be continued indefinitely. The card index is a great aid to such classification, as all entries are in order.

Another form of tabulating is in figuring tables for the shop. The draftsman's familiarity with figures and facilities for doing such work, often by the aid of the slide rule or calculating machine, makes the drafting room the natural and economical place for it to be done. The figuring of a table of all leads than can be obtained on a milling machine, with the regular change gears furnished, will illustrate. Those that have had to do with the cutting of spiral gears will appreciate the value to the shop of such a table.

There are many things to be preserved for reference that naturally find their way to the drafting room, such as trade catalogues, photos, copies of patents and technical journals. The treatment of these in indexing makes all the difference whether they are valuable—of growing value as time goes on —or as worthless as so much scrap paper.

UNIQUE HEATING AND VENTILATING PLANT.

An interesting heating and ventilating equipment was furnished the Twin City Telephone Co., St. Paul, Minn., some time ago, by the B. F. Sturtevant Co., Boston, Mass. In this installation special precaution was taken to purify the air supply. It has been demonstrated that about 90 per cent. of the trouble caused by imperfect contact in the switchboard connections can be prevented by thoroughly cleansing the air as it enters the building. Many experiments have been tried in the way of dry-cleaning by filtering through screens of wire and cheese-cloth or cotton-batting, but all such devices require frequent renewal, sometimes at considerable trouble and expense. By continued use any filter of this character must deteriorate and eventually become clogged, and in order to avoid the results of neglect it ought to be practically automatic. This point is essential in an air-cleaning system.

The action of the air-purifying and cooling apparatus adopted by the Twin City Telephone Co. consists in thoroughly saturating the air with water by passing it through a fine spray and afterward precipitating the moisture with the collected impurities and discharging it into the sewer. The water, which is taken up at high velocity and held in mechanical suspension, is extracted by centrifugal force by passing it through a series of tubes in which spirals are so placed as to give the air a whirling motion, causing the suspended particles, which are heavier than the air, to be thrown outward and brought in contact with the tubes, from which they flow through perforations to a drip-pan below.

The washing process imparts about 70 per cent. humidity at a temperature of 70 degrees Fahr. in the operating room. This is considered the most desirable for health and comfort and avoids the excessive dryness resulting with other systems of heating and ventilating which often require a humidostat to correct the defect. Moreover, in the summer time, with the temperature outside at 80 degrees Fahr. and with the normal temperature of the city water, the air delivered to the rooms can be readily reduced to 70 degrees.

The air after being tempered, washed and dried is blown by the fan through the reheating coils into the tempered air chamber. A mixing damper is placed with connections to both so arranged that the hot or tempered air, under the control of the Power's thermostat in the operating room, is mixed automatically to the proper degree, maintaining throughout the year a constant temperature in the room with uniform air delivery and humidity.

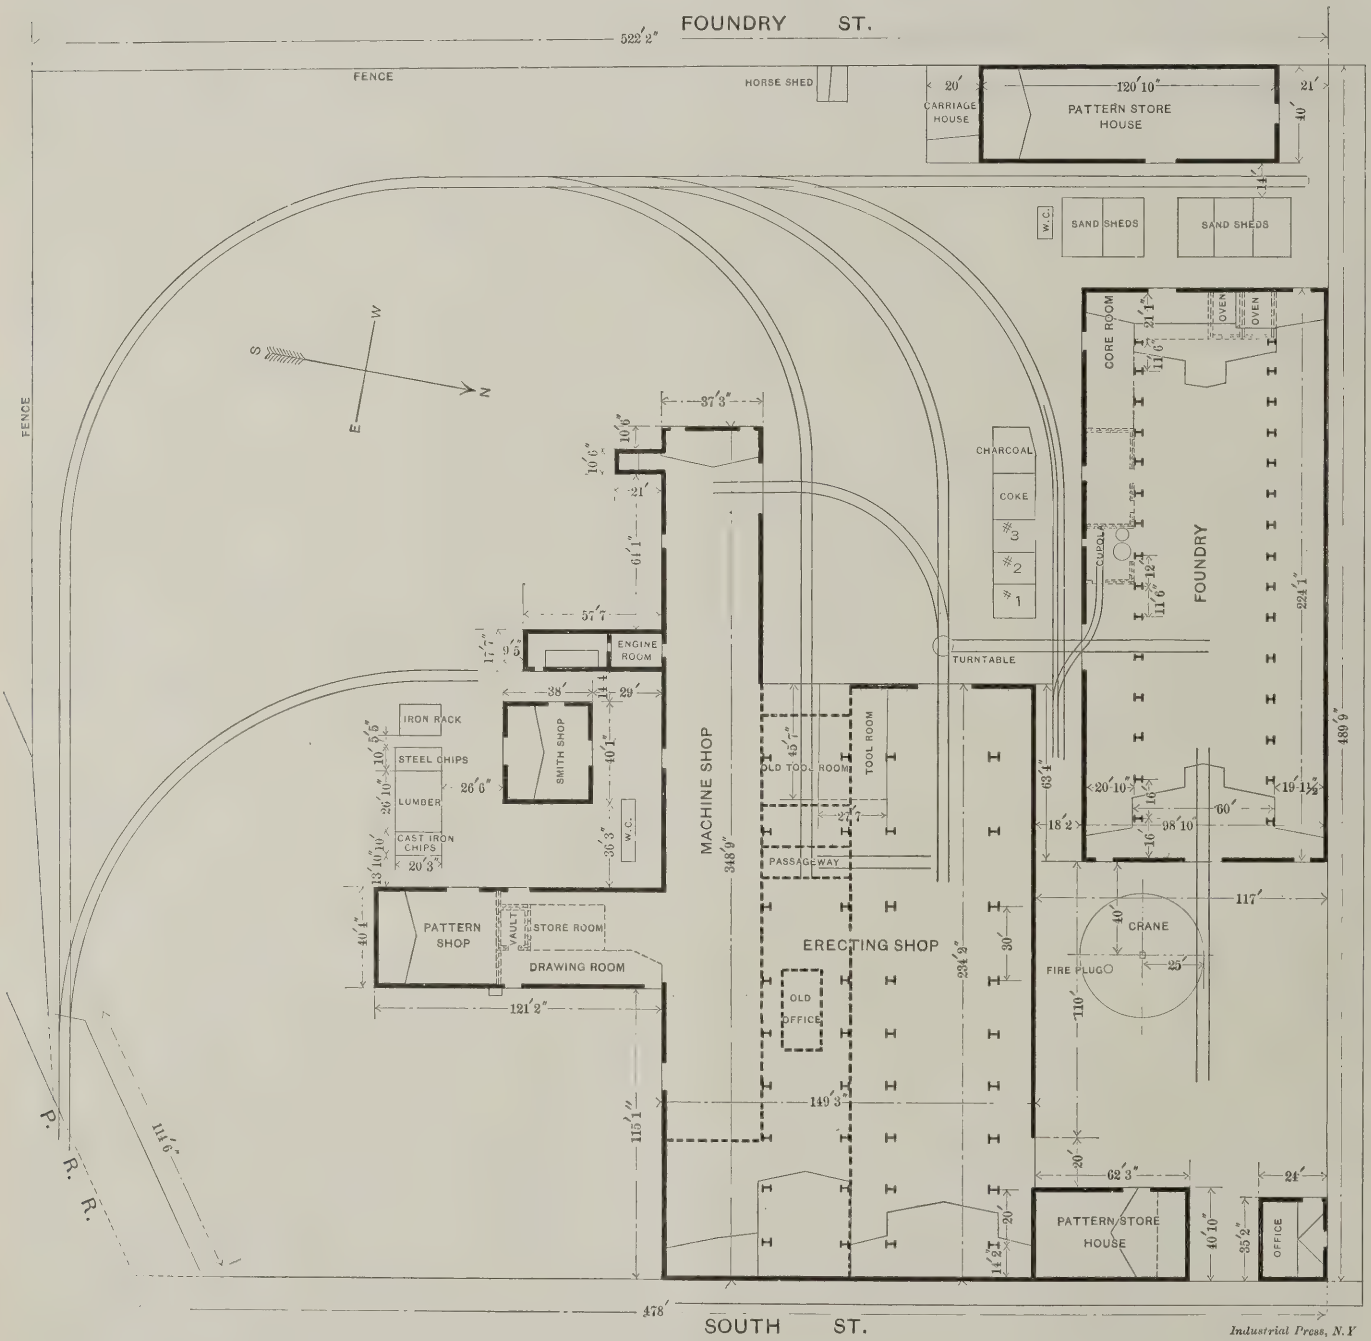
While such a system is practically a necessity in a modern telephone building, especially in cities where soft coal is burned, it is equally applicable to all public buildings, particularly in large cities where the air is laden with impurities and where the summer heat is almost unbearable. The time is probably not far distant when the marked advantages of such a system will be fully recognized and people will insist that they should be kept cool in summer as well as warm in winter.

* * *

A radial brick chimney was recently built in Newark, N. J., to accommodate an extension to the street railway power house. It is 250 feet high, 9½ feet inside diameter at the top and 13¾ feet inside diameter at the base of the circular column. The base is built of common brick, but the circular column is entirely composed of radial brick containing dead air spaces. The height of the base is 39 feet, and its width across "flats" is 21 feet. The base contains 160,000 common brick and the circular column 150,000 radial brick. The cost was $15,000.

THE RECONSTRUCTED SHOP OF THE BETTS MACHINE CO.

Machine shops built in these days and in accordance with modern ideas usually provide for expansion in some manner more or less consistent with the original plan of layout. This provision for future growth is very well illustrated, for instance, in the great plant of the Allis-Chalmers Co., at West Allis, Wis. Regarding the layout of this plant Mr. Edwin Reynolds is reported to have remarked, in a spirit of humorous exaggeration, that the wings of the main building could be extended indefinitely east and west, if need be, until they meet on the opposite side of the globe, and with that point reached, sufficient offset had been provided in the plan so that the extensions could pass by one another without interference and each make a complete circuit! But in the shop construction of the days gone by the probability of future growth usually appeared so remote or improbable that rarely was there any provision made for it. The result is that many a shop owner or manager has spent some bad days and nights trying to devise plans for extending his plant without tearing them down and building anew. And it has somtimes proved that an old plant can be remodeled into an up-to-date shop without tearing down the old shop or seriously disturbing the regular routine of work. An excellent illustration of an old machine shop converted into a modern plant with traveling cranes and other appurtenances for the economical production of heavy machine tools, is that of the Betts Machine Co. at Wilmington, Del., which forms the subject of the following description. The product of this well-known concern which was started by E. and A. Betts in 1860, is horizontal boring and drilling machines, planing machines, boring and turning mills and slotting machines.



Industrial Press, N.Y.

Fig. 1. Plan of Bett's Machine Co.'s Works, showing excellent Switching Facilities, etc. Note Outline of the Old Machine Shop partly indicated by Dotted Lines.

The layout of the plant is given in Fig. 1. The plot of land on which the buildings stand, extends about 490 feet on Maryland Avenue, and is bounded on the sides by South and Foundry streets. On the back is the Philadelphia, Baltimore & Washington Railroad, part of the Pennsylvania Railroad system, which gives unexcelled shipping facilities by rail. The plan of the old machine shop is included in that of the present machine shop, an end and a part of a side wall being indicated by heavy dotted lines. The locations of the old office, tool-room, etc., are also indicated in the same manner. A new office has been built on the corner of the plot at the junction of Maryland Avenue and South Street. The first addition to the shop was made some four or five years ago. It consists of a monitor roof erecting shop and heavy machine shop, 234 feet long and 75 feet wide, which was built parallel to the machine shop and at a distance from it of about 38 feet. It extended through to the street so that all the available space in that direction was taken up, the street line forming, as it were, the point of departure. A covered passageway connected the new erecting shop with the old machine shop. This section is equipped with two Shaw traveling cranes, one 10 tons and the other 20 tons capacity. The span of the cranes is confined to the width of the monitor; the aisles at the sides being reserved for tools. There are no galleries, all the floor space being on the ground. The machinery in this part of the plant is driven by electric motors belted to line shafts. Electric current for driving the motors is supplied by the city power station. The heavy planers and other heavy machine tools are located in this part. Across the northeast end is a 10-foot planer embodying a new feature of design of which we shall probably hear more later. It has a platen 38 feet long and but 6 feet wide. The platen is made in two parts which may be uncoupled in the center, and a one-half section used on short work. The side heads are mounted on supplementary, horizontal slides mounted on side rails of the housings. These slides solidly support the side heads when they are extended clear in to the sides of the platen. In this manner the capacity of a large planer is obtained with a comparatively light platen, which feature enables it to be advantageously used on work of a size and weight far less than its normal capacity.

Soon after the building of the erecting and heavy machine shop the increasing demand for heavy machine tools made it imperatively necessary to have more room, as the space between the old machine shop and the erecting shop, was roofed over, and the brick walls between them torn down. This gave one floor nearly 150 feet wide and 234 feet long in the main part. The old machine shop was extended to South Street, making it nearly 349 feet long. Its width is about 37 feet. The building of the new part and the tearing down of the walls supporting the roof of the old machine shop proceeded without stopping the machinery. When it is considered that the portion of the roof to be supported was nearly 300 feet long and that it carried a heavy lineshaft in motion, some difficulty of the work will be appreciated.

The roof of the new erecting shop was built considerably higher than that of the first one so as to give more head room under the crane. This was required by the increasing sizes of machine tools built by the company. The head room under the hook is about 27 feet. It is a Pawling & Harnischfeger, capacity 20 tons. The lighting in this section is superb. A large proportion of the side area above the adjacent sections is given up to glass, as will be seen in the illustrations, Figs. 2 and 3. Reference to the plan, Fig. 1, will show that the new erecting shop, in effect, acts as a large monitor or clearstory for the adjacent sections, the old machine shop forming one side. The floor in both of the new sections is of heavy plank laid on beams which are bedded in steam ashes. The floor in the machine shop is of brick, being the original floor and still in fair condition. Railroad switches run directly into both sections of the erecting shop, and a switch is laid along the side of the foundry. Crossing these tracks are shop tracks of standard railway gage for short cars on which heavy castings may be delivered from the foundry to the machine shop or erecting shop, by different routes, using either the railway tracks or the shop tracks. Another switch delivers coal directly into the boiler rooms supplying the shop engine.

The superintendent's office is in the drafting room, and just back of the drawing room is the pattern shop. This arrangement brings the two departments in close touch. The location of the superintendent's office is convenient to all

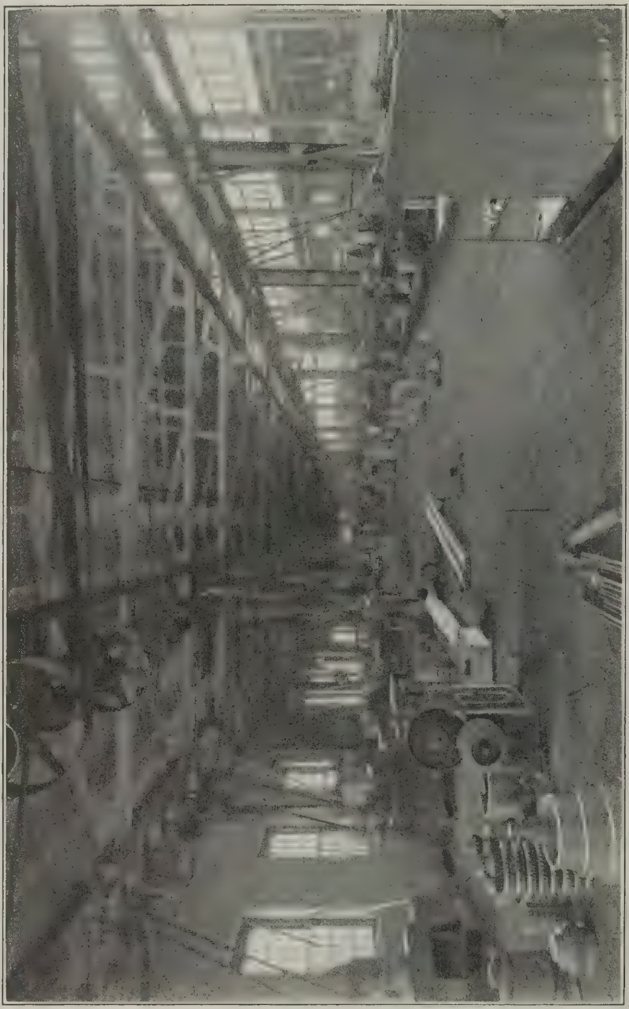

Fig 6. View of Old Machine Shop from opposite end. The Screw Machines are at this end.

parts of the machine and erecting shops, but is somewhat removed from the foundry. The small blacksmith shop is also close at hand.

In the illustrations, Figs. 5 and 6, which are views of the old machine shop taken from opposite ends, it will be observed that the roof trusses are of a peculiar construction seldom or never seen now. They are made of cast iron, and the same principle of construction, but of much longer span, was employed for the roof trusses of the old part of the foundry. The old part is about one-half the length of the present structure. In the new part of the foundry steel trusses, of course, were used. The length of this building is 224 feet and its width is 98 feet. It is well equipped with large cupolas, traveling cranes and the other accessories of a modern foundry. Besides making all their own castings considerable work is done for other parties.

A large storehouse for patterns stands back of the foundry, and another pattern storehouse is located at the opposite side of the plot near the office. As previously remarked, a railroad switch is laid alongside the foundry so that coal, coke, sand and iron may be brought directly to the door or unloaded into the adjacent storage sheds.

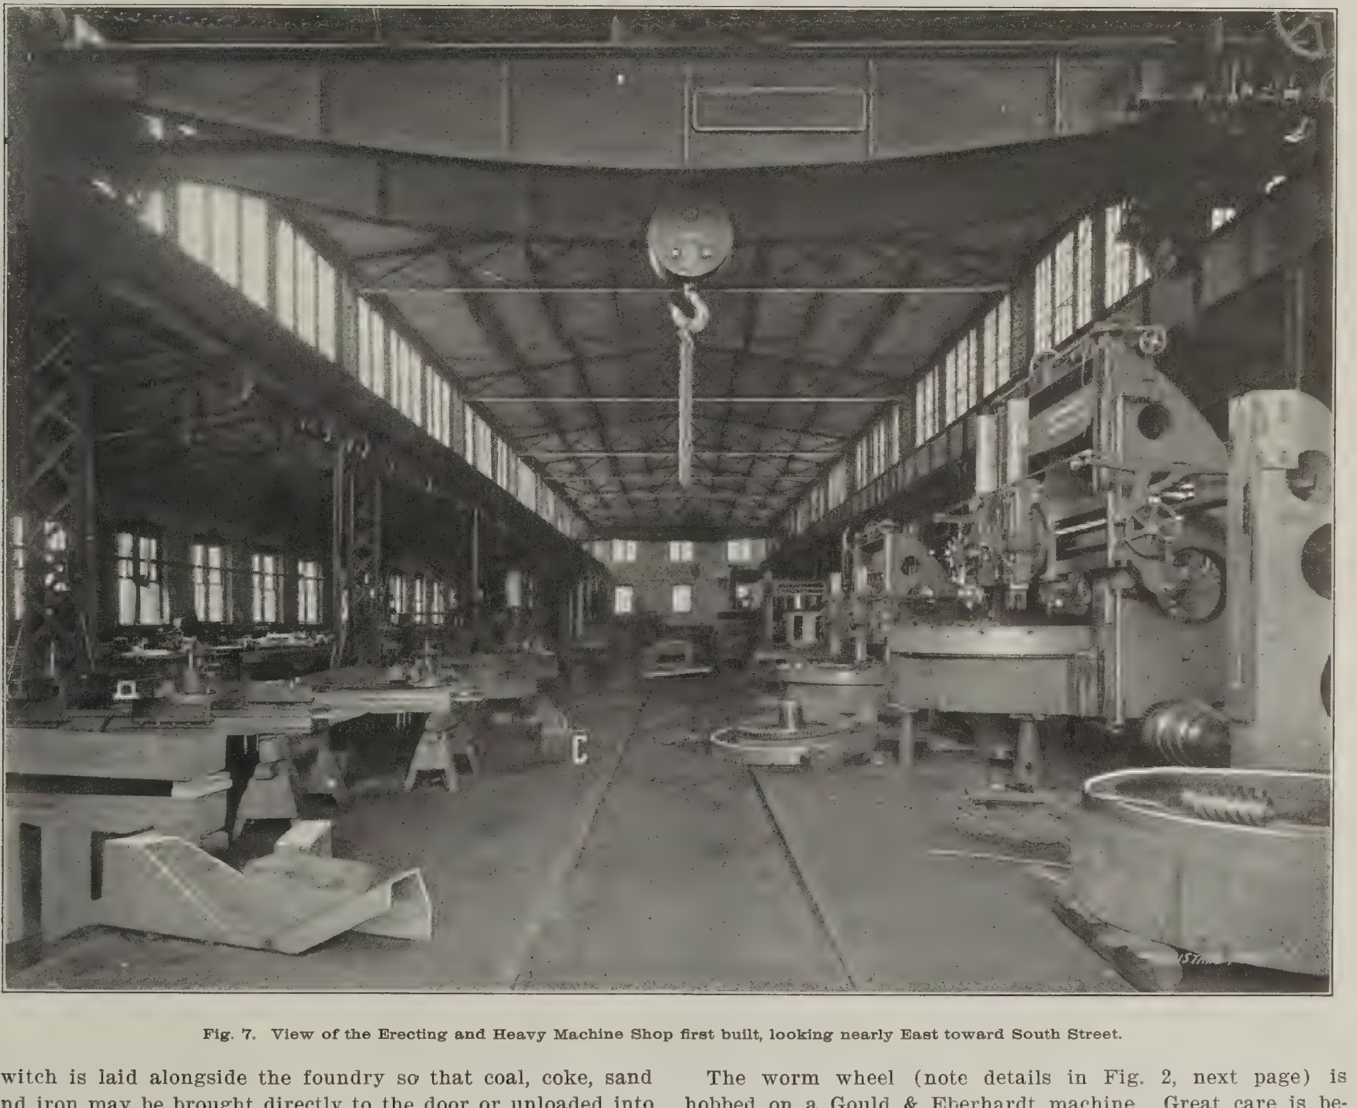

Fig. 7. View of the Erecting and Heavy Machine Shop first built, looking nearly East toward South Street.

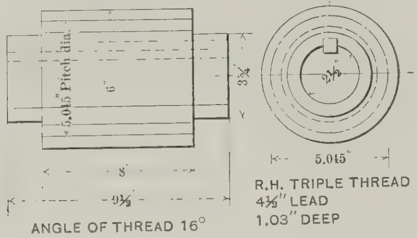
THE BETTS WORM-DRIVEN BORING MILL.

An interesting feature of the product of the Betts Machine Co. is the design of their worm-driven boring mill, which they have been manufacturing for the past few years. In this machine—made in 5-foot, 6-foot and 7-foot sizes—the cone pulley is mounted on a shaft carrying a triple-thread, bronze worm engaged with the teeth of a cast-iron worm wheel, which is bolted directly to the under side of the revolving table or faceplate. The worm-gear driving mechanism makes a simple and powerful combination, since a large velocity ratio may be effected with only two members, and efficiently, too, it appears, when the proportions of diameter and pitch are correctly designed. In the 5-foot mill the worm wheel has 72 teeth of 1½ inch pitch, and since the worm engaging it has a triple thread of 4½ inches lead (1½ inch pitch), it follows that the velocity ratio is 24 to 1, that is, the cone pulley must make twenty-four turns to one revolution of the faceplate.

In the first design of the boring mill a worm wheel and worm of the hour-glass or Hindley type was used, but with indifferent success. What advantage this type of worm gear is supposed to possess in the matter of tooth contact was more than offset by lack of accuracy in the tooth spacing of the worm wheel. That is, it appeared to be impossible to get this type of gear made with the accuracy demanded by modern boring mill practice. In the boring of a small hole, when it is necessary to run the table at high speed, and which is the supreme test of accurately cut gearing, every tooth in the worm wheel insisted on being in evidence in the bored hole, it being possible to tell the number of teeth by simply counting the chatter marks. So the Hindley type of worm and worm wheel was discarded in favor of a plain worm and a simple hob-cut worm wheel.

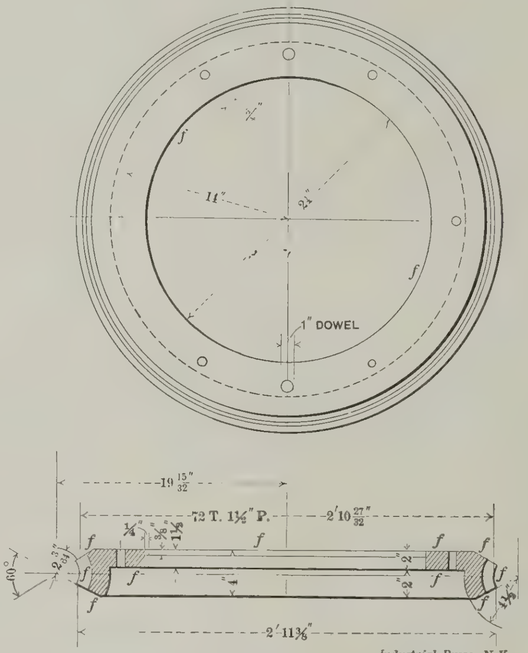
The worm wheel (note details in Fig. 2, next page) is hobbed on a Gould & Eberhardt machine. Great care is bestowed on the cutting of the worm wheel and in chasing the worm, but after all possible care has been taken it is necessary to carefully grind the two together under exactly the same conditions they will be in in use. This is done, of course, by assembling them and grinding in the boring mill for which they are designed. A tooth space of the worm wheel is first marked; also a spot on a thread of the worm. The two are then engaged so that these marks coincide, and the grinding begins. White sea sand mixed with water is the abrasive used, it having been found superior to other combinations. It has also been found that when grinding has once been started, there must be no let-up in pressure, but that the worm must be forced against the teeth with considerable pressure, and followed up as the grinding proceeds. If the attempt is made to grind with the two running together freely, the invariable result is an inaccurate job which can be corrected only with difficulty. But by forcing the worm down during the grinding process the high spots are worn down uniformly, and the tendency seems to be to form all the teeth to same thickness and pitch. This applies, of course, only when the original limits of inaccuracy were narrow. Another effect of the grinding is that the mating members are, to a minute extent, made to imitate the shape of the Hindley worm and worm wheel. During the grinding process the boxes *E E′*, Fig. 3, are held loosely by their bolts. Simple wrought-iron fixtures with setscrews are clamped to the boring mill frame behind the boxes, and the screws are used to force the worm against the worm wheel.



Industrial Press, N.Y.

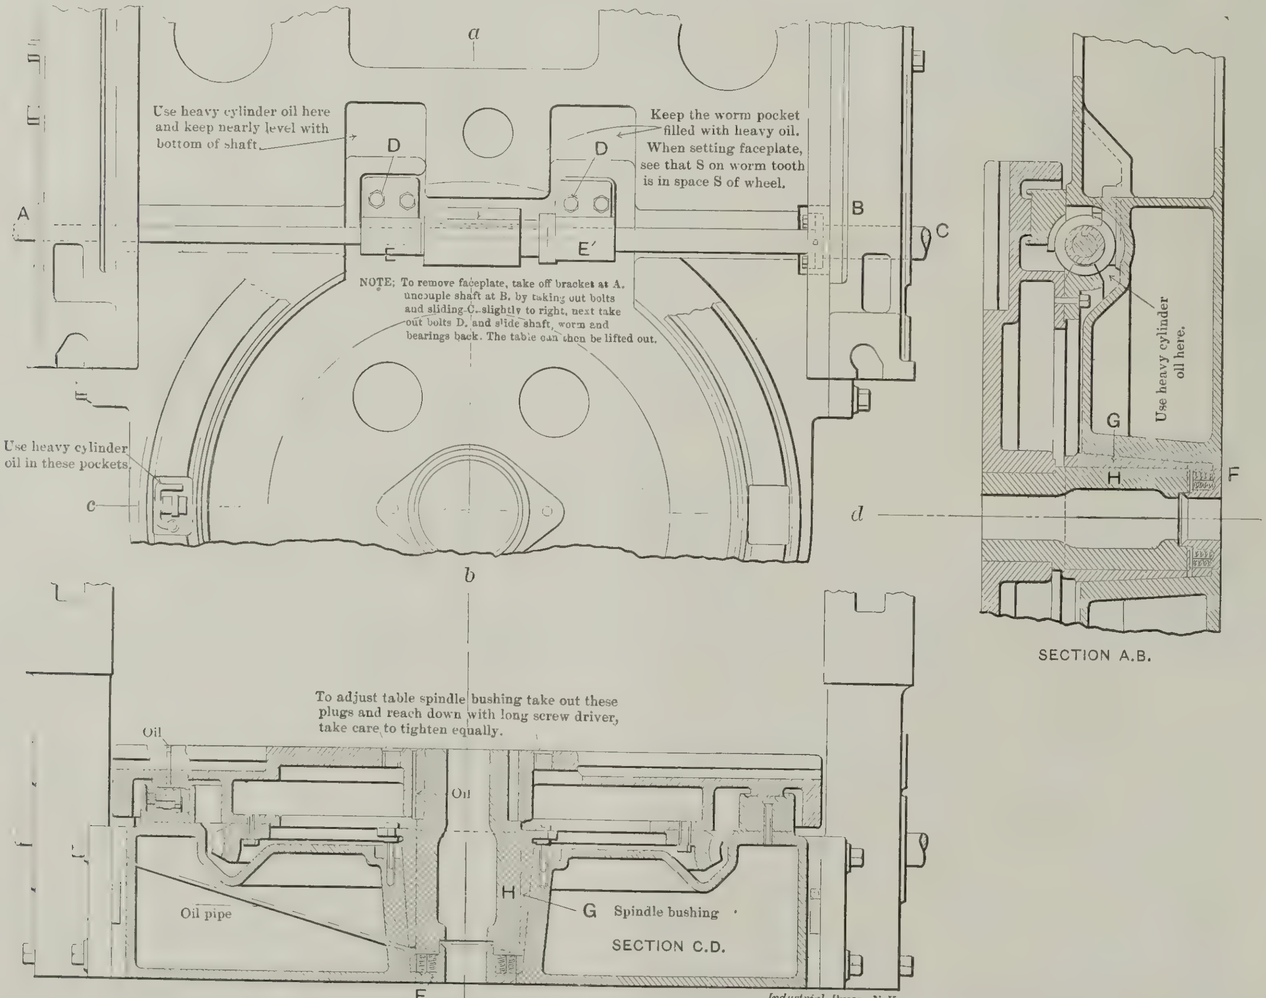
Fig. 1. Details of Worm for Five-foot Mill.

The end thrust of the worm is taken by a ball-bearing containing 14 balls ⅞ inch diameter, in the case of a 5-foot mill. Regarding the use of a ball bearing for duty like this there seems to be no trouble when the balls are proportioned for the work they have to do. Most of the trouble encountered when the ball bearing has been used for heavy work, is due either to its not being proportioned to the pressure, or to the speed having been too great. In this case the highest speed is about 600 revolutions per minute, which is the speed necessary to give the periphery of a 4-inch hole a velocity of 25 feet per minute. The worm and worm wheel run in a bath of oil, insuring perfect lubrication at the comparatively low speed at which the worm wheel operates. In the 5-foot mill the worm is 8 inches long, 6 inches outside diameter, 5.045 inches pitch diameter, depth of thread 1.03 inches. As already stated it is triple thread, 1½ inch pitch and 4½ inches lead. The angle of thread, with a line perpendicular to its axis, at the pitch diameter is 16 degrees. Fig. 4 shows the faceplate removed and the worm and ball bearing exposed to view.



Industrial Press, N.Y.

Fig. 2. Details of Worm-wheel for Five-foot Mill.



Use heavy cylinder oil here and keep nearly level with bottom of shaft.

Keep the worm pocket filled with heavy oil. When setting faceplate, see that S on worm tooth is in space S of wheel.

NOTE; To remove faceplate, take off bracket at A. uncouple shaft at B. by taking out bolts and sliding C. slightly to right, next take out bolts D. and slide shaft, worm and bearings back. The table can then be lifted out.

Use heavy cylinder oil in these pockets.

Use heavy cylinder oil here.

To adjust table spindle bushing take out these plugs and reach down with long screw driver, take care to tighten equally.

Spindle bushing

Industrial Press, N.Y.

Fig. 3. Instruction Sheet sent out with Worm-driven Boring Mill, showing Construction and giving Directions as to Care, etc.

Another interesting feature of this design of boring mill is the step bearing, and the manner of relieving the load on the outside ring bearing. The common practice in boring mill construction, as we all know, is to provide screw connection in the front of the base by which the operator can take part of the load off the ring bearing and place it on the pivot or step bearing, when running at high speeds. Like all features of adjustment in machine construction, this one is likely to be abused. If the table is lifted too high, which is likely to be the case unless the operator is more than ordinarily careful, there will likely be a lack of concentricity between the turned periphery of, say, a pulley and the hole bored in the hub. In the Betts mill no adjustment is provided for the operator to manipulate. The load on the outer bearing ring is relieved automatically and at all speeds. A circular cast-iron disk fits in the bottom of the spindle hole. This is drilled with a number of $\frac{7}{8}$-inch holes, say, 24. In these holes are placed a certain number of coiled springs, the number being determined by experiment on each mill. On top of the springs is a bronze plate upon which rests the spindle *H*, Fig. 3, of the table. When the mill is assembled, the disk *F* is partly filled with springs, say 22 are put in. The table is lowered with strips of thin paper placed on the outer bearing ring. If, when the table is down, the strips of paper are found loose, some of the springs are removed—say 2. This leaves 20, and then the table is replaced. If then the strips of paper are found to be pinched, it is fair to presume that the weight of the table is approximately balanced by the springs. The condition of approximate balance having been determined, the table is again removed and one-fourth of the number of springs taken out, leaving in this case 15 springs in place. In this way it is calculated that 75 per cent. of the weight of the table is balanced on the step bearing. Of course the weight of the work on the table reduces the proportion of the load borne by the step, but as it is usually only comparatively light work that is run at high speeds, this objection is not considered serious. The step bearing is also shown in Fig. 4, setting beside the spindle bushing.

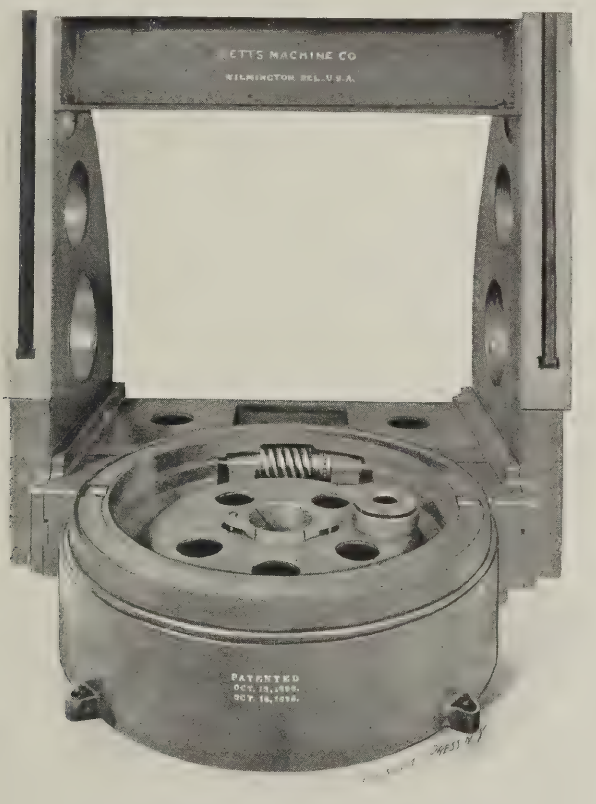


Fig. 4. View of Boring Mill with Faceplate removed, showing Worm, Ball Thrust Bearing and Step Bearing.

The cut, Fig. 3, used to show the principle of construction, was made from an instruction blueprint regularly sent out with all worm-driven boring mills. The plain directions for the care and adjustment of the mill are reproduced. While there is nothing new in sending out instruction sheets like these, in our opinion many machine tool builders could very profitably follow and extend the practice. Anything that will help a machine to be understood and cared for is to the mutual profit of all concerned.

THE DIFFERENTIATION OF ENGINEERING.

The best definition of civil engineering is probably that which was given seventy-five years ago by Thomas Tredgold, namely: "Civil engineering is the art of directing the great sources of power in nature for the use and convenience of man." At the time this was written, however, there were but two recognized branches of engineering, one designated as civil engineering, and the other as military engineering, the former including all those branches not directly connected with military operations. But the remarkable series of mechanical inventions which distinguished the last third of the eighteenth century—the spinning jenny by Hargreaves, the spinning frame by Arkwright, the mule by Crompton, the power loom by Cartwright, the steam engine by Watt, the puddling process by Cort, and others—followed in the first third of the past century by the development of the steam locomotive by Stephenson, the steamboat by Fulton, and by further great improvements in the manufacture of iron and steel, soon led to the differentiation of civil engineering into several branches. The first branch to leave the parent stem was mechanical engineering, followed by metallurgical and mining engineering as the developments in the mining and reduction of metals progressed; and toward the middle and end of the last century the tremendous advance in all branches of applied science speedily differentiated engineers into the classes named, as well as into others. For instance, within the last quarter of a century the development of the electric motor and other great discoveries in electrical science have led to the development of electrical engineering as a distinct profession, while the advances in sanitary science and the discoveries with reference to the nature, causes and prevention of disease have resulted in the development of sanitary engineering as a branch of civil engineering quite extensive enough to constitute a profession by itself. But notwithstanding the divergence of all these branches from the parent stem of civil engineering, even what is left to be included under this title remains undoubtedly the widest in scope of all the engineering professions, and in practising it a man must become a specialist in some one branch. It comprises the construction of railroads, of roads, of canals, of street and interurban railways, the improvement of rivers and harbors, the construction of lighthouses and other works necessary for carrying on trade and commerce; it includes structural engineering, or the construction of bridges, aqueducts, foundations, steel frames for buildings, etc.; it treats of hydraulic engineering, including the development of water powers, and the construction of dams and power plants up to the point at which the mechanical engineer is called upon to supply the motors; it deals with surveying, which is necessary in the laying out of works of all kinds, but constitutes also a branch by itself known as land surveying, which, when extended to the survey of very large areas in which the curvature of the earth must be taken into account, leads to the intricate problems of geodesy, or the measurement of the earth, and touches upon the field of terrestrial physics; and it further includes a great variety of problems due to the congregating of persons in cities—undoubtedly the most striking sociological development of the last century—including works of water supply, sewerage, the drainage of buildings and lands, the disposal of wastes, and the construction and maintenance of streets and pavements. This last group of problems, involving the health of communities, although now the special field of the sanitary engineer, is more generally considered as a branch of civil engineering. Broadly speaking, it may be said that civil engineering deals with structures, or works at rest; while mechanical engineering deals with machines and motors, or works which are in motion. It will be seen, however, that the execution of civil engineering works requires at many points the collaboration of the mechanical or the electrical engineer, and that it also brings the practitioner into close contact with economic and sociological problems.—*Prof. Geo. F. Swain in the N. Y. Tribune.*

Machine shop profits to-day are made up out of time that used to be wasted by the old methods.

ACCURATE MACHINE DESCRIPTION.

A NOVEL METHOD OF MAKING NOTES OF MACHINE DIMENSIONS.

CHARLES H. FITCH.

In order to solve a problem we must know its elements. If the solution is graphical, these elements are measures of lines or dimensions. If it be arithmetical the elements are numbers. If analytical or algebraical the elements are quantities designated by letters to which numeral values may be assigned, or which may have definite relations to each other whether values are assigned to them or not. It is usually more convenient to solve problems graphically than analytically, but the analytical solution may be more exact, and the study of the problem by analysis sometimes leads to the discovery of new and useful relations. A well qualified mechanical engineer and mathematician is able to use analytical methods, although where equations become involved and complicated most practical men would beg off from the time, mental labor and difficulty involved by this treatment.

I hold, however, that all methods have their uses, and that there is in particular a useful unoccupied field for such accurate text descriptions as will enable a draftsman to sit down with them and develop therefrom all the drawings necessary to make patterns and do the machine work—in fact, to build the machine from the text.

As it is now, we all know that machine descriptions are very loose and incomplete. The text gives us an idea of the general nature of the machine by appealing to our familiarity with similar constructions and mechanical elements. This is usually assisted by a picture of the machine in perspective, and perhaps by sectional drawings on too small a scale for accurate reproduction by taking off measurements with dividers.

This may suffice very well for general public information in cases where it is not desired to tell too much or to make it too easy to copy the machine. To do this the machine must be re-designed. The description and cuts are, in fact, a language designed "to conceal thought," although it would be more accurate in this case to say that the language was partly to conceal and partly to reveal the thought embodied in the machine.

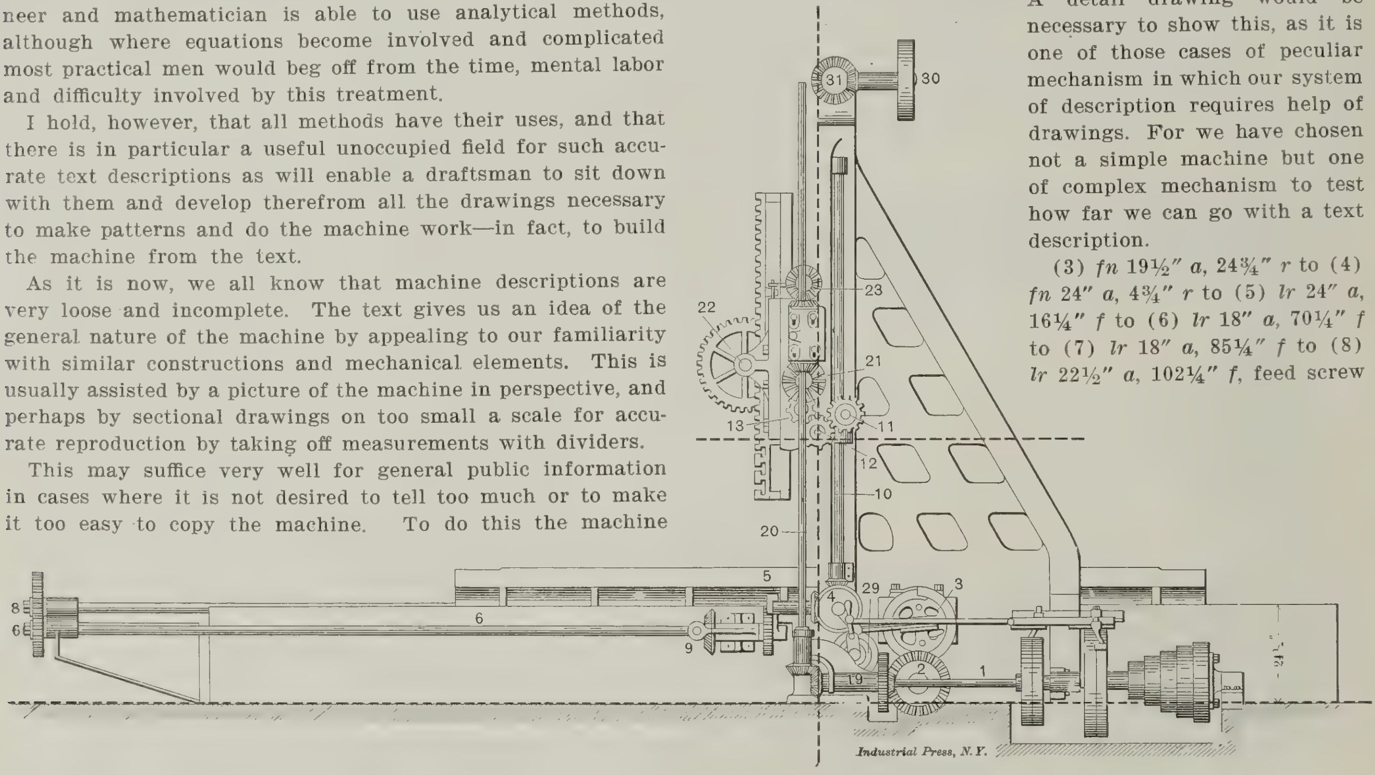

Fig. 1.

We have to offer in this article a kind of description which will suffice for the location of all the center lines and axes of motion and working surfaces of a machine, and take for illustration the slotting and drilling machine shown in cuts Fig. 1 and Fig. 2.

The scheme of description is as follows:

All points, lines and regular definable surfaces in space can be referred to three planes and will then be completely determined. In some cases it may be convenient to choose parallel planes for convenience of reference, but practically we have three planes in any case. The planes chosen have traces or projections shown by broken lines on Figs. 1 and 2. Directions with reference to the several planes are indicated by letters.

From the horizontal plane, *ab* = above, below.
From the face vertical plane, *fn* = far, near.
From the cross vertical plane, *lr* = left, right.
These planes are as assumed in Fig. 1.

Now if we start our description with the driving shaft of the platen power feed, its direction is *lr*, left to right. Its center is 5″ *a*, that is 5″ *above* horizontal plane; and 4¾″ *f*, that is, 4¾″ *far* or beyond (not near, or this side of) the face vertical plane. The location is not shown in Fig. 2, being behind plate of frame, the axis being No. (1) gearing with No. (19).

Designating axes of motion by numbers in parenthesis, the above description may be condensed and proceeded with as follows:

Platen power feed. (1) *lr* 5″ *a*, 4¾″ *f*, driving shaft to (2) *fn* (far near direction) 5″ *a*, 24″ *r* (24″ to the right) to (3) *fn* 19½″ *a*, 24¾″ *r*.

Note on (2-3); feed escapement. The intermittent feeds are given by a peculiar escapement movement which, in conjunction with ratchet wheels in the dependent trains, regulates the feeds. A friction pinion grooved about its girth meshes with a friction wheel having a segmental half-around grooved rim, either end of the grooves having a partial extension in a toothed pawl hung within the wheel, so that while connection is broken after a half turn either way, and the feed motion is positively stopped by lugs, upon reversal of motion of the pinion the wheel re-engages by means of one of the pawls. A detail drawing would be necessary to show this, as it is one of those cases of peculiar mechanism in which our system of description requires help of drawings. For we have chosen not a simple machine but one of complex mechanism to test how far we can go with a text description.

(3) *fn* 19½″ *a*, 24¾″ *r* to (4) *fn* 24″ *a*, 4¾″ *r* to (5) *lr* 24″ *a*, 16¼″ *f* to (6) *lr* 18″ *a*, 70¼″ *f* to (7) *lr* 18″ *a*, 85¼″ *f* to (8) *lr* 22½″ *a*, 102¼″ *f*, feed screw for platen nut. (6) may also be driven from (9) *fn* 18″ *a*, 31″ *l*, constituting the platen hand feed.

Slotter-frame Power Feed.—(4) *fn* 24″ *a*, 4¾″ *r* to (10) *ab* 16¼″ *f*, 4¾″ *r*.

Branching of Power Feeds.—(4—5 and 4—10). The stud on *n* (near) face of *n* (near) side post carries a bevel gear rocked by connecting rod and arm, and this gear at once meshes with two bevel pinions one on *ab* (above-below or up and down or vertical), and one on *lr* (left-right) shaft, making it the branching piece for slotter frame and platen feeds, respectively.

Slotter-frame Power Feed Continued.—(10) *ab* 16¼″ *f*, 4¾″ *r* to (11) *fn* 7″ *a*, 4½″ *r* to (12) *fn* 2½″ *a* 2, 1½″ *l* to (13) *fn* 8¾″ *a* 2, 4 3-16″ *l*, feed screw for slotter-frame nut. The *a*2 merely indicates that we have transferred our horizontal reference plane to an upper movable plane.

Slotter-frame Hand-feed.—(14) *lr* 26″ *a*, 192¾″ *f* to (15) *ab* 2¾″ *r*, 192¾″ *f* to (16) *fn* 2¾″ *r*, 8¾″ *a*2, to (13) *fn* 4 3-16″ *l*, 8¾″ *a*2.

Drill Frame Hand Traverse.—(17) *lr* 6 7-16″ *a*2, 9½″ *n*2 to (18) *lr* 11 7-16″ *a*2, 9½″ *n*2, axle of traverse wheel meshing with thread of screw (13). The use of *n*2 obviously indicates transition to another *fn* (far near) vertical reference plane, parallel with the first, and movable.

Slotter Tool Train.—(1) *lr* 5″ *a*, 4¾″ *f* to (19) *lr* 5″ *a*, 6″ *n*, to (20) *ab* 4½″ *l*, 6″ *n* to (21) *fn* 4½″ *l*, 14¼″ *a*2, *to* (22) *fn* 18″ 55 *l*, 19½″ *a*2.

Drill Tool Train.—(20) *ab* 4½″ *l*, 6″ *n* to (23) *fn* 4½″ *l*, 40⅜″ *a*2, to (24) *ab* 4½″ *l*, 11″ *f*2 to (25) *ab* 11¼″ *l*, 0″ *f*2. Note on tool train engagements (20 to 21) and (20 to 23): A single train of mechanism serves to operate either drill or slotting tool with the following disengaging device. The upper part of *ab* (or vertical) power shaft for the tool motions is carried by a bearing bolted upon *n* (near) end of cross-slide with bolt holes elongated *ab* (or vertically) so that the bearing may be slipped and set up or down, carrying with it a bushing having a bevel pinion below and a miter above the bearing, either one of which may be thus disengaged, while the other is thrown into gear with its train.

The Slotting Bar (22 and following). The rack of slotting bar has a 6″ face *fn*, and extends *l*-ward (or to the left) from a 12″ *fn* by 2½″ *lr* slide bar retained on either side by gibs, while take-up for wear is provided by three long *ab* keys two on *l* side, either side of rack and one on *n* side of bar, which keys are set by means of stud bolts in the slotter frame, with jamb nuts.

Drill Feed Train.—(23) *fn*, 4½″ *l*, 40⅜″ *a*2 to (26) *fn* 8¾″ *l*, 47⅞″ *a*2 to (27) *fn* 14 15-16″ *l*, 33″ *a*2, to (28) *ab* 19 1-16″ *l*, 13″ *f* to (25) *ab* 11¼″ *l* to 0″ *f*2. Drill feed train (23 to 26) spurs are geared 50 to 58 teeth, (26 to 27) cone pulley of 4 steps 12″ diameter to 4″ diameter, faces 1⅝″, belting to cone pulley 6½″ diameter to 14½″ diameter. (27 to 28), worm gearing with worm wheel (28 to 25), spurs geared in ratio 3 to 5, the latter keyed on nut of feed screw extension of drill spindle. The screw is right hand, square thread, ½″ pitch, 47¼″ long, and with thrust bearings above and below. Where it joins drill spindle there is keyed upon it a cross-bar whose *fn* wings guide in slots of *ab* pillars of the drill frame.

Belt Shifting Train.—(1) *lr*, 5″ *a*, 4¾″ *f* to (29) *fn* 12″ *a*, 9¼″ *r*.

Cross Slide (ab) Traverse.—(30) *lr* 158 *a*, 12″ *f* to (31) *fn* 158″ *a*, 6″ *r* to (32) *ab* 27½″ *f*, 6″ *r* and (33) *ab* 174½″ *f*, 6″ *r*.

This sufficiently illustrates the plan of a universal system of description of machinery trains and elements.

The first suggestion is that it may add new terrors to technical reading. That may be so, but if we take up a magazine devoted to textile design or ladies' embroidery we will encounter long descriptions for making patterns and stitch work designs which are essential to communicate the necessary information and which are very useful although they may have to be read needle in hand, and be no more suited to thrill the soul than are the genealogical records in the books of Moses.

This plan is, I think, worth putting on record in the technical engineering press, because it has utility. The foregoing description looks a little complex, but it is of a complex machine with many trains, the full details of which would require a large drawer full of drawings. I have found it useful in simpler cases in several ways.

First, as a time and labor saver. I can borrow a set of drawings and in a very short time can take off all the details necessary for their entire reproduction.

Second, as an inconspicuous record. These notes take hardly any space, and are a sort of shorthand which the casual reader cannot make out. They are private to that extent.

Third, as a check. A draftsman can use these dimensions to check his drawings.

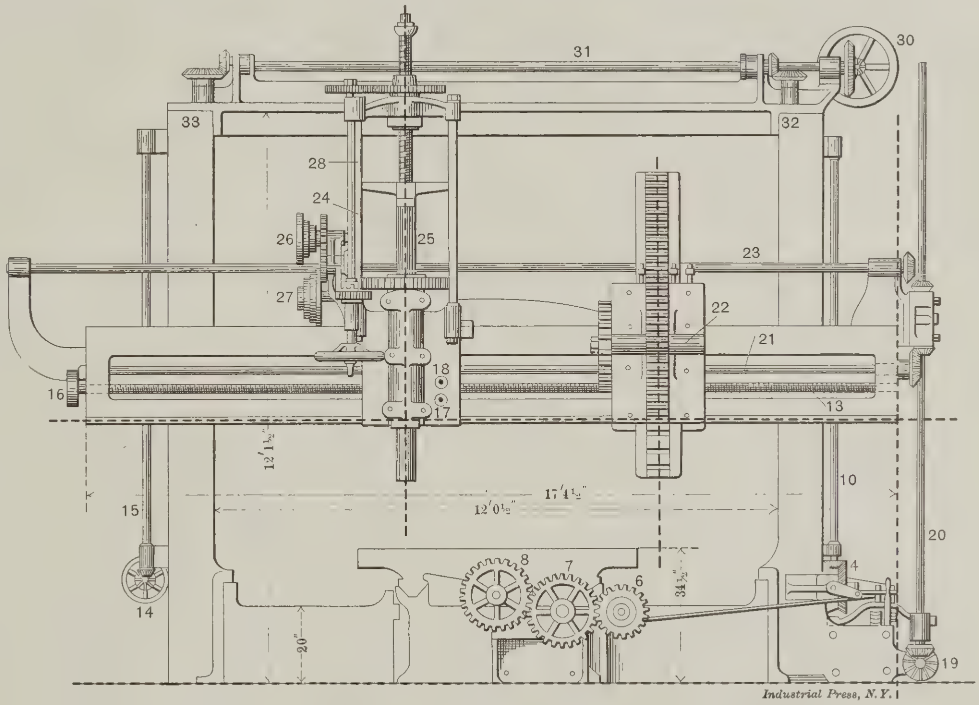
Fourth, for clearness of ideas. No one can analyze a machine in this way without knowing it better, and remembering clearly points that would otherwise be left in doubt or obscure.

There is still another useful purpose to which this method can be put. In comparing designs and designing in series, it helps to determine what is best, what parts can be worked to interchange, or used on several sizes or modified designs of a machine.

THE REVOLUTION EFFECTED BY FARM MACHINERY.

Farm machinery may some time do work for us that will be worth $1,000,000,000 a year. Theoretically it is already saving us nearly three-fourths that sum; for as far back as 1899, if all the crops to which machinery is adapted could have been planted and gathered by hand, they would have cost nearly $700,000,000 more than if they had all been planted and gathered by machinery. It has not only added so much to our wealth, but it has made us the foremost exporting nation, and it is changing the character of the farmer by freeing him from monotonous hand-toil. More than that, it is fast changing the immemorial conception of agricultural and the pastoral and idyllic associations that have gathered about it since the time of Abraham. Wealth, industry, commerce, the character of men and even their sentiment are all affected by it.

Yet so sudden have been these changes that we have yet hardly caught their meaning. The cradle-scythe is only a little more than a century old, and the cast-iron plow was first used even later than the cradle-scythe. In other words, a century ago agricultural machinery was almost as primitive as it was a thousand years ago. Now we have steam plows, combined harvesters and threshers and auto-mowers. They have come into use so recently that only a small part of the population have ever seen them at work. Yet they are changing our life in all its wide reaches—from commerce to poetry.—*World's Work.*



Industrial Press, N. Y.

Fig. 2.

* * *

A dozen miles up the Tyne Valley is the village of Wylam, where George Stephenson was born, in 1781. The old home is still there—a very plain, peak-roofed, stone cottage, now tenanted by a peasant family. On the ends of the cottage there are no windows, and there are but five on the front. In the eighteenth century, in England, windows were a luxury, for the householder had to pay a tax on them. This window tax was the outgrowth of the hearth tax. In earlier days the collector came around to count the number of fireplaces, that the householder might be taxed on them, but the English spirit—"every man's house his castle"—was opposed to this invasion of the privacy of the home, and the window tax was substituted as a tax that might be assessed from outdoors. Just in front of the Stephenson cottage runs one of the railways made possible by the genius of the inventor.—*Four Track News.*

Prof. Forrest R. Jones, who has contributed to our columns occasionally, is to leave Worcester Polytechnic Institute to become Professor of Machine Design at Sibley College, Cornell University.

SPIRAL GEARS.

DEVELOPMENT OF THEORY AND RULES FOR THEIR CALCULATION.

C. E. COOLIDGE.

The fact that the design of a pair of spiral gears involves so many possibilities and probabilities before the "eternal fitness of things" results, has stimulated a great many interested in the development of a pair of spiral gears to evolve methods which would require a minimum amount of labor. Graphical methods are most easily followed and understood by many, but a rigid and expedient treatment can only be obtained by the use of true and convenient equations which express the kinematic and kinetic relations of known properties of the gears.

The introduction of the terms sine, cosine, and tangent into the equations should not be held in abject terror by those who have thus committed themselves through the columns of current periodicals. The trigonometrical terms sine, cosine, and tangent of an angle express the ratio of two particular sides of a triangle with reference to the particular angle used, and with the multitudinous number of available books which contain the values of the ratios, common everyday arithmetic is substituted for the science of trigonometry as such.

The fundamental kinematic features of screw gearing, and in fact of all gearing, are nothing but special cases of the skew gear which is the general case. In other words, the skew gear with its hyperboloidal pitch surface is the mother gear of all.

A brief presentation of that particular feature might aid some in plucking a "brand from the burning" and I take the liberty of indicating a proof by the analysis of a pair of skew gears as follows: In the two views in Fig. 1, let *A-A*, *B-B*, and *l-l* represent the axes and line of contact respectively of a pair of skew and screw gears in contact whose axes are parallel to the plane of the paper. Also let

V = component linear velocity of point P common to both gears and perpendicular to line of contact l-l,

V' = component linear velocity of point P in line of contact taken perpendicular to axis A-A,

V'' = component linear velocity of point P in line of contact taken perpendicular to axis B-B,

α = angle between lines $V'P$ and PV,

β = angle between lines $V''P$ and PV,

R = radius of gear whose axis is A-A,

R' = radius of gear whose axis is B-B,

$R\ P\ M$ = rev. per min. of gear whose axis is A-A,

$R'\ P'\ M'$ = rev. per min. of gear whose axis is B-B.

The angular velocities of the two rolling hyperboloids are directly proportional to their R. P. M's and since the angular velocity equals the linear velocity divided by the radius of the rotating body we have

$$\frac{R\,P\,M}{R'\,P'\,M'} = \frac{\dfrac{V'}{R}}{\dfrac{V''}{R'}} = \frac{V'}{V''} \times \frac{R'}{R}, \tag{1}$$

$$\frac{V'}{V''} = \frac{\dfrac{V}{V''}}{\dfrac{V}{V'}} = \frac{\cos\beta}{\cos\alpha} \tag{2}$$

$$\frac{R}{R'} = \frac{R'\,P'\,M'}{R\,P\,M} \times \frac{\cos\beta}{\cos\alpha} \tag{3}$$

From (3) it is evident that the radii of the two gears are inversely proportional to the rotations about their axes if in Fig. 1 the angles made by the line of contact with the axes are equal, which is often of advantage in laying out screw gears.

The special cases of the skew gear as found in the more common gears are as follows: When the throat of the hyperboloidal surfaces contracts to a point, a double nappe cone with intersecting axes or the pitch surfaces of bevel gears results, with a zero velocity at P. When the hyperboloids are infinitely long, cylinders with parallel axes or the pitch surfaces of spur gears and twisted gears result with angles α and β equal to zero and the line of contact l-l making zero and equal angles respectively with the axes. When comparatively narrow lengths of the hyperboloidal surfaces, which are close approximations to cylinders, are used and the teeth are twisted into regular helices, the line l-l becomes a tangent to the helices at the point P and screw gears known under the more general term of spiral gears result.

Worm gears come under this head as a species of screw gear.

The designing draftsman of a pair of spiral gears must furnish the following data for use in the shop:

1. Outside diameters of the gears.
2. Pitch and number of cutter used.
3. Number of teeth cut.

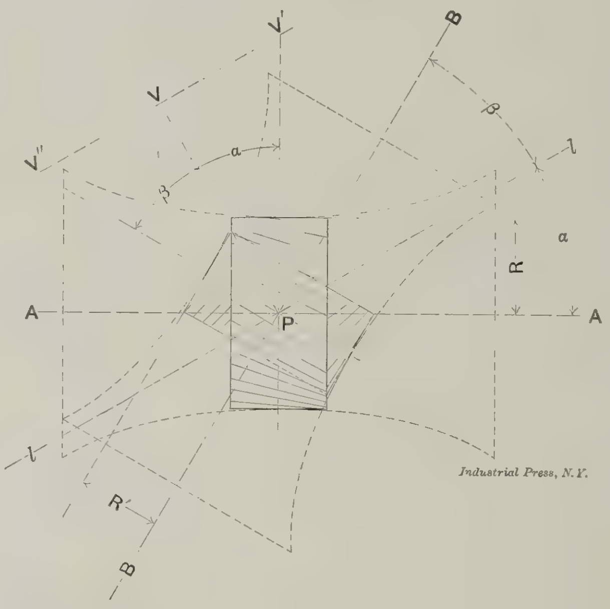

Fig. 1

4. Lead of spiral.
5. Angle of spiral with axis.

For working out the data for the shop the following formulæ with their derivation are adequate and convenient. Using the notation above and adding

d = sum of pitch radii of gears and shortest distance between axes,

N = number of teeth on gear whose axis is A-A,

N' = number of teeth on gear whose axis is B-B,

n = number of teeth on osculating circle of gear whose axis is A-A,

n' = number of teeth on osculating circle of gear whose axis is B-B,

D = diametral pitch,

a = lead of spiral of gear whose axis is A-A,

a' = lead of spiral of gear whose axis is B-B,

we have

$$\frac{N}{N'} = \frac{R'\,P'\,M'}{R\,P\,M} \tag{4}$$

$$\frac{R}{R'} = \frac{R'\,P'\,M'}{R\,P\,M} \times \frac{\cos\beta}{\cos\alpha}, \tag{5}$$

$$n = \frac{N}{\cos^3\alpha}, \tag{6}$$

$$n' = \frac{N'}{\cos^3\beta}, \tag{7}$$

$$a = 2\,\pi\,R \operatorname{tang}\,(90^\circ - \alpha), \tag{8}$$

$$a' = 2\,\pi\,R' \operatorname{tang}\,(90^\circ - \beta), \tag{9}$$

$$\frac{2\,d\,D}{N'} = \frac{1}{\cos\beta} + \frac{R'\,P'\,M'}{R\,P\,M} \times \frac{1}{\cos\alpha}. \tag{10}$$

(4) is self-evident, being the common property of all gearing, (5) has been derived for skew gears and answers for spiral gears which are a special case of skew gears as indicated above. In equation (6) the derivation is as follows: In Fig.

2 is shown one of the pair of gears shown in Fig. 1, whose axis is *A-A*. Using the notation above and adding

p = normal pitch,
c = circumferential pitch,
s = semi-major axis,
r = radius of osculating circle.

If a cutting plane be taken perpendicular to the plane of the paper and to the tangent line *l-l* at the point *P* an ellipse will be cut from the cylinders whose true configuration is shown revolved into the plane of the paper. The radius of the osculating circle (a circle touching the greatest number of points) to the ellipse at the end of the minor axis is derived most easily from Calculus and its value is equal to the square of the semi-major axis divided by the semi-minor axis or from Fig. 2,

$$r = \frac{s^2}{R}, \qquad (11)$$

also from Fig. 2, $s = \dfrac{R}{\cos a}$. (12)

Substituting s in (11), $r = \dfrac{R}{\cos^2 a}$. (13)

Multiplying the diameter of a circle by the diametral pitch gives the number of teeth on the circle or the number of teeth on the osculating circle just found,

$$n = 2\,r\,D = \frac{2\,R\,D}{\cos^2 a} \qquad (14)$$

$$\text{Since } D = \frac{\pi}{p}, \qquad (15)$$

and from Fig. 2, $p = c \cos a$. (16)

Substituting p in (15), $D = \dfrac{\pi}{c \cos a}$. (17)

Substituting D in (14), $n = \dfrac{\dfrac{2\,\pi\,R}{c}}{\cos^3 a}$. (18)

Since $\dfrac{2\,\pi\,R}{c}$ = number of teeth on gear, $n = \dfrac{N}{\cos^3 a}$.

Equation (7) is derived similarly to (6). Equation (8) is derived as follows: In Fig. 3 let one of the pair of spiral gears shown in Fig. 1 with axis *A-A* be sufficiently extended to complete one turn of the helix about the pitch cylinder. In the lower view of Fig. 3 the development of the cylinder and the helix on its surface readily shows that $a = 2\,\pi\,R \text{ tang } (90° - a)$.

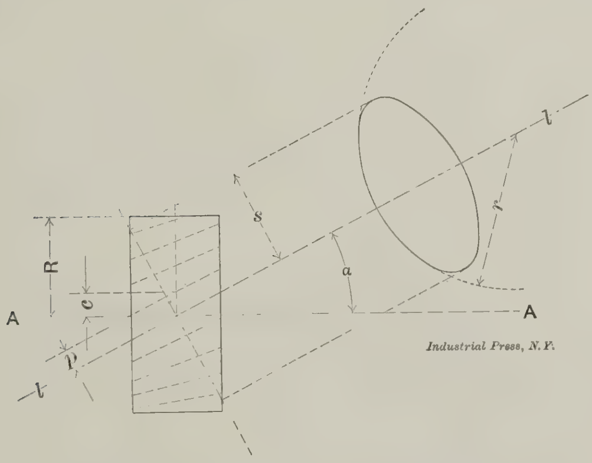

Fig. 2.

Equation (9) is derived similarly to (8).

Equation (10) is derived as follows: With notation as above,

$$\frac{2\,\pi\,R}{2\,\pi\,R'} = \frac{c \times N}{c' \times N'} \qquad (19)$$

which is an equation whose members are identities.

Adding numerators and denominators of each member of (19).

$$2\,\pi\,(R + R') = c \times N + c' \times N'. \qquad (20)$$

From Fig. 1 and Fig. 2 it is seen that

$$c = \frac{p}{\cos a} \qquad (21)$$

and

$$c' = \frac{p}{\cos \beta}, \qquad (22)$$

also $p = \dfrac{\pi}{D}$. (23)

Substituting p in (21) and (22),

$$c = \frac{\pi}{D \cos a}, \qquad (24)$$

and

$$c' = \frac{\pi}{D \cos \beta} \qquad (25)$$

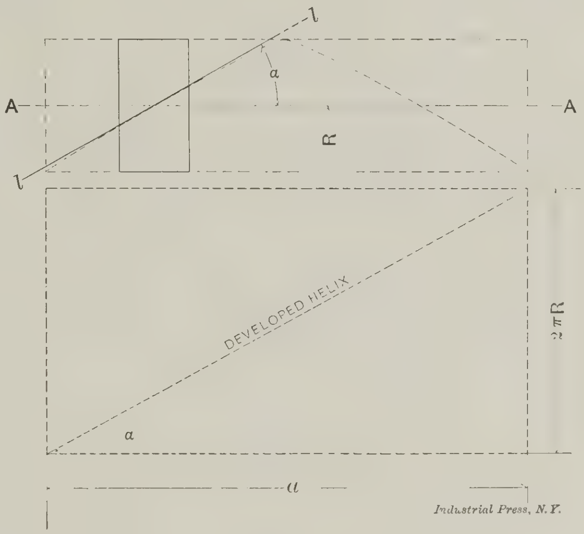

Fig. 3.

Substituting c and c' in (20),

$$2\,\pi\,(R + R') = \frac{\pi\,N}{D \cos a} + \frac{\pi\,N'}{D \cos \beta} \qquad (26)$$

Multiplying through by D, dividing by N' and π, and noting $R + R' = d$,

$$\frac{2\,D\,d}{N'} = \frac{1}{\cos \beta} + \frac{N}{N'} \times \frac{1}{\cos a}. \qquad (27)$$

Substituting $\dfrac{R'\,P'\,M'}{R\,P\,M} = \dfrac{N}{N'}$ in (27),

$$\frac{2\,D\,d}{N'} = \frac{1}{\cos \beta} + \frac{R'\,P'\,M'}{R\,P\,M} \times \frac{1}{\cos a}.$$

If the equipment of the shop was complete and there were no objectionable kinematic considerations, the simplest and perhaps the most efficient pair of gears would obtain when the tangent to the helices makes equal angles with the axes, However, the following considerations are important and condition the final data which is sent to the shop:

1. If the number of R. P. M.'s of each shaft is fixed, the ratio of the number of teeth is also fixed and there can be no fractional tooth.
2. A stock cutter must be used which approximates size of tooth designed.
3. Occasionally the gear shafts are fixed in position and consequently the distance between them is fixed.
4. The leads of the two spirals must be such as can be cut on a universal milling machine or some special gear cutter.

It is usually the case that all four conditions cannot be satisfied. Those in 1 and 2 are usually fixed. Those in 3 can often be changed in the early stages of a new design by changing the angle of shafts and the distance between them. Those in 4 can usually be met by making new gears for the machine which is used in cutting the spirals and it may be that it is quite possible to change the angle of teeth and distance between shafts so as to cut at least the lead of one of the gears with the regular change gears on the machine.

To illustrate the procedure for applying the formulæ used in determining the necessary data for the shop, a specific problem will be taken. Suppose there are two non-intersecting shafts making an angle of 60 deg. with each other when their axes are parallel with the plane of the paper; the driving shaft makes 70 R. P. M. and the driven shaft 120 R. P. M.; the shortest distance between axes will be taken tentatively as 12 inches; and a 3-pitch cutter will be used.

We will assume that the angle of the teeth is the same for both gears, or 30 deg. Then substituting in formula (10),

$$\frac{2 \times 3 \times 12''}{N'} = \frac{1}{\cos 30^\circ} + \frac{120}{70} \times \frac{1}{\cos 30^\circ} = 3.134''$$

$N = \frac{72}{3.134''} = 22 +$ which indicates that the teeth on the driven gear should be somewhere in the vicinity of 22. It is at once seen that

$$\frac{4 \times 12}{4 \times 7} = \frac{48}{28} \text{ and } \frac{3 \times 12}{3 \times 7} = \frac{36}{21}$$

both of which can be used. Since $N' = 21$ in the last equation is nearer to 22 we will use it. Keeping the angle as before and substituting again in (10) and solving we have

$$d = \frac{3.134 \times 21}{6} = 10.969''$$

which is the required distance between shafts.

Since the pitch radius of one gear is 10.969 minus the pitch radius of the other, by substituting $10.969 - R$ for R' in (5) and solving we have

$$R = \frac{12 \times .866\,(10.969'' - R)}{7 \times .866} = 6.928''$$

and

$$R' = 10.969'' - 6.928'' = 4.041''.$$

The leads of the spirals of the gears are found in (8) and (9) respectively.

$a = 2 \times 3.1416 \times 6.928''$ (tang $60^\circ = 1.732$) $= 75.393''$.

$a' = 2 \times 3.1416 \times 4.041''$ (tang $60^\circ = 1.732$) $= 43.983''$.

If the spirals are cut on a Brown & Sharpe universal milling machine, we find that gears 100, 40, 72, 24 on worm, 1st on stud, 2d on stud, and on screw respectively will cut a spiral with a lead of 75 inches, and gears 100, 40, 56, 72 on worm, 1st on stud, 2d on stud, and on screw respectively will cut a spiral with a lead of 43.75 inches. These two results are unusually close for a chance pair of gears. If we consider the inaccuracies and imperfections which result in the setting of the shafts, in the use of the unsuitable stock cutter, and in the setting of the cutter tangent to the helix, the probabilities are that the gears are practically all right without any change.

The outside diameters of driver and driven are:

$2 \times 6.928'' + \frac{2}{3}'' = 14.522''$ and

$2 \times 4.041'' + \frac{2}{3}'' = 8.748''$ respectively.

The number of teeth in driver is from (6)

$$n = \frac{36}{\cos^3 30^\circ = .649} = 55 +$$

and a No. 2 cutter is to be specified. (The value of the cosine and its cube should be taken directly from tables found in hand books.)

The number of teeth in driven is from (7)

$$n' = \frac{21}{\cos^3 30^\circ = .649} = 32 +$$

and a No. 4 cutter is to be specified.

Occasionally the condition arises where there is a certain fixed distance between shafts as would be the case if a pair of spiral gears replaced some previous driving mechanism in a machine whose shafts could not be changed without great expense. Suppose in the problem above everything was as given except that the distance between shafts must be exactly 12 inches. Our procedure then would be to try equal angles between tangent line and axes and substitute the rest of data in (10) as before. We found above that equal angles gave us fractional teeth which indicates that we will have to change the angles and use the next lower number of teeth that will give the proper ratio which is 36 and 21. (If we had used in this case 48 and 36 we would not have been able to satisfy equation (10). The left-hand member of the equation then is constant and its value

$$\frac{2\,d\,D}{N'} = \frac{2 \times 3 \times 12''}{21} = 3.428''$$

will, by method of trial and error, have to be satisfied by changing α and β in

$$\frac{1}{\cos \alpha} + \frac{R'\,P'\,M'}{R\,P\,M} \times \frac{1}{\cos \beta}$$

until the two members of equation (10) are equal.

Three or four attempts may have to be made before the desired angles are found but very little labor is involved when tables of natural cosines and reciprocals are used. The angles α and β which satisfy the equation are found to be 44°-10′ and 15°-50′ respectively.

The diameters of gears, numbers of cutters, and leads of spirals will again have to be found in the same manner as before, to meet the changed conditions. In the last case if the leads are such as cannot be cut by the use of the regular change gears on the universal milling machine, the only recourse is to make new change gears.

In a design of a pair of spiral gears sound conclusions which are the result of theoretical and practical investigation point to the fact that the efficiency of a pair of spiral gears is very appreciably reduced by too low angles of the spirals, and by too low or too high (generally too low) velocities of the rubbing surfaces. When there is a choice in the angle of a pair, equal angles for both gears should be used. The proper velocity of the rubbing surfaces are a function of the following: The load on the tooth and thrust bearings; the materials of which the gears are made; the condition of the surfaces; the lubricant used; and the arc of action which will vary with the angle of teeth.

Although there is limited data of experimental velocities with worm gearing there seems to be a dearth of proven data for spiral gears with varying angles. It has been stated that Mr. Wilfred Lewis recommends that a general average pitch line speed should be from 200 to 300 feet per minute. In all probability there is more difficulty in the design of a durable tooth than in the design of a strong enough one. However, the normal pitch of the teeth must be selected and in any one design it is a function of the magnitude of the load normal to the teeth, the length of tooth, arc of action, shape of tooth, and velocity.

By substituting the proper values in Mr. Wilfred Lewis' expression $W = s\ p\ f\ y$ (found in July Supplement to MACHINERY), and dividing p by 2, a pitch will be found which will meet the average requirements. It is to be noted that the factor, y, in the expression, relates to the number of teeth which in spiral gears should be taken along the normal helix as found in the expression $n = \frac{N}{\cos^3 \alpha}$.

In conclusion it may be said that when spiral gearing are properly designed, well lubricated, and run at an efficient speed, they should not be condemned as often as the traditional faddishness of some and conservatism of others seem to demand.

* * *

NEW PLAN FOR IRRIGATION.

Many thousands of acres in the arid regions of the West may be improved by irrigation, but the cost of irrigating canals and leveling the land is something enormous, especially the latter. *Forestry and Irrigation* says that a Wisconsin man has made a valuable contribution to the practice of irrigation in humid regions, and the same applies to arid regions. His method of applying the water to the fields is to convey it to the higher points in a sluice hose, perhaps 15 inches diameter, made of oiled duck with lateral ports which discharge into furrows. The sluice hose may be moved wherever required. Thus no land is required for ditches, and there is no expense for leveling. Less water is wasted than where ditches are employed and the water can be delivered where it is wanted and in any quantity desired.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

A railroad has been built from mines near Gellivare, Sweden, to Ofoten, on the coast of Norway, which is said to be the most northerly railroad in the world. It was constructed by English capitalists, who wanted a supply of Swedish iron the year around.

The bronze propellers of the twin-screw steamship *Kaiser Wilhelm II.*, are 22 feet 10 inches diameter. Each propeller is driven by two four-cylinder, three-crank quadruple expansion engines of 20,000 horse power, making the total propelling force of the vessel 40,000 horse power.

The firm of Robert Poole & Son Co., Baltimore, Md., recently cast a gear wheel weighing 65,000 pounds. The teeth of this gear, as of practically all the gears made by this company, are of the epicycloidal form. Since casting the heavy gear they have cast a smaller one having a pitch diameter of about 9 feet and only 31 teeth. The circular pitch is 11 inches—the largest they have ever made.

As a test of what a modern battleship might do in times of emergency or war, the U. S. S. Kearsarge, recently with the European squadron, was directed to cross the Atlantic under full speed, with natural draft. She arrived at Bar Harbor, Me., in perfect condition, having traversed 2,900 miles in nine days, four and one-half hours, at an average speed of 13.1 knots against variable head winds. Enough coal was left to have continued 1,000 miles further.

In mining operations it would naturally be believed that masses of pure metal could be more profitably worked than any other form of deposit, but such is not the case with copper. In the Calumet and Hecla copper mines in Northern Michigan, great masses of pure copper have been found, and it has proven very expensive to handle on account of the great difficulty of working it with tools and the impossibility of breaking it up by blasting. One mass of over 500 tons of virgin copper was such an expensive undertaking to remove that it was a debatable matter whether it would not be more profitable to abandon that section of the mine for other portions that could be worked easier and more profitably.

In a paper read before the American Foundrymen's Association at Milwaukee, Wis., June 9-11, by W. E. Dickson Sharpsville, Pa., it was stated that pig and cast iron borings lose perceptibly of their sulphur contents after standing for some time, even if contained in sealed bottles. The phenomenon is not noticed in steel turnings, and the difference is attributed to the fact that in cast iron borings every particle is cracked throughout so that a large surface is exposed to oxidizing influences; the steel borings or turnings roll up into a compact mass without cracks, so the surface exposed to the atmosphere is relatively much less.

The production of platinum from domestic ores in the United States decreased from 1,408 ounces, valued at $27,526, in 1901—the largest output recorded—to 94 ounces valued at $1,814. The domestic supply of platinum in recent years has been obtained as a secondary product chiefly from gold placer deposits in Trinity and Shasta Counties, California. It is reported that the metal occurs, though not in commercially rich deposits, in many other gold placers of California, as well as in Washington, Oregon, Idaho, Montana, Colorado, and Alaska. The Russian sources of platinum supply, which furnish about 90 per cent. of the total consumption of the world, are comparatively limited. The imports of platinum into the United States during 1902 were valued at $1,987,980, showing how small a percentage of the quantity used is obtained in this country from our own mines.

Electric automobile chairs will be one of the features of the World's Fair at St. Louis in 1904. The chairs will have a uniform speed of three miles per hour, the operator having no control over the speed. The chair takes the form of a low phaeton without a cover. There are two large rear wheels and two small ones under the foot rest, all pneumatic-tired. On the inside of the chair, attached to the arm, is a lever, which puts the chair in motion or stops it at the will of the rider. A long lever attached to the front truck has its handle directly in the center of the chair and is used for steering. A feature of the machine is a "sensitive rail" which surrounds the chair on all sides, save at the rear. This prevents any accidents, for when the rail comes in contact with any object, even though it weighs but a pound, it presses against a device that locks the wheels and brings the chair to a dead stop.

The retirement of Rear Admiral Melville from his active duties as Chief of the Bureau of Steam Engineering and Engineer-in-Chief of the United States Navy, through the government requirements as to age limit, brings to a close a remarkable career in the public service. The Rear Admiral is only 62 years of age and is vigorous, so that it is to be hoped he still may have special commissions to carry out for the government and that his ripe experience may often be drawn upon in the advancement of sound engineering principles, progressive, yet conservative, for which he has always stood. It is to be regretted that he could not have remained at his post a few years longer now that the advent of the water-tube marine boiler is at hand and the possibility of the steam turbine for naval vessels may shortly be realized. Admiral Melville began his duties as engineer at a time when the only modern vessels of the navy were the original John Roach ships of the white squadron, having a speed of from 14 to 16 knots. From this small beginning he has directed the engineering features of our whole navy, and these constitute the splendid and unusual record of his more important engineering work. He was a member of the engineer corps during the civil war, and later had many thrilling experiences in connection with several Arctic expeditions, among them the search for the missing crew of the ill-fated *Polaris* and as an engineer officer of the tragic expedition of the *Jeanette*. At present Admiral Melville may be regarded as one of the three or four engineers who are at the head of the engineering profession in its various branches.

The destruction by fire of a train of cars in the subway at Paris, France, last month, and the deplorable loss of life in consequence, has led people of New York City to speculate on the possibility of a similar catastrophe in the new subway of this city. In commenting on the event the *Street Railway Journal* says:

The most conspicuous feature of the new subway cars, which are being built for the New York subway, is the precaution taken to guard against accidents through fire, collision or derailment. The cars were built unusually strong, and were designed especially with the view of withstanding heavy impact. The plans for the electrical features were also made to provide against the possibility of fires from defective wiring, faulty insulation and improper installation of apparatus. A careful study of car construction in European cities, especially with reference to tunnel operation, was undertaken at an early stage, and an earnest effort was made to avoid the defects which have been revealed in former installations. The New York subway management has profited by the experience of the London and Paris companies, and those who are best qualified to judge say that such a disaster as the Paris conflagration could not be repeated in this city. Not only has every effort been made to insure safety by employing fireproof material, including a copper sheathing for the car body, but the tunnel construction and equipment show marked advance. Moreover, the lighting service is entirely independent of the power supply for the operation of the trains, a condition that did not exist in Paris.

THE VARIOUS EDISON INDUSTRIES.

A recent issue of the *Electrical Review* contains a description of the Thos. A. Edison works at West Orange, N. J., where are located Mr. Edison's laboratory and experimental departments. While Mr. Edison's fame as an inventor is world-wide and his name is probably known by more people than that of any other living inventor, we doubt whether people are generally familiar with the fact that Edison is also a large manufacturer. There are several Edison plants in New Jersey, turning out a variety of products and in large quantities. At the West Orange works are manufactured nearly all of the parts of the various machines made for the different selling companies which represent the Edison interests. Here are made the stampings and turnings for the Bates and Edison numbering machines, fittings and appurtenances for the Edison phonograph, the Edison kinetoscope apparatus, and some of the material which goes into the assembling of the Edison primary battery and the Edison primary battery fan motor. While the primary battery is assembled at the works at West Orange, the manufacturing of the parts is mostly all done at Silver Lake, N. J. The manufacture of these several products constitutes an immense business, as can be judged when it is considered how many Edison phonographs alone are in use in every part of the country. There is still some experimenting being done on the Edison storage battery at the West Orange works, but the machinery, outside of the experimental machinery, is being put up and placed in operation at Glen Ridge, N. J. Mr. Edison is also interested in Portland cement works, and experimental machines for them are being constructed at the experimental department at West Orange, but the heavy machinery and manufacturing equipment for this plant are located at Stewartsville, N. J.

SLEEPING CARS FOR ELECTRIC LINES.

The development of interurban electric lines in all parts of the country, and particularly in the Central West, is becoming nothing short of remarkable. The convenient service which such roads are able to render, the cheap fares and reasonably quick running time; the frequent stopping places, the neat and attractive cars, and the ability of the cars to enter the various towns and cities on the tracks of the regular street railways render the interurban lines justly popular. That they are to encroach still further upon the domain of the steam lines is evident from the fact that preparations have been made for sleeping cars on some of the interurban roads where the length of run is sufficient to make them profitable. It is expected that the new sleeping car service will be patronized largely by traveling men, who find the schedules of the older roads inconvenient for travel by night. These roads run their best trains for the benefit of through traffic, and their times of departure from many cities, midway between main destination points, is at almost any inconvenient time of the night or early morning. A traveling man has to work and work hard daytimes, and does not like to take a train at two o'clock in the morning and lose half a night's rest in order to be on hand for business at the next station the following day. The Holland Palace Car Company, Indianapolis, Ind., has recently been organized for building sleeping cars for electric lines. Their car differs radically from the Pullman design, but may be used, like the Pullman car, as a day coach as well as a sleeper. All of the partitions are made on the principle of the roller top of a roller-top desk, and slide down between the double floors in the daytime. These partitions are in front of the berths, as well as at the ends, except for a narrow opening for entrance and exit, which is covered by a portiere. The berths are 27 inches wide, and there are 15 inches between the edges of the berths and the front partitions, giving standing room within the compartment itself. Two cars are nearly finished and will be used on lines in Ohio and Indiana.

LARGE TURBINE PLANT.

The *Western Electrician* states that the Edison Electric Illuminating Co., Boston, Mass., is about to erect on L Street, South Boston, a new electric light station, which, when completed, will constitute one of the most important and, in point of equipment, one of the most modern in the country. The particular feature of interest is that turbine units are to be installed instead of reciprocating engines, coupled to generators.

The station, consisting of a boiler room, turbine room and switchboard room, will be built upon the "unit" system, comprising 12 distinct units, each of which will have its own steam and electrical equipment, as well as individual auxiliaries, so that each unit will be virtually a station in itself, arranged to run independently or in conjunction with any or all of the others. These sections will be built and added to from time to time, as the increasing business of the company requires, until finally the building will cover an area about 650 feet long and 250 feet broad, which is nearly four times the area occupied by the present station building, while the plans call for an ultimate equipment in boilers equal to an engine capacity of 96,000 horse power, and an electrical capacity of 60,000 kilowatts, which, together with the 9,000 kilowatts already installed in the old station, will provide a total of 69,000 kilowatts (or 92,000 horse power), available from the L Street station.

The installation will consist of Babcock & Wilcox boilers, rated at 500 horse power each, and 5,000-kilowatt General Electric steam turbines, to each of which will be direct-connected one General Electric, three-phase, 60-cycle, 6,900-volt generator of the same capacity. To facilitate the handling of heavy pieces of machinery, there will be installed, in the turbine room, a 50-ton electric traveling crane. The walls up to the level of the crane track will be lined with tiles, while the space above will be finished in fancy brick.

Beneath the turbine room, running its entire length and extending to the water of the channel, will be constructed three brick-lined tunnels, two having a diameter of 8½ feet each, for the intake of water for condensing purposes, and one 10 feet in diameter for its discharge. The lower inside surface of these tunnels will be about 30 feet below the level of the floor, and their construction will require, to a certain extent, the same class of engineering necessary in the building of the East Boston tunnel. Towering above the station, one common to each consecutive pair of units, will be seen six graceful chimneys, 250 feet high, each 25 feet in diameter at the base and with a minimum internal diameter of 16 feet.

THE EDISON BATTERY.

At various times adverse comments upon the Edison storage battery for automobiles have been made by writers in the technical press, and we remember a discussion by one electrical engineer who demonstrated to his own satisfaction, and perhaps to others, that the battery simply could not be any better than any of the lead storage batteries on the market, for the reason that it was no better in principle, and in fact had serious faults of its own. Time alone will prove the truth or falsity of this assertion, but be it said that Edison himself has full confidence in his battery and his confidence apparently is based not only upon theoretical grounds but upon practical results of extended trials. Reporters of the *New York Times*, the *Newark (N. J.) Evening News* and the *Electrical Review*, New York, have recently interviewed Edison upon the subject. Edison contends that American automobiles are not built substantially enough for hard usage and at present is about to construct four automobiles complete, modeled along French lines, but equipped with electric motors and his batteries instead of with gasoline motors. With these he expects to be able to subject his batteries to even harder and more severe tests than they have yet had.

The following points were brought out by the reporters: There are now three heavy trucks operated by current from the Edison battery. One is a two-ton truck which formerly had over 1,200 pounds of lead battery. It is now equipped with about half this weight of the new battery, which will carry the truck 35 miles before the voltage begins to fall off. In one test a battery was used in a runabout for a distance of 5,000 miles, being recharged over and over again with electric current and at the end showed no deterioration of its component parts, and appeared to be good for an indefinite amount of use. At present one set of batteries is being made a day. Recent improvements enable the battery to be charged even more rapidly than possible with the earlier types, which had rapid charging as one of their characteristics. This has necessitated changes in the fixtures and machines for manufacture. Another difficulty in putting the battery on the market has been the trouble in getting the kind of sheet metal needed. This is now imported, under a heavy duty, but a rolling mill will be in operation in this country this fall for its production. The present cost of the battery is fixed at $15 a cell. Four cells are required per horse power hour, and twenty-one cells are installed in the ordinary runabout machine, which they will drive for 81 miles on a single charge. Thirty-eight cells will drive a machine weighing one ton 60 miles, and a delivery wagon weighing two tons will go 36 miles on one charge of thirty-six cells. Mr. Edison confidently predicts that within a few years the gasoline machines now in use will be entirely replaced by machines driven by electric motors actuated by his batteries.

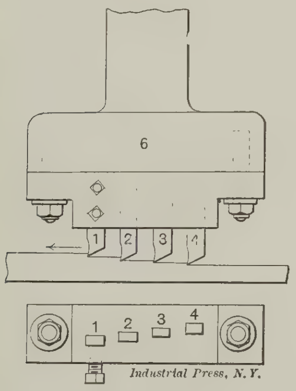
THE BIGGEST HARVESTER IN THE WORLD.

World's Work, August, 1903.

Last year there was in operation in the San Fernando Valley of California the largest combined harvester in the world. It consists of a traction engine capable of hauling seventy-five tons and which takes the place of sixty horses; a header or mowing machine which cuts a thirty-six foot swath, and a complete threshing machine. The header and threshing machine are run by a separate thirty-horse power engine getting its steam from the same boiler as the threshing engine. The drive wheels of this monster traction engine are eight feet in diameter, with tires forty-eight inches wide on which are ridges an inch and a half high. It can average three and a half miles an hour in good grain. The thresher has a capacity of 100 acres a day. Eight men are employed on the thresher. The grain is threshed clean and finally carried to a bin from which it is sacked. When twelve sacks have been filled they are allowed to slide off the cart to the ground. This huge machine will work equally well on level or hilly country, having sufficient power to take a twenty per cent. grade without difficulty. It is sixty-six feet long, half as wide, and weighs more than 100 tons. Oil is used as fuel. This harvester has been successfully used for shelling peas and beans as well as grain. It is purely a Californian production.

GANG PLANING TOOL.

Zeitschrift fur Werkzengmaschinen und Werkzenge, January 15, 1903, p. 163.



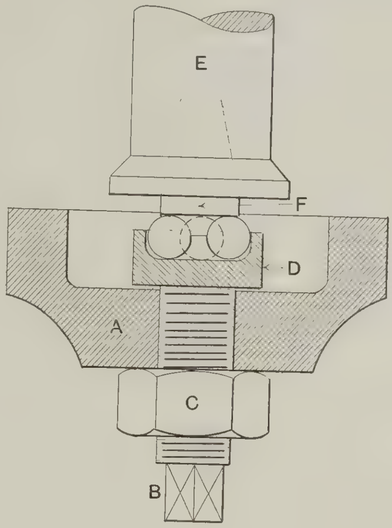
Gang Tool.

The gang cutting tool has gained for itself a prominent place in German shop practice, and the accompanying illustration shows one that is doing good work. The construction will be readily understood from the drawing. The cutting tools 1, 2, 3 and 4, are inserted in the holder and fastened by setscrews. The holder itself is attached to the tool post or carriage by bolts, thus making it possible to remove and replace it with great ease and rapidity. By this means the cutters can be taken away and ground to the proper dimensions and shape without disturbing them in their position.—G. L. F.

A STEP BEARING.

Zeitschrift fur Werkzengmaschinen und Werkzenge, January 15, 1903, p. 158.

This step bearing is acting very satisfactorily upon a number of vertical shafts running at high speeds on woodworking machinery. It consists of a cup-shaped base, *A*, which is integral with the frame of the machine. This base is threaded for the screw *B*, which is fastened by the check nut *C*, and serves to support the cup bearing *D*, in which the balls are placed. The spindle *E* rests upon these balls through the intervention of a hardened steel bearing block *F*. This latter is let into the spindle with a taper fit and is driven home. The arrangement thus provides a ball bearing for the foot of a spindle with a vertical adjustment that can be made at any time without difficulty, while the actual bearing parts admit of quick and ready renewal.—G. L. F.



Ball Step Bearing.

TEST OF HIGH-SPEED TOOLS.

L'Echo des Mines et de la Metallingiè, February 16, 1903, p. 185.

Some interesting tests have recently been made by Yarrow & Co. with drills made of common and special tool steel, for the purpose of ascertaining the maximum speeds at which they can be run, their relative endurance and the power required to drive them.

It was found that the common steel could not be run at a speed greater than 76 revolutions per minute with a feed of 1-200 inch, while the special steel could be run at a speed of more than 100 revolutions. The relative endurance of the two classes of drills was estimated from the increase of power required to drive them after a certain amount of work had been done. It was found that, with the special steel, there was an increase of 8½ per cent. in the amount of power required to drive them after thirty holes had been drilled at a speed of 96 revolutions per minute, while, in the case of the drills made of common steel running at 76 revolutions per minute, an increase of 37¼ per cent. was required.

It was found that drills 1¾ inch in diameter could be worked in soft steel at a speed of 100 revolutions per minute without difficulty. Hence, in order to obtain the most economical results in drilling, a special steel must be used.—G. L. F.

TRAIN RESISTANCE AT HIGH SPEEDS.

Zeitschrift fur Electrotechnik, March 1, 1903, p. 127.

In a formula worked out by Herr J. Davis he considers that: 1, the friction of the journals is independent of the speed; 2, the friction of the rails is in proportion to the speed; 3, the air resistance is in proportion to the square of speed and is also dependent upon the shape and size of the car and the number of the same in the train.

Experiments were made with a train consisting of a locomotive, a brake van and four cars, noting the results obtained with the locomotive alone, the locomotive and one car, the same with two cars, etc.

The curves that have been plotted from these figures may be represented by the formula:

$$S = \frac{4 + 0.13V + 0.004AV^2\,[1 + 0.1\,(n-1)].}{T_1}$$

where

S = the train resistance in horse power per ton;
V = the speed in miles per hour;
A = the cross sectional area of the car in square feet;
n = the number of cars in the train inclusive of the locomotive.—G. L. F.

HIGH-SPEED STEELS AND THEIR USE FOR CUTTERS OF COMPLICATED SHAPE.

Abstract from paper read by Edmund L. French before the American Society for the Advancement of Science.

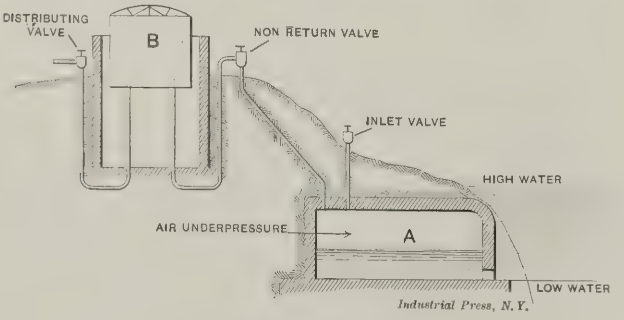
These high-speed steels have worked a complete revolution in modern engineering, necessitating the building of new and more powerful machine tools, and nearly doubling the output of shops where they have been adopted. All the best makes of high-speed steels show ability to withstand the heat engendered in heavy lathe and planer work to such a remarkable degree that it is a common sight in machine shops where the latest high-speed steels are used to see a tool doing heavy cutting work with that part of the steel where the chip curls off actually red hot. Here comes in the distinction between a plain carbon steel and the high-speed self-hardening product. When a tool made of the former becomes so heated by work as to show the temper colors, it softens, and the cutting edge is quickly rubbed off, while a high-speed tool similarly heated retains sufficient hardness to do the work required.

Until recently the extensive use of self-hardening steel has been confined to extremely simple forms of tools, where all the work necessary to fit them for service could be done by forging and grinding to shape. Now, however, there have been perfected processes of annealing which admit of self-hardening steel being as easily machined as most of the ordinary carbon grades. The high-speed qualities of the steel, as found in lathe and planer tools, can thus be utilized for cutters of all kinds, complicated or simple in pattern, at a great saving of time through the increased amount of work such tools are capable of turning out. The greatest advantage, however, which such a steel possesses over the ordinary water-hardening varieties lies in the fact that there is absolutely no danger of loss in the hardening bath, where so many costly tools meet their end, for it is only necessary to heat such a steel to redness and lay it aside to cool, when it will have regained the hardness it possessed before annealing.

MEANS FOR UTILIZING THE POWER OF TIDES.

Compressed Air, July, 1903, p. 2460.

The plan of Mr. Charles Eugene Ongley, of Mons, Belgium, for utilizing the power of tides, is to build a subterranean chamber at right angles to the shore line which shall be connected with the ocean by an opening at the low water line and low in height as compared with the rise of the tide and the total height of the chamber. The rise of the tide by virtue of this construction, imprisons air in the chamber and subjects it to pressure which depends upon the difference in height between the tide level and the level of the water in the chamber. Thus if the high tide level were six feet higher than the level of the water in the chamber the pressure per square inch would be approximately three pounds. This pressure, while comparatively slight, can be raised to higher pressures by means of accumulators working on the well-known principle employed in hydraulic accumulators for presses, riveters, etc. In the cut, *A* is the subterranean chamber communicating with the sea. The roof of this chamber is supposed to slope upward away from the water so that the imprisoned air has free access to the pipe leading to the air-holder *B*. This air-holder works on the same principle as the well-known gas-holder and serves to store the power and distribute it over those periods when the tide is falling, etc. The chamber *A* need not necessarily be located immediately at the water's edge; it may be connected with the sea by a suitable tunnel as well.



Compressing Air by the Tide.

TEST OF DIFFERENT METHODS OF JACKETING LOCOMOTIVE BOILERS.

Revue Generale des Chemins de fer, February, 1903, p. 91.

A series of experiments, made at the shops of the Paris, Lyons & Mediterranean Railway, on the radiating qualities of different methods of jacketing boilers, shows that in the matter of the influence of surface on heat radiation as far as the metals themselves are concerned either dull or polished brass is to be preferred to any of the others. It was also found that polishing makes a sensible diminution in the amount of heat radiated, and thirdly, that if a coat of paint is applied, the character of the sheet has no influence whatever. The radiation is governed by the painted surface only, and the loss is considerably greater than with the bare surfaces.

The work also included tests of different methods of jacketing in calm air as well as where there were currents.

The bare jacketing radiated less than the painted, the difference being from 55 to 185 heat units per square foot of surface per hour. In calm air and under the same conditions, a single jacket of mineral wool radiated about one-half as much heat as a bare jacket, and one-third as much as a painted one. Where a double layer of mineral wool was used, the losses per square foot were about one-half as much as they were in the case of the single layer.

With a double jacket and a layer of mineral wool between, the losses were about one-half as much as they were with a single jacket without the wool.

It was found that in air currents when the velocity was greatly increased the losses were doubled, and that a layer of mineral wool reduced these losses by one-half. The effect of painting is to increase the loss but not to so great an extent as in calm air.

A further test was made of pipe coverings, using a copper pipe 7 inches inside and 7½ inches outside diameter and about 7 feet high; the comparison being made with a bare pipe and one having a brass jacket enclosing a covering of one or more thicknesses of corrugated paper, the whole being wrapped with a sheet of tarred paper.

The results obtained in condensation of water per hour under the same conditions, the pipe being vertical, in free contact with the air and connected to a boiler carrying a pressure of 213 pounds per square inch were as follows:

	Pounds.
Bare pipe	25.3
Pipe with special covering	15.4
Pipe enclosed in brass jacket	16.5

G. L. F.

DEVELOPMENT OF TOOL STEEL.

Edmund L. French before the American Association for the Advancement of Science.

The author stated that the hardening of steel dates back to the remotest antiquity, the name of the original inventor or discoverer having been lost to the world. The ancient Egyptians made a low grade of steel capable of being hardened by heating meteoric iron for a long time in the forge, during which period it absorbed sufficient carbon from the fuel to harden when plunged into water. The metal-workers in the dark ages also hit on the same discovery and this was the actual birth of the steel industry and the beginning of the development of the crucible process.

The progress of steel-making as an art, until within the last two hundred years, was slow but gradual. Weapons of war and rough implements for tilling the soil were for centuries fashioned by skillful smiths who worked at isolated forges, and who guarded their mysterious secrets carefully and well. Gradually, however, as a demand grew for fine swords and armor of steel, axes, knives, and other tools, these steel workers formed themselves into colonies for trade purposes at places where good iron could be easily obtained, and the industry developed to a commercial scale. Notably in Austria and England this centralization took effect, and in the city of Sheffield large furnaces were in operation in the seventeenth century for the conversion of Swedish and Norwegian iron into blister steel by the cementation process.

This process was essentially the same as that employed by the ancient workers of iron, but on a larger scale, with furnaces especially built affording facilities for converting the pure iron bars into steel in quantities which soon made the industry an important one. Although the industry grew rapidly, and the product was of such a quality as to permit of the manufacture of the finest tools, these old steel makers worked on a "hit-or-miss" plan, with no clear idea of the way and wherefore of their process. A steel was obtained which had uncertain percentages of carbon, higher on the outside than on the inside, and varying in hardness from one end to the other, according as the bar came in contact, in the converting furnace, with more or less of the carburizing material or a higher or lower degree of heat.

It was not until about 1730, when Huntsman, of Sheffield, the inventor of the crucible process, began to make his experiments, that the industry was actually born. Huntsman's invention grew out of the necessity for a more uniform product than that afforded by the cementation process alone—in fact, for a metal of absolute homogeneity. He conceived the idea of cutting the blister bar in pieces and melting it in crucibles to get a uniform carbon. The charge was then allowed to cool and the crucible broken away from the mass of steel, which was used as an ingot. Molds for casting the metal were subsequently introduced, thus saving the crucible for further use.

Huntsman's process of melting materials in crucibles was not new. His invention really consisted in successfully solving the great difficulties met in applying his process to the actual production of steel, and it is thought probable that his knowledge and skill in producing crucibles of a sufficiently refractory nature to withstand the high heat required, were responsible for his success. The new process developed by Huntsman, and improved on by such men as Jessop, Mushet, Lucas, Sanderson, Spencer, and others, soon gave to England the first rank among steel-making nations, and made the name Sheffield a synonym for the best that was known in the form of a razor, a knife, or a bayonet.

Then the crucible-steel industry was started in other countries, but there have been no important changes in the essential processes of crucible-steel manufacture. An advance over the use of the cemented bar has taken place in the American practice largely in vogue of using a highly carburized and very pure iron, called washed metal, as a vehicle for introducing carbon into the steel, giving more regular percentages than can be obtained by the use of charcoal, and lowering the cost of making without any deterioration in quality.

It is along the line of special steels or alloys made in the crucible that the greatest advances have taken place. The makers of the old-fashioned crucible steel found that when they had produced a material with the highest amount of carbon possible, quality being at the same time of the best, they had reached the limit of cutting power in tools, and competition made it necessary for each maker to attempt something to excel his neighbor's product.

The first great advance was made by Mushet, who succeeded in melting with his charge of steel the mineral "wolframite," which gave him certain regular percentages of tungsten and manganese. The steel so produced had the peculiar property of being "self-hard"—that is, of requiring no heating and subsequent cooling in water to induce hardness. It had also an ability to withstand the heat developed by friction in cutting work, and the product, called "mushet," which name is still used in some localities to designate this variety of steel, became a recognized institution. As soon as the chemist found out the ingredients of this new steel, the various makers began to imitate it.

Tungsten metal and ferro-tungsten were later made to facilitate the manufacture, and gradually chromium, molybdenum, and other metals were employed in the production of this class of steel. Even uranium, titanium, and vanadium are used to some extent to-day as ingredients of special crucible steels. A large variety of combinations of iron and carbon with tungsten, chromium, manganese, nickel, silicon, or molybdenum characterize the special steels on the market to-day. Every maker furnishes, besides his regular carbon steel, a self-hardening steel and an intermediate grade which may be called a semi-self-hardening. The latter is capable of being hardened in water without cracking, and suited for extremely hard cutting. The self-hardening steels cannot be brought in contact with water while hot on account of the danger of cracking. Some of the milder grades rely on the assistance of an air blast, after forging, to give them the proper degree of hardness for their work, and are called "air-hardening steels."

It was thought for years that the greatest degree of perfection and the limit of cutting power had been reached in the best self-hardening steels, but within the last three years new products, similar in character and analysis, have been perfected, with capabilities of high-speed work which far surpass the old. Many of the latter steels owe their high-speed qualities to special heat treatments given the tool after forging, while some of the newer products are of such combination chemically that no treatment, or only a simple one, is necessary.

TESTS OF THE RATEAU STEAM TURBINE.

Street Railway Journal, July 25, p. 118.

The steam turbines designed by Prof. A. Rateau, Paris, France, and manufactured by the Oerlikon Machine Works, Switzerland, and Sautter, Harlé & Co., France, are assuming a prominent position and appear to give good results. Their operation is similar in principle to the Curtis turbine in this country. In his tests Rateau determines the efficiency from the ratio of the real steam consumption to the theoretical consumption of an ideal machine. The theoretical steam consumption is defined as corresponding to the maximum work which the steam can produce under the conditions under which it is delivered to the machine, by expanding adiabatically and without losses, from the initial pressure to the exhaust pressure. Prof. Rateau shows that the theoretical consumption depends largely upon the pressure in the condenser, as shown by the following example:

If a machine using saturated steam at a pressure of 213 pounds per square inch exhausts into free air, the theoretical steam consumption is 12.85 per horse power hour. If, however, the same machine be provided with a condenser which reduces the exhaust pressure to 27 inches the theoretical steam consumption is only 7.82 pounds, i. e., 39.3 per cent. smaller than before.

Following are the results of some tests of a turbo-generator of 540 electric horse power, which is one of a group of three similar machines made in the Sautter-Harlé works for the Penarroya mines in Spain, where they have just been installed. Each set consists of two turbines of high and low pressure, and two direct-coupled direct-current dynamos, giving each at normal load 830 amperes at 220 volts. The normal speed is 2,250 revolutions per minute. These turbines operate condensing, with "ejector" condensers of the Rateau type. The boilers supplied steam under a working pressure of 140 pounds to 210 pounds, maintained at the turbines by a reducing valve at 140 pounds per square inch as maximum. The consumption and the efficiencies are given in the following table:

TESTS OF RATEAU TURBINES.

	¼ Full Load.	½ Full Load.	Full Load.	Over-load.	Over-load at 2,400 r. p. m.
Electric horse power at the brushes	135	259	525	627	641
Working pressure at gage in lbs. per sq. in.	31.	61.	12.1	141	141
Absolute pressure in lbs. per sq. in. of exhaust	1.247	1.34	1.64	1.82	1.82
Theoretical consumption in lbs.	10.91	9.77	8.82	8.71	8.71
Actual consumption in lbs. in horse-power at the brushes	21.3	18.0	15.74	15.31	14.86
Combined efficiency of generating set	0.513	0.540	0.560	0.569	0.586

This table shows that the combined efficiency, i. e., that of turbine and dynamo together, varies between 51 per cent. and

58.6 per cent., while the steam consumption per electric horse power hour may be as low as 14.86 pounds. Also, that the combined efficiency of the turbo-generator is practically constant, the variations being not more than 8 per cent. between overload and one-quarter full load.

The efficiencies of turbines when a high vacuum is used suggested to Prof. Rateau the possibility of utilizing, by their means, the exhaust of steam from engines running at intermittent load, such as steam hammers, mine hauling and rolling mill machinery. In such cases to secure a continuous flow of steam to the turbine Rateau uses an apparatus which he calls a "regenerative accumulator of steam;" it consists of sheet-iron cylinders, containing a series of cast-iron plates, which condense the steam on its arrival from the prime mover and allow it to vaporize when the exhaust from the first machine stops. The pressure of the exhaust steam is nearly constant, and equal to about 3 pounds. An adjustable valve, regulated by hand, permits a variation within certain limits of the steam pressure from the accumulator; in general this pressure is from 2.8 pounds to 5.2 pounds.

A very interesting application of this principle has been made at the Bruay mines at Pas-de Calais. The exhaust steam of the hoisting machine is fed to a turbo-generator of 300 horse power. The test showed a production of 1 electric horse power per hour at the terminals of the generator, with a steam consumption of 39.68 pounds; the steam being admitted at atmospheric pressure and the vacuum in the condenser being 24.8 inches of mercury, hence, relatively bad. This figure Professor Rateau believes could be reduced to 28 pounds per electric horse power hour with a better vacuum in the condenser, which is perfectly obtainable in practice. Under these conditions the low-pressure generating set performed about three times as much useful work per pound of steam as the hoisting machine, even with a steam consumption of 30.68 pounds against 100 pounds, the ordinary figure for a simple non-condensing hoisting engine.

STEEL, AND STEEL AND CONCRETE TIES.

Railway and Engineering Review, August 1, 1903, p. 580.

Now that railway and government authorities have become thoroughly aroused to the question of future timber supply, any measure undertaken with a view to conserve this supply, increase the life of timber that is used for structural purposes, or substitute other material, wherever timber is in demand in large quantities, is necessarily a subject of a good deal of interest.

The thought of using iron or steel in substitution for wood in structural work comes naturally, and in foreign countries there is a large mileage of track laid with iron or steel ties. In this country experiments with steel ties, in years past, have been unsatisfactory, principally owing to the fact that the designs which have been tried have failed to properly support the track and to admit of surface repairs by ordinary methods of track work. The general rise in the price of steel a few years ago also had the effect of turning the attention of railway men from the use of this material for railroad ties. Within recent years a few men have proposed the use of concrete reinforced with steel.

The man who has labored most persistently along these lines, so far as we are aware, is Mr. C. Buhrer, roadmaster with the Lake Shore & Michigan Southern Railway, at Sandusky, O. Three years ago Mr. Buhrer laid some steel ties in the main track of this road at Sandusky, and a year later other ties of the same kind were laid on a curve in the main track at Sandusky Junction, about 2½ miles east of Sandusky, where the trains make full speed.

These ties have maintained the track in good surface, alignment and gage, with much less work than has been required for wooden ties under like conditions, and it has been unnecessary to disturb the embedment of these ties to make renewals, as is necessary with wooden ties each season. The piece of track laid with these ties bids fair to remain in first-class condition for many years to come, at an expense for maintenance which is very much less than that required for track laid with wooden ties.

Mr. Buhrer's principal aim in experimenting with these ties has been to ascertain their effectiveness as a track support, and to show a decrease in the amount of work necessary to maintain the track in surface and alignment. The test has proven that his expectations have been realized, and the facts are indisputable. The only remaining consideration of importance is the expense. Owing to the state of the steel market for several years past, Mr. Buhrer has not been able to get the rolling mills to undertake the manufacture of the ties by rolling them from old rails. This would be the desirable method of construction, as then the tie would be in a single piece, and, if they could be rolled out of scrap rails by reheating, without remelting, the same, the expense of manufacture would be a minimum.

In any event the tie could be rolled from new metal, and Mr. Buhrer is ready to demonstrate that, even when so made, the maintenance cost of track laid with such ties can be reduced to a figure much lower than the present cost with wooden ties, with a very satisfactory showing for the ultimate economy.

Mr. Buhrer's experiments with concrete for tie material were begun in June, 1902, when a few ties of concrete, reinforced with a piece of old rail molded in the top face, with the head downward, were laid in the main track of the L. S. & M. S. Ry. 2½ miles east of Sandusky, O., adjoining the steel ties above referred to. Later ties were laid on short lengths of other roads and in every case have proven satisfactory in all particulars. The reinforced concrete tie affords substantial bearing for the rail and a very secure arrangement for the fastenings. As the head of the rail projects downward into the body of the concrete the latter secures a very firm hold of the rail, and a strong and stiff tie is secured. It is fully understood that the use of old rails in these ties involves a good deal of metal, undoubtedly in excess of the requirements; but as the principal aim of the experiments was to determine how the concrete would bear up under the traffic and sustain the shock of rolling loads, the excess of metal was of minor importance. The inventor has in view the possible use of various metal shapes for the top face of the tie, such as old rails of lighter weight than the ones used, which weigh 60 pounds to the yard; T-irons, bulb irons, a channel with the flanges downward, and other shapes.

Mr. Buhrer has made a careful study of the concrete mixture required for tie material, and the result has been a selection of sizes and proportions differing somewhat from ordinary practice in general concrete construction. Methods of mixing and molding have also been evolved to suit the requirements of the material. The experiments cover the use of both fine gravel and finely crushed stone as ingredients of the concrete mixture. After setting 30 days the concrete of these ties is remarkably strong and hard, and will bear smart blows from a sledge hammer without fracture. The ties are unloaded by being thrown from the cars. The only precaution taken is not to let one tie fall across another. Mr. Buhrer says he has no fear of damage to the ties so long as they do not strike anything harder than the ground, and from tests of the material made in our presence it does not appear that they are an article requiring delicate handling. The track laid with these ties can be raised and tamped with bars or picks equally as feasible as track laid with wooden ties, and a misdirected blow or "lick" from a tamping bar does not "faze" the material.

ENGINEERING FEATURES OF A GREAT DEPARTMENT STORE.

Insurance Engineering, July, 1903. p. 27.

The department store of Marshall Field & Co., Chicago, is the largest retail establishment of the kind on this side of the Atlantic and there are only two larger in the world, those being in Paris. The total floor area of the Field store is 1,000,000 square feet, which is about one-third larger than the area of the new Macy store in New York City. The store is composed of several sections, or buildings, one of which, recently constructed, is 12 stories high. Seven thousand people are employed.

There are 53 elevators, of which 41 are for passenger service, all of the improved electric type, operated in most cases by a 35 horse power motor for each. The motors are all located in the attic, so that no space is occupied in the basement by elevator machinery. The passenger elevators have a capacity of 3,000 pounds each at 350 feet a minute and the freight elevators 3,500 pounds at 250 feet a minute.

Considering the large number of lights, and power necessary to properly equip this wonderful store, one would think that economy would lie in having its own power plant. Nevertheless this is not the case. While space has been reserved for the installation of a 3,000 horse power generating plant, the whole plant is operated from the mains of the Chicago Edison Company. The installation for electric light and power supplied from a central station is probably not surpassed in this country or abroad.

The connecting load in this block of buildings amounts to more than 2,800 horse power in motors and an equivalent in light of over 40,000 16-candle-power lights. Reducing the power and light to 16-candle-power equivalent shows a total connecting load of about 82,000 16-candle-power lights.

There are 35,000 16-candle-power incandescent 115-volt lamps and 500 2,000-candle-power arc lamps at 115 volts, with 2,000 extra outlets for special and local displays. There are 2,000 lamps in the display windows on the street frontage. These are arranged in trough reflectors, and so far as outside observation is concerned no lights are in sight.

One can conceive a fair idea of this immense power and lighting system by mental comparison. Marshall Field & Co.'s combined electric light and elevator plant would furnish lights for a city the size of Toledo, Minneapolis or St. Paul.

To light the various cases throughout the store, watertight iron floor boxes are installed, each box being fitted with a brass cover. About 400 of these boxes are installed, having a total capacity of over 5,000 lights. From these boxes tap circuits are run to light up the cases. Considering that the framework of these cases is but ¾ inch wide, the matter of lighting them, concealing the work, and retaining the line of beauty, called for considerable ingenuity. This was accomplished by the use of small specially constructed troughs placed in the upper front edge of the show case, and protecting them from view by means of mirrors about 2 inches wide. In the troughs are placed special small Edison sockets with miniature lamps.

Ventilation is provided for the enormous room in the basement by a system of blowers, which in reality is a combination ventilating and heating plant. During the warmer months it cools and ventilates, while in the winter months the air is drawn over heated pipes and forced into the room heated, thus serving the purpose of a heating plant.

The water system which supplies the 150,000 gallons of water used in this store daily is located in the basement and is equipped with four pumps, run by electric motors, each of which is equal to 100 gallons a minute.

An indication of the amount of business handled through this busy store is shown by the large private telephone exchange installed in the building. The exchange is a branch of the Chicago Telephone Company's system, and is located on the third floor. The switchboard represents the highest type of private branch-exchange switchboard construction, and has all the details as complete as the latest relay central-office switchboard. It is now equipped for 250 private branch-exchange lines and 40 trunk lines leading to the central exchange. The ultimate capacity of these six operating boards will be 400 lines.

The refrigerating plant is operated by 20 horse power brine pumps and two 75 horse power ammonia compressors, all electrically driven. This system has a capacity of 50 tons of refrigeration a day. Cold water is forced throughout the buildings and to the tea rooms for drinking purposes by two 15 horse power motor-driven pumps.

The pneumatic cash-carrier system is operated by two 75 horse power and two 40 horse power motor-driven blowers. There are now some 200 stations installed, and others will be added as fast as found necessary.

For protection, the entire establishment, excepting the annex, is equipped with automatic sprinklers installed by the General Fire Extinguisher Company, Providence, R. I. The water supplies for the sprinklers comprise two 30,000-gallon gravity tanks, four 4,500-gallon pressure tanks, two 1,000-gallon Eastern Underwriter fire pumps, taking 12-inch suction from a 6,000-gallon surge tank, which has an 8-inch connection from the city main.

The tanks are in two batteries, each comprising one gravity tank and two pressure tanks, with a separate 8-inch tank riser running down to the underground pipe, then to a 12-inch header at the fire pump. Each lead from this header has its own indicator gate for shut-off. The system embraces an aggregate of over 2,000 feet of cast-iron pipe in sizes ranging from 4-inch to 10-inch, and connecting to the several risers in each of the two buildings; also to nine Siamese steamer hose connections.

The installation comprises 15,500 sprinklers and is provided with 23 variable-pressure alarm valves and five Grinnell dry-pipe valves. There is also an electric alarm system of gongs throughout the buildings, and annunciator located in the power plant. At every riser shut-off and drain valves are provided on each floor. The first seven stories of the new building have all the pipes concealed, only the sprinklers and the hand-wheels of the valves being visible below the ceiling.

THE BURNING OF PULVERIZED COAL.

C. O. Bartlett in the Journal of the Association of Engineering Societies, July, 1903, p. 44.

To burn coal in a powdered form successfully, three things are necessary, (1) uniformity of moisture, (2) uniformity in size of grain, and (3) the amount of air required for perfect combustion. In my judgment, it is impossible to get perfect combustion by feeding coal in different states of moisture.

First. Coal varies in moisture from 4 per cent. to 15 per cent. During the summer season, especially, ordinary bituminous coal frequently has not more than 4 per cent. moisture, while during the winter and spring or during the rainy season, and especially when the coal is saturated with water and then frozen, the same kind of coal will contain as high as 15 per cent. moisture, and much of this moisture in the form of ice.

Second. It is impossible to get the best results by burning large pieces of coal together with the dust of the coal. The coal must be reduced to grains of equal size and should be 80 mesh fine.

Third. About 140 cubic feet of air are required to burn a pound of coal. The admission of air cannot be successfully controlled by natural draft. Forced draft must be used.

If the three requisites named are secured, perfect combustion can be had, and perfect combustion means no black smoke, no cinders, and very little ashes, and a saving of practically 40 per cent. in the amount of coal used.

A test was made on a 60 x 18-inch horizontal tubular boiler, of about 125 horse power, as follows: First we would run a day on powdered coal, the next day on slack coal and the next day on run-of-mine coal. We afterwards made a test of longer duration, running 88 hours on powdered coal and 48 hours on the same kind of coal without drying and pulverizing and by hand firing, and the gross saving was found to be about 40 per cent. in the amount of coal used. Six per cent. of moisture was taken out of the coal. When burning the powdered coal, the amount of ash did not exceed 3 per cent., while in the ordinary way of firing it was a little over 19 per cent.

The first matter to consider in balancing the results of such a test is the cost of drying. Our firm recommends the use of the rotary cylinder dryer, using direct heat, and the products of combustion passing on the outside of the cylinder only. In some few cases the products of combustion are first allowed to pass on the outside of the dryer, then to pass through the coal, and when this is done it is safe to estimate on a basis of 10 pounds of moisture evaporated by 1 pound of fuel, but the operation is not a safe one. I think it is safe to estimate the cost of drying the coal on a basis of 8 pounds of evaporation to 1 pound of fuel. Estimating on a basis of $2 per ton for coal and taking the loss in moisture at 5 per cent., the cost of drying and the loss in moisture will be less than 12 cents per ton. This estimate is based on drying not less than 40 tons a day.

Second, the cost of pulverizing. With one good mill, using 25 horse power, 4 tons of coal can be pulverized in an hour. At the present time there are three systems:

The French Buhr or emery wheel system.

The Huntington or centrifugal type.

The ball or tube mill system.

To these I might add the Kent mill which is now being put on the market, and in which the pressure of the rolls against the casing is obtained by means of screw pressure, which adds to the capacity and at the same time admits of great reduction in speed, adding greatly to the life of the mill. At present it is safe to estimate on a cost of ten cents per ton for pulverizing.

Third. The cost of elevators, conveyors, bins, cost of running blower or feeder, interest on investment, and wear and tear should not amount to more than 10 cents per ton, and probably not more than 5 cents per ton, making the total cost of drying, shrinkage, pulverizing, feeding and cost of driving the machinery, interest on investment, etc., in quantities of 40 tons a day, about 32 cents per ton. This shows, on 40 tons of coal a day, coal costing $2 a ton, a net saving of a little less than $20 a day, or 50 cents per ton.

Another important factor, which I have not considered, is the doing away with the fireman, as in the use of this system no fireman is required. The fireman's wages are therefore saved. Also, there is not more than one-third as many ashes, and there are no cinders at all.

To burn pulverized coal economically it must be burned in fairly large quantities; in other words, I do not think it would pay to put in a drying and pulverizing outfit unless the amount of coal used is at least 10 tons per day. In large cities this difficulty can be obviated by having a central drying and grinding plant and selling the pulverized coal to small consumers. In this case it would be necessary simply to put in a feeder, for feeding the coal in a powdered form, and a tank for holding it.

The next obstacle, and one which I consider of very great importance, is the danger arising from storing large quantities of powdered coal. From the best information that I have been able to obtain I do not think it is practical to store large quantities of pulverized coal for any length of time, and this means that it would not be practical to dry and pulverize the coal at the mines and ship it in this form.

The next question, and quite a serious one, is the construction of the arch. In our experiment we used the Rowe system, which consists in blowing the pulverized coal, by means of an ordinary fan or blower, up against an arch over the fire. The arch wall becomes very hot and immediately ignites the coal, and when the proper amount of air is used the combustion is perfect. We find that a 2-ounce pressure is best for this purpose. It will be readily understood that, in order to withstand this excessive heat, the best kind of arch wall is necessary, and that specially constructed brick should be used. While this is really quite a serious question, I do not doubt that it will be satisfactorily answered. Mr. Fred Sieg-heim, of Germany, has an invention for covering the arch wall, by which it can be made to withstand a tremendous heat, up to 3,000 degrees or more, without injury, and to last for a long time; in fact, until the draft of air has worn away this material. As near as I can ascertain, this mixture is composed largely of the dust of carborundum, which is now being manufactured in large quantities at Niagara Falls. In taking the matter up with this company, I find that Mr. Siegheim has contracted for the exclusive output of this dust for five years. I consider this a very important invention and well worthy the most careful consideration of the engineers of the United States. It seems a little humiliating that the Germans should get ahead of us, but such appears to be the case.

* * *

ANECDOTES OF THE FAIR OF '46.

"It has not been sixty years since the sewing machine made its appearance in Washington," said an old timer to a "Star" reporter, "and there are quite a number of not very old people who remember the occasion. During the great mechanics' fair, which was held in 1846, opening May 21 of that year, in a specially constructed frame building in Judiciary Square, it was one of the star exhibits. It was said at the time that one of the main objects of the fair was to influence legislation in Congress on the tariff to show what the American workingman could do, and how little we were dependent on other countries for the necessaries of life.

"I remember that the sewing machine was the greatest attraction of the fair and interested the crowds about it, and there was difficulty experienced in getting near it. As may be supposed, the machine at that period had not been brought to the perfection it reached by subsequent improvement, but it did its work to the amazement of the thousands of visitors, and as a labor-saving machine, together with McCormick's reaper, then first exhibited here, caused much discussion. Among the seamstresses the sewing machine was looked upon as the instrument which would deprive them of a living, and it was predicted that its adoption would drive hundreds to poverty. At that time the price was high, and many hoped that so much would be asked for it as to prevent its general use.

"The effect of its introduction was to some extent discussed in the papers of the day, and I believe in some of the manufacturing cities the working people were much excited over the revolution its adoption was expected to bring. I read an abstract of an address by a pastor in one such city, in which he said to the factory people and seamstresses that they had nothing to fear from its introduction. He said notwithstanding so much more sewing could be done by machine, the tastes of the women were such that should the cost of making a dress or other garment be cheapened, more elaborate garments would become the style and there would follow such a demand that instead of taking work from the sewers there would be more. In other words, while the cost of making a plain dress would be lessened, the additional trimmings, extra plaits, seams, etc., would make up for any loss.

"There was no fear that the labor-saving mower and reaper would have such an effect upon the masses," continued the narrator, "for all recognized that should it be effective the cost of daily bread would be lowered. I should mention that the revolving pistol, patented by Colonel Samuel Colt, some ten years before, was an object of much interest, especially to military men, and the fact that it was then on trial in warfare—the Texas Rangers of Captain Samuel H. Walker, engaged in the Mexican War, being armed with the pistols—imparted an additional interest to the subject.

"There were many other exhibits at the fair mentioned, and the display was a revelation to the masses, a great educational object lesson, and probably the most important exhibits were those named. I should not, however, omit to notice another. As is customary, admission tickets were issued to all exhibitors, and hundreds of our younger people were benefited thereby, these being mostly girls who had specimens of sewing, embroidery.

"There was a boy living in the old Second Ward who got up an elaborate aggregation of cogwheels, levers, shafts, etc., so intricate in looks as to bewilder any but the initiated, whose sole object was to obtain an admission ticket. This he entered, but not for a prize, and called it a 'wing wang.' By winding up the motive power, a clock spring, it went into operation with such a clatter as to drown the noise of the larger machines. Curiosity led to many inquiries as to its use, but the only reply obtained was that it would grind smoke, when forced in the hopper, and cool the air with its revolving flippers. Useless though the machine was at the time, it drew the attention of an influential gentleman to the boy, who made him his protege, and the result of the boy's ingenuity was subsequently seen by an improvement in drawbridges and in the matter of lanterns for lighthouses."—*Washington Star.*

* * *

Josef Madersperger, a native of Kufstein in Tyrol, is said to have invented a sewing machine in 1814 which was improved by him in after years so that it was a practical operative mechanism, considering the state of the mechanical arts in that era. But from lack of financial assistance the machine was never manufactured and Madersperger, in common with many early inventive geniuses, never profited by it since history has it that he died a pauper in the workhouse. In after years the worth of his invention was recognized and now the rich sewing machine manufacturers of Vienna, Austria, have unveiled (June 7) a beautiful monument to his memory.

SCREWS.

EXTRACT FROM ARTICLE IN THE "MICHIGAN TECHNIC," BY EDWIN H. EHRMAN.

The purpose of this article is to present a series of notes of a practical nature, relating to the several standards of screws, that may be of service to those engaged in machine design or shop management. It is at the outset advisable to review the different forms of screw threads in use, with some note and comment as to their fitness for the various kinds of screws.

Of the styles of threads in common use in the United States, the United States Standard (also known as the Franklin Institute, or Sellers' form) is the most feasible form to use in the manufacture of screws and bolts. While the thread itself may be a trifle weaker than the sharp V form, it gives a screw that for the same nominal size and pitch is much stronger than the screw with the V form of thread, as the core diameter of a screw with U. S. S. threads is greater by .43 of the pitch than that of a screw with sharp V threads. The increased danger of a screw with U. S. S. form of threads to fail, due to the threads stripping, as compared with that of a screw with sharp V threads, is more apparent than real, as experience has shown that a screw will give way almost invariably by breaking across the diameter at the bottom of the threads before the threads themselves will shear or strip.

Whitworth	5	4½	4½	4½	4	4	4	4	3½	3½	3½	3½	3¼	3¼	3¼	3¼	3	3	3

The U. S. S. thread is used on milled screws, finished studs and nuts, especially those entering into the construction of steam engines and other engineering work of large proportions, and the better grades of machine tools and machinery. This form is admirably adapted to rough bolts and studs, and many manufacturers are using it in lieu of the V thread. A sharp V thread die has a tendency to tear the tops of the threads in threading rods or bars that are larger than the finished diameter of the screw; and as bar iron varies considerably in diameter, and is liable to be slightly over size, it has been the custom in cutting threads on it to use dies that are 1-32 inch larger than the nominal size, so that the die will not cut down the diameter of the bar, with the attendant liability of making a poor thread as well as unnecessarily overworking the die. Occasionally the writer has noticed that rough bolts and studs have been threaded even size when the diameter of the bolt was small enough to admit of so doing. This leads to confusion, especially in those sizes where more than one standard of pitch is in use. For instance, in purchasing ½-inch machine bolts one might get ½ inch over size or even size with 12 threads, or ½ inch over size or even size with 13 threads, or ½ inch, 13 threads U. S. S. The adoption of the U. S. S. form of thread would entirely obviate the present difficulty.

In the manufacture of nuts there is the same tendency in threading for the threads to tear if made perfectly sharp, and also a greater liability of the tap breaking from overwork and clogging; consequently, it has become the custom to ream the nut blanks large enough to leave the thread flat, quite as much so as in the U. S. S. form. A valuable point to the manufacturer, both in the making of nuts and in the machine shop, is the greater strength of taps having the U. S. S. form of thread as compared with those having V threads, which means a double economy, due to the longer life of the tap and the greater duty of which it is capable. A good feature of the U. S. S. thread, and one that will bear extending, especially in the smaller sizes, is that it tends toward a finer pitch than the V and Whitworth standards, notably in the ½, 1⅞, 2¼, 2¾, and 5-inch sizes, and it might have been well when the system was planned if the threads per inch for ¼ inch in diameter had been made 22 instead of 20; for 5-16 diameter, 20 instead of 18; and for 1⅛ diameter 8 instead of 7. At present some of our foremost manufacturers of machinery are using ¼ and 5-16 inch screws with the finer threads above noted, styling them the U. S. F. (form) instead of U. S. S.

The sharp V thread will long continue in general use, due primarily to its simple form and secondarily to its having so thoroughly established itself in mechanical industries. It has another very strong claim, however, in the fact that it is admirably adapted to the making of steam-tight joints. Both in boiler bolts, patch bolts, and in iron pipes and fittings it answers the purpose better than any other practical form of thread.

There is no variation at the top and bottom of the thread, as there may be in both the U. S. S. and Whitworth forms of thread, with the resulting liability of leakage through the clearance thus formed. Sharp V threads are used on machine screws, on rough bolts, on boiler bolts, and other bolts where a steam-tight fit is needed, and largely on milled screws.

The square form of thread is usually made about twice as coarse in pitch as the V or U. S. S. threads, and partly for this reason and partly because the perpendicular walls of the thread do not allow the chips to free, it is a troublesome thread to cut with taps and dies. There is also difficulty where more than one cut is made to produce the finished screw, due to the succeeding taps or dies not registering with the partly cut thread, and consequently cutting away the thread already formed. This form of thread is largely used on adjusting and power conveying screws.

The Acme screw thread was designed to overcome the objectionable features of the square thread. It has many good points, not the least of which is its strength and the ease with which it may be cut, compared with the square thread. This is due to the greater strength of the teeth in both taps and dies, as well as to the facility with which the cuttings free themselves. This thread is advocated as a substitute for, and in preference to, the square form of thread.

The Whitworth form of thread has two points of merit that commend it highly where heavy service is required. First, screws with this form of thread have all of the strength possessed by screws with U. S. S. threads, with the advantage over the latter of having no sharp edges or corners from which fractures may start. Second, screws and nuts with this form of thread will work well together after continued heavy service where the other forms of thread would fail. Whitworth threads are used (in the United States) chiefly on special screws, such as screws for gasoline needle valves where a liquid-tight and yet working fit is desired, also on some makes of ordnance breech blocks.

The standard thread in the International System (*Systeme International*), adopted by the International Congress for the unifying of machine screw threads, held at Zurich in October, 1898, resembles our own U. S. S. thread. The formulas are the same but the pitches are somewhat finer, a distinct advantage, especially in the finer sizes. To provide for a thread with a clearance at the bottom such as is in general use in France, the Congress specified that "the clearance at the bottom of the thread shall not exceed 1-16 part of the height of the original triangle. The shape of the bottom of the thread resulting from said clearance is left to the manufacturers. However, the Congress recommends rounded profile for said bottom." By this wise provision, choice is given manufacturers in the several countries interested to make the bottoms of their threads flat or rounded, as desired, and yet have them conform to a common standard so as to interchange, if necessary.

The S. I. thread has been adopted by the Swiss Union of Manufacturers, the German Association of Engineers and the Society for the Encouragement of National Industries.

The British Association Standard Thread is patterned after the Whitworth, though more acute and shallow, and with larger rounds at top and bottom. The dimensions of screws with the thread are given in mm., the largest being 6mm. in diameter, which is the smallest size of the International system. It corresponds to our system of machine screw sizes smaller than ¼ inch in diameter.

Attention has been drawn to the matter of pitch in the foregoing paragraphs in comparing the several systems of threads, and comment made on the desirability of using finer threads. The pitches of the U. S. S. thread are no doubt suited to bolts used in the larger work in mechanical and civil engineering, but perhaps not quite so well adapted to the screws used in smaller work—especially the sizes of screws below one inch, and there has been a tendency among manufacturers to use screws one, two and even four threads finer than standard. This leads to much annoyance and possibly to confusion, but it suggested a scheme that the writer has adhered to for some years. The plan has been that where a deviation from standard is deemed desirable, the pitch used is one of a range of pitches, the units of which are suited to the different materials and purposes. Out of this scheme, intended to cover the use of screws and nuts only, has developed the system of making all special taps—even to 6 inches in diameter—with one of the following pitches: A pitch of 8 threads is used for screw threads on large pieces and on smaller work where the material is cast iron. A pitch of 12 threads is used where a finer thread is needed and where the material, in part, is brass. This pitch is that commonly used on boiler bolts, planer head bolts, and to a large extent in the nuts fitting on milling machine cutter arbors. A pitch of 16 threads is used where a still finer pitch is wished, and is adapted to adjusting rings, collars and nuts on shafts and spindles used in machinery—especially on hollow spindles used on lathes, drill presses and screw machinery. Other pitches for smaller screws, each pitch covering several diameters, have been established. This has been done largely to enable quick repairs of special cutter heads and holders. The following list explains itself, additional sizes of taps being added as occasion requires:

Machine screw sizes—Nos. 6, 8, 10, 12, and 14, all 32 threads, 7-32, ¼; 9-32, 5-16, 11-32, ⅜, all 24 threads; ¼ to ½ all 20 threads; with isolated sizes of one or another of the above pitches up to 1 inch and 1¼ inches in diameter. The foregoing may be quite unpractical in some shops, but on the other hand the carrying out of some systematic plan in establishing special sizes of screw threads would undoubtedly add to the economy of the tool-room and the machine shop.

Passing from the shop into the drafting room, one finds many ways and means of making and keeping lists of the screws used in the shop for special purposes. In one office will be found large sheets of drawings of screws burdened with a network of dimensions and lines. In another a tabulated sheet is used for each style of screw employed; a drawing of the screw with lettered dimensions above, and below it the table of dimensions with the proper index letter at the top of each column. In still another office will be found descriptive lists of the screws, bolts and nuts used in each machine or article manufactured, with reference numbers indicating the number of the piece or drawing from which each item is taken. Ofttimes a board of mounted samples takes the place of drawing or list. Each system, no doubt, answers the requirements of the office using it, otherwise it would be replaced by a better one; each has its good points, too—from the completeness of the first system to the simplicity of the last.

For special screws and formed pieces that are quite different from stock goods, a drawing of each piece is probably the only way of fully describing it, but for the average screw, resembling in some degree the stock patterns, the most compact record is by tabulated dimensions, referring to a diagram of a typical screw of its class. As one purpose of these records is to facilitate the ordering of screws, it follows that the specifications, drawings, and description should be explicit and entirely free from ambiguities. Many curious screw sheets and blueprints come under the writer's notice, and they lead one to think that either too little thought or too much time and paper has been spent in making them, and they prompt a few comments and general suggestions.

In general—Screws that enter a tapped hole have their lengths measured to the extreme points. (See *L*, Fig. 1, and *X*, Fig. 3.) Screws that enter a nut (i. e., bolts and studs), have their lengths measured to the end of the thread, leaving the oval additional. (See *L*, Figs. 2, 3 and 4.) Measurements of length are made from the outer diameter of the under side of the head. (See *L*, Figs. 1 and 2.) The diameter of a square or hexagon head is understood to mean the short diameter. The blank part of a screw body is understood to extend to the first marks of the thread, and should measure in cap screws as shown in Fig. 1. (See *B*, Figs. 1, 2 and 3.) The length of the thread is understood to apply to the useful part of it. (See *T* and *N*, Figs. 1, 2 and 3.) Note that the lengths *N* in Figs. 2 and 3 should not include the partly formed thread made by the leads of the die, as a nut would bind if forced over them. This is true also of cap screws, as shown in Fig. 1. The length of the thread on the tapped end of a stud, however, includes the "lead" or partly formed thread, as the stud when screwed tightly into a tapped hole will enter it practically the whole length of the thread. (See *T*, Fig. 3.)

Ordinarily.—The length of the blank (*B*, Fig. 1) part of the body of a cap screw (except for very long screws) is ¼ *L*. The length of thread (*N*, Fig. 2) on coupling bolts, is 1½ times the thickness of the nut, where only one nut is used. The partially formed threads made by the leads of the die is, on most screws, about three threads in length; on set-screws and tap ends of studs about two threads in length. The angle *A* (Fig. 1) in cap and machine screws is 40 degrees. The angle *A* in boiler patch bolts is 45 degrees. The short diameter of hexagon nuts, both finished and semi-finished, and rough square nuts is equal to $1\frac{1}{2}B + \frac{1}{8}$ inch where $B =$ size of bolt. This is true also of coupling bolt heads (hexagon) which are not finished on their sides. (According to the Franklin Institute Standard this would apply only to unfinished heads and nuts. The diameter of finished heads and nuts would be 1½ *B* + 1-16 inch). The regular thickness of finished and unfinished hexagon nuts and unfinished square nuts is equal to the diameter of the bolt. This is true also of the heads of coupling bolts.

According to the Franklin Institute Standard, the above would be true only of unfinished hexagon heads and nuts. The thickness of finished hexagon nuts and heads would be *B* — 1-16 inch. Square heads are not supposed to be finished and their thickness is one-half the short diameter or ¾ *B* + 1-16 inch. The thickness of check and jamb nuts is ½ *B* + 1-16 inch, where *B* is less than 1¼ inch, and ½ *B* + ⅛ inch where *B* is equal to, or greater than, 1¼ inch. The diameter is the same as that of unfinished nuts. The length of head for milled screws equals the diameter of the screw. The dimensions of a screw should be expressed in terms of the diameter × the length (diameter first).

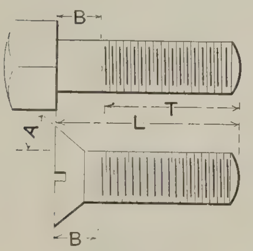

FIG. 1

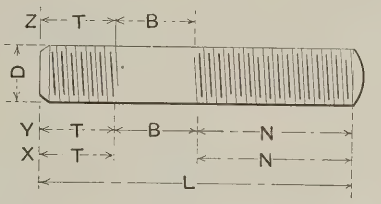

FIG. 3

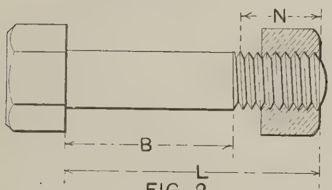

FIG. 2

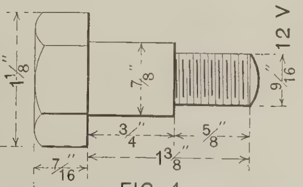

FIG. 4

Industrial Press N.Y.

The fact that the proportions of nuts and screw heads are governed largely by formulas has led the writer to formulate rules that govern those parts of machinery in which screws and nuts are used. Among the parts that may be standardized are: Finished washers suited to cap screws and to nuts; bosses on castings for setscrews; lugs on castings suited to roundhead screws, to square and hexagonal head screws, and to nuts or bolts; thickness of collars of collar screws; sizes of taper pins relative to the diameters of the shafts in which they are used, etc. Diagrams standardizing parts and pieces such as those enumerated save much time in the drafting room and relieve the draftsman of a large part of the detail that otherwise must be worked out anew in each recurring case.

Returning to the subject proper, it might be of profit to inquire into the ways of expressing by drawing, diagram or words the dimensions of screws and bolts. It is quite a common practice to overload a sketch or diagram with dimensions, and it is also of frequent occurrence that dimensions are given which are complements of the ones intended. This may be made clearer by an illustration or two. A sketch such as Figs. 1 or 2, with the dimensions *L* and *B*, indicates that the piece is wanted with the blank part of the body a specified length, whereas this is very unusual; and if the piece was made as called for, the working useful part of the thread would probably be too short. What is usually intended to be expressed are the dimensions *T* and *L*, or *N* and *L*. A sketch such as Fig. 3, with the length expressed as shown at *Y*, leads to confusion, as it is impossible to leave as much blank as the dimension *B* calls for if the lengths of useful thread are as called for by the dimensions *T* and *N*. Ordinarily what is desired is the length of the threads *T* and *N*, as shown at *X*, which, with the dimension *L*, is enough. If the blank part is to be of a specified length, the dimension should be written as shown at *Z*, stating also the length *L*.

At this point it might be well to state that a stud with one end chamfered is usually threaded large enough on that end to fit tightly in a tapped hole; and if it is desired that both ends are to be threaded to fit nuts, then both ends are made rounding and the lengths of thread for both ends are expressed as shown at *N*. Other points are brought out by Fig. 4. Though apparently very clear and exact, it does not mean just what it states. In the first place, the dimension 1⅛ inch should be explained by words under it such as "short diam.," as the intention is no doubt that the head is desired 1⅛ inch hexagon, and not 1⅛ inch across the corners. It is conventional to show three faces of a hexagon head, as the other view showing but two faces might be mistaken as showing a square head; while a square shown by a view of one only might easily be taken to represent a round head. The words "short diam." would remove all doubt, while the view shows the style of head. In the second place the drawing shows the thread running abruptly into the shoulder, a practical impossibility, and the dimensions would also lead one to think the nut should screw close to the shoulder. While the thread can be cut with a die of extremely short lead so that a nut could be screwed up to the shoulder, it would be difficult to make a very satisfactory job of it. To avoid any ambiguity it would have been better to have shown a neck in the screw under the shoulder, if the nut is to screw direct against it, or a short blank left under the shoulder if a washer is to be used under the nut.

Another matter not yet touched on, and one that pertains, or should pertain, to all specifications for screws (or other turned machine parts) is that of "fit." Some instruction such as tight, steam-tight, loose, snug, journal fit, tight wrench fit, finger fit, driving fit, etc., is necessary to make a specification complete. No two persons, of course, can or will interpret instructions such as the above in the same way, but the personal element is not so uncertain but that much good would result if the draftsman would give some attention to this matter in making up his sketches or lists. From trade experience, and from machine shop experience as well, it can be said that by being explicit in stating how the several parts of a machine (including screws and bolts) are to fit one another much trouble, time and money can be and is saved; perhaps more than can be saved in other ways requiring the same amount of thought and care.

Turning our attention again to Fig. 4, it is seen that changed as suggested, it clearly shows what is wanted, and, if put into words, the description would read:

Hexagon head shoulder screw.
Head 1⅛ inch hex. × 7-16 inch, nut finish on top.
Shoulder ⅞ × ¾ inch, journal fit in reamed hole.
Body 9-16 inch, 12 V threads, × ⅝-inch, oval additional, light wrench fit in C. H. nut. Necked under shoulder.

Other ambiguous statements are often made in specifications, more frequently in written descriptions, however, than in drawings. A little thought used at the right time will enable one to avoid them in either case. Attention is called to two common errors: (1) That of specifying "standard" without stating which standard, U. S. S. or V, is meant; and (2) that of not properly stating the angle of the head of a screw, such as the lower one in Fig. 1, or of the point of a conical pointed screw. To say the angle is 30, 40 or 60 degrees is indefinite unless qualified so as to plainly indicate whether the angle with the axis of the screw is meant, as shown at *A*, Fig. 1, or the included angle which equals 2*A*. For instance "30 degree point" and "60 degree point" are usually taken to mean the same thing, although in interpreting these phrases one is assuming to mean the angle made by the sides of the point with the axis and the other the angle included by the sides of the point. Though 30 degrees (included angle) and 60 degrees with the axis (or 120 degrees included angle) are both uncommon, nevertheless a mistake is possible in assuming to interpret them either way.

* * *

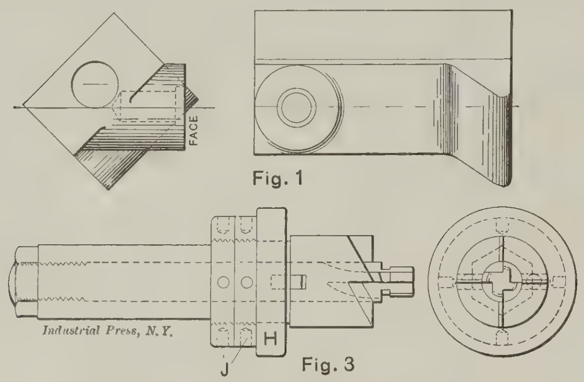
It would be theoretically possible to arrange a compressed-air motor so that it would drive the compressor that supplied it with air for its operation, and still have a surplus of power that could be used for other purposes. This could be accomplished by heating the air before it reached the motor, thus increasing the volume of the air and its capacity for doing work. The apparatus would then become a heat engine similar in principle to the Rider or Ericsson engines, power being derived from the fuel used in heating the air.

LETTERS UPON PRACTICAL SUBJECTS.

A DRILL JIG AND COUNTERBORE.

Editor Machinery:

The design of the jig and counterbore for machining the piece shown in Fig. 1 entailed not a little difficulty, and the tools with which it was finally accomplished may be of interest to anyone engaged in jig work. The casting to be drilled had one hole through its entire length while a second hole, which was afterward tapped, was drilled at an angle of 45 degrees to the side of the casting and with its center tangent to the diameter of the first hole. This hole was counterbored body size for a short depth and the boss in which it was located was faced to an exact distance from the first hole.



Piece to be Counterbored and the Counterbore.

The jig in which the piece was held is shown in Fig. 2. For drilling the long hole the drill was guided by the bushing *A*, while the jig rested upon the legs *BB*. The work was held against a stop *C* by means of a knurled head screw *D* that was carried in a swinging arm *E* which fastened to the body of the jig and received the thrust of the drill. The body of the piece was fastened by means of a clamp *F* into a V-block formed in the jig casting. For drilling the second hole the slip bushing *G* was employed to guide the drill. This was then removed and the combination counterbore and facing tool, shown in Fig. 3, was run into the drilled hole until the loose collar *H* brought up against the face of the tight bushing *I*.

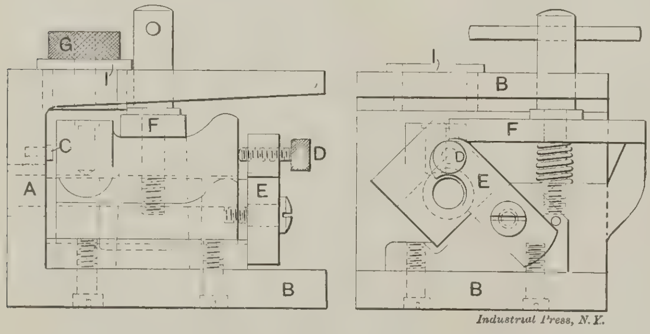


Fig. 2. Jig for Holding Piece shown in Fig. 1.

In this counterbore provision was made, by means of the lock nuts, *JJ*, for readjusting the depth of the cut after grinding the facing tool, and the body size of the counterbore had an independent adjustment which was locked by the nut at the upper end of the holder. After this operation the hole was tapped while still held in the jig, thus insuring that the tapping would be perfectly true with the face of the hole.

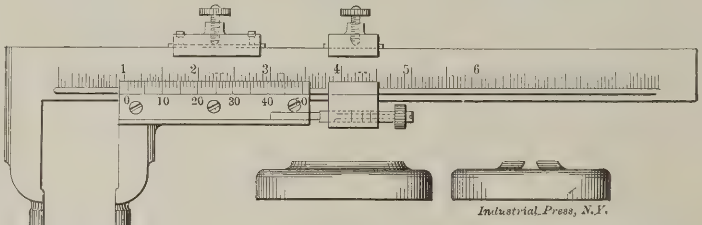
A SPECIAL DESIGN OF SIX-INCH VERNIER.

Editor Machinery:

The accompanying sketch illustrates a 6-inch vernier, of the writer's design, which has several points of advantage over the usual form of vernier caliper and is suitable for use both as an outside and an inside caliper gage. The graduations on the beam and vernier plate are open to reading and no part of them is obstructed to view by the cross bar of the sliding head, as is the case in some calipers of this class. The reading on the bar gives the value for outside measurements, i. e ,.those made on the inside of the jaws; while the same size on the outside of the jaws is provided for, in the adjusting or follower head, by simply slackening the binding screw on the caliper head and moving it until it comes to a stop. To illustrate: the gage as shown is set to 1 inch outside diameter and if we desire to bore out a hole for the same exact size, or any amount under or over, as for drive or running fit, we first loosen the binding screw on the follower head and move it to the left until it comes to a stop against the caliper head, in which position we clamp it securely. Next loosen the binding screw on the caliper head and move it to the left until it is stopped by the interference of the knurled screw head against the follower. We then have the same size on the outside points that was indicated for the inside. Provision is made for adjustment when correction is necessary. This duplication, in the hands of an expert, equals that of any standard inside and outside gages and has the additional advantage that any fractional measurement, in thousandths, is obtained over or under standard size.



Six-inch Vernier of Special Design.

This vernier may be used as a height gage by inserting the base in the dovetailed block shown in the cut, as the height of the block is such that it is 1 inch from the base of the block to the face of the caliper jaw. A scribing point may be clamped on the vernier head and lines scribed to exact height in thousandths. The groove at the base of the lines on the beam is for the purpose of cutting the graduations, as cutting out a chip disturbs the normal length of the bar less than the ordinary way of marking the lines.

F. W. Clough.

TOOLS FOR MOLDING PORCELAIN.

Editor Machinery:

While there may be nothing novel or strange in the construction of the mold here described, yet the method and tools by which porcelain is molded may be new to many of the readers of Machinery. A surprising feature of this work is the allowance that must be given for the shrinkage of porcelain, it being no less than 9-64 inch per inch, and one company engaged in the manufacture of porcelain goods, recommends an allowance of 5-32 inch to each inch of measurement. In the mold here described some of the center distances required to be quite accurate and the writer found it most convenient to work to decimals and so used 1.14 as a constant for all of the measurements. Thus the center distance between the holes *AA*, Fig. 1, is to be $2\frac{3}{8}$ inches and in the mold was made $1.14 \times 2.375 = 2.707$ inches.

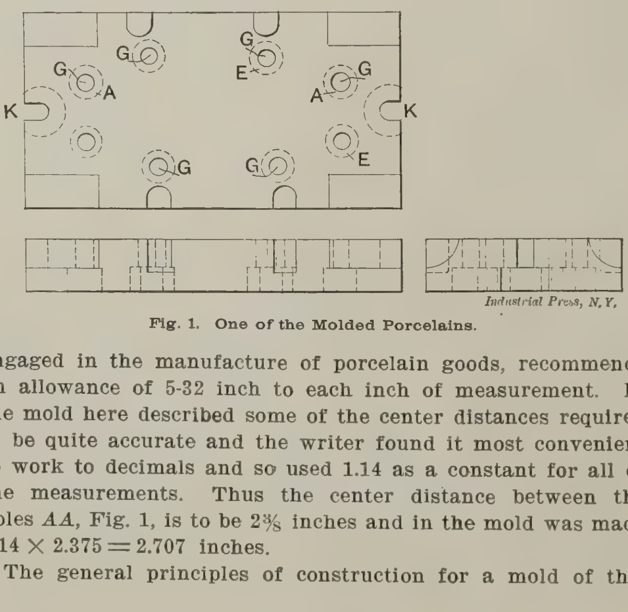


Fig. 1. One of the Molded Porcelains.

The general principles of construction for a mold of this kind will be seen by reference to Fig. 2, which is a detail of the mold used for making the piece shown in Fig. 1. The materials from which these molds are made are cast iron and steel. The molds wear away quite rapidly as the clay has an action like that of pumice stone against the wearing parts. The making of such molds requires considerable care and where sharp corners are needed the fits should be as good as can be obtained. Some draft is required where the bosses for making holes are long, but this will never be very great. The molds are fitted to presses and some pressure is required but not very much and this fact simplifies somewhat the problems of construction.

The views in Fig 2 show the mold with the top block *B* removed. It will be seen that it is essentially a rectangular cast iron box with the bottom held away from the sides by means of collars which are slipped over the screws that hold the bottom to the sides. *C* is the stripper which is made to move up and down in the mold but must be a good fit if a clean porcelain is desired. The bushings *DD* are driven firmly into the stripper and their projecting heads or bosses form the recesses shown in the porcelain at *EE*, Fig. 1. Sliding freely through these bushings, and riveted to the bottom of the mold, are various wire rods of suitable size to make the holes marked *GG*. The stripper rods *HH* slide freely through the bottom of the mold and are of such a length that when the nuts on the strap *I* touch the bottom, the top of the stripper will be slightly above the top of the mold. The pieces *JJ* are inserted in the ends of the mold and form the slots *KK* in the porcelain.

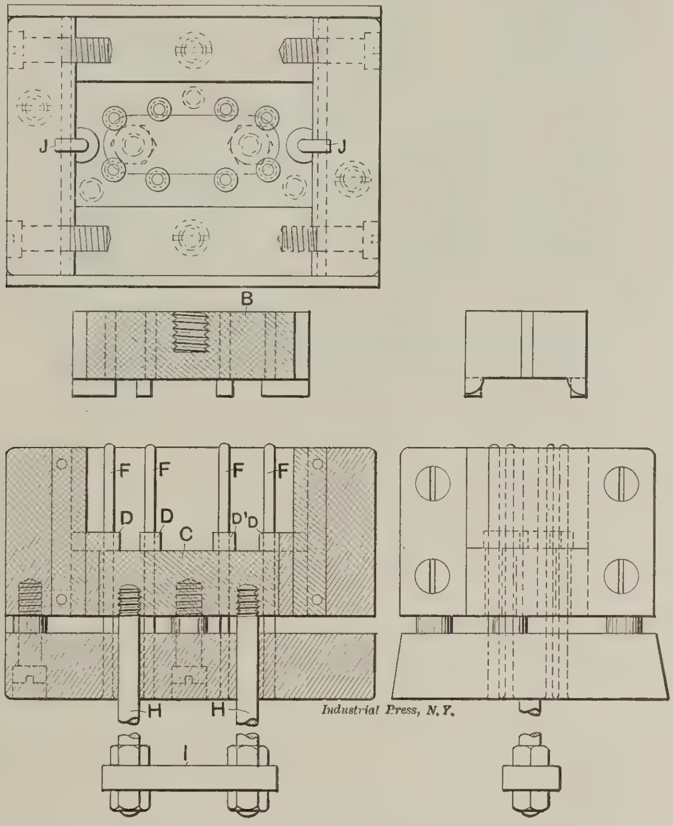

Fig. 2. Mold for Forming Porcelain.

The block *B* is made to fit snugly into the mold and has holes which receive the rods *FF*. There are various projections on it which make the corresponding depressions in the porcelain. The thickness of the porcelain is determined by the distance to which the block is pushed into the mold.

J. R. Gordon.

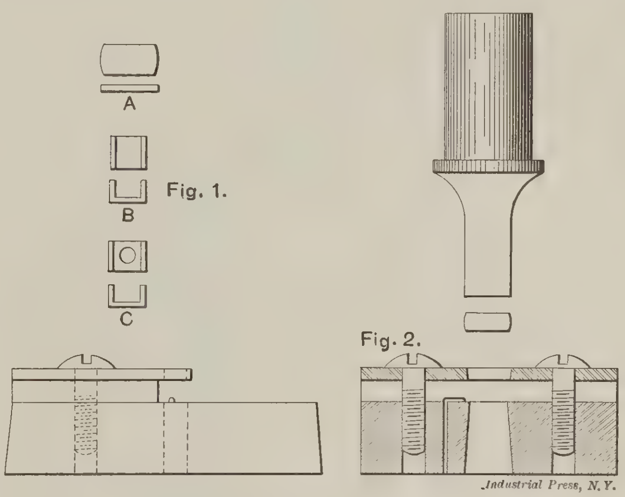
A JEWELRY PUNCH AND DIE JOB.

Editor Machinery:

Fig. 1 represents a piece of punch work that was made from gold stock and which required great accuracy in shaping as well as being bent at a very sharp corner as shown at *B*. Three operations were performed upon the piece as follows: First, cutting the blank as shown at *A*; second, bending as at *B*; and finally, punching the small hole in the bottom as at *C*. The metal was .020 inch thick and was lapped after being soldered onto a piece of jewelry. Several methods of bending were at first tried, but they proved unsatisfactory as too much trimming was required to obtain the necessary finish. The problem of bending was solved satisfactorily by the use of the punch and die here described.

The work was produced by the operations in the order above mentioned, but in order to obtain the proper size of the blank, the bending die was made first. This is shown in Fig. 3 and, as will be seen, is very simple in construction. The die proper, *D*, was planed on its face to receive the gage plates *E E*. A slot *F* was also planed to facilitate sliding in of the blanks, and another slot, running at right angles with *F*, served in conjunction with the tongues of *E E* to locate the blank in position for bending.

In order to obtain the square hole, which was of the exact outside dimensions of the blank, a hob punch was made in the milling machine and the opening broached through the die, starting from the back. In broaching a hole of this nature care must be taken not to remove too much metal, otherwise the surface will be rough and the corners not well defined. As the broach approaches the front of the die the amount of metal removed should decrease until the corners only are touched. After broaching, the die should be highly polished with a lapping stick and hardened, drawing the temper but slightly. It is then again polished brightly with a brass stick and flour of emery. In the opening was fitted the plunger *G* which served as a seat for the work while being formed, as well as acting as a plunger to release the piece when it was completed. This plunger rested on the knock-out *H* which was actuated by the coiled spring, upon which it rested. *I* represents the cast iron bed plate into which the brass casing for the knock-out was screwed. The forming punch was twice the thickness of the stock, narrower than the opening one way and of the same size the other way. With this punch and die we were able to bend the metal to a very sharp corner.



The Blanking Punch and Die.

By the cut-and-try method, in connection with the bending die, it was a simple matter to determine the proper length of the blank, and the blanking punch and die were then made. The punch was simply turned down and milled to the proper width and with this the die was broached. The writer has always found it to be good practice to make the punch first in all cases where it can be machined and then with it broach out the die; this method of procedure invariably resulting in a saving of time. The blanking punch and die are shown in Fig. 2 and will be understood without further explanation.

The perforating die by which the last operation was performed is illustrated in Fig. 4. A stripper plate *K* was fastened onto the base of the die *J*, by screws and dowel pins, and had a projecting arm *L* through which a hole, the size of the perforating punch, was drilled in line with a corresponding hole in the center of the hardened steel die. The indexing dial was made of steel about 3-32 inch in thickness. The top and bottom were accurately faced and the edge knurled to facilitate turning. The stud *M* was inserted in place with a thickness of paper under the head so that it would bind the disk tightly to the surface of the die. The die was then placed on the milling machine and the slot for the lever *N* was milled in the disk, using the slot in the hardened die as a guide. The die was then turned one-quarter of a revolution and the next slot milled in the disk; and so on until all of the four had been cut, using the same cutter that was employed for making the original slot in the die. The index lever *N* is forged from a piece of tool steel and fits snugly the slot in the die, while the part engaging the disk, projects somewhat over the surface of the disk and tapers slightly to take up any possible wear. The lever is pivoted upon the pin *O* which ends about halfway through the hole *P*, thus facilitating its removal should it be necessary. The most particular feature of this die was the location of the four holes, *R*, *R*, *R*, *R*, which served to hold the pieces while they were being perforated. Great care was observed to have the edges of the slots free from burrs, and the index lever was hardened before the holes were drilled. After the lever had been pressed into one of the slots, a hole corresponding in size to the perforation in the die was drilled through the disk from the back side. The disk was then turned to the next slot and so on, the four holes each being drilled while held in correct position relative to its respective slot. After drilling they were enlarged, by counterboring or by the use of several drills, to such a size that the punching might be slipped in without effort yet without leaving any play. The upper side should be slightly countersunk so that the pieces will locate themselves easily. The punch used with this die was of the usual form and is, therefore, not shown.

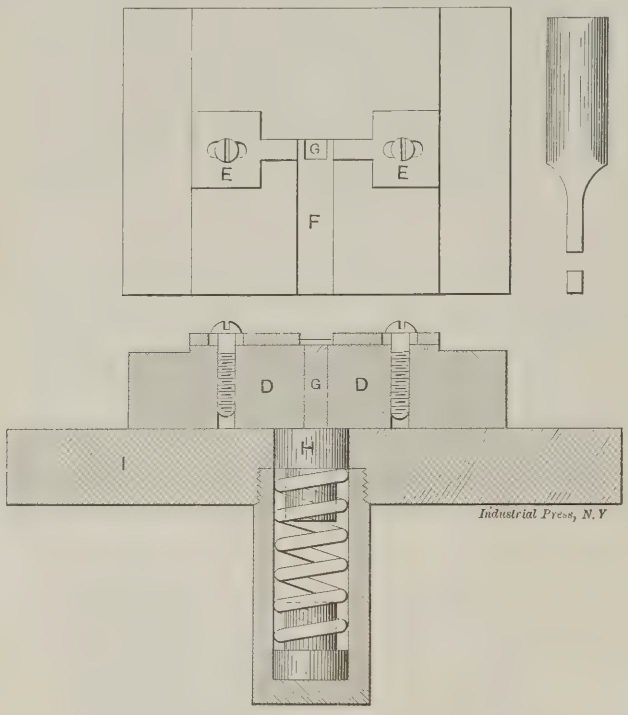


Fig. 3. The Bending Punch and Die.

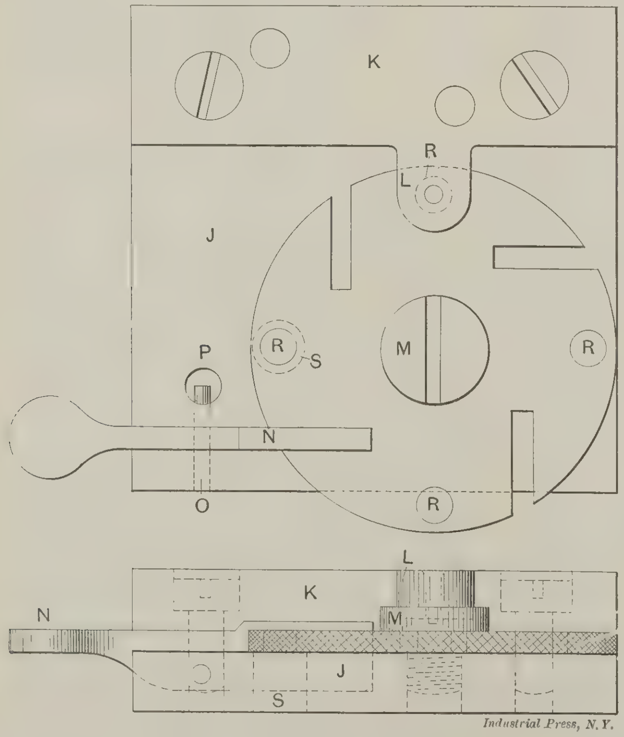

Fig. 4. Magazine for Die Piercing.

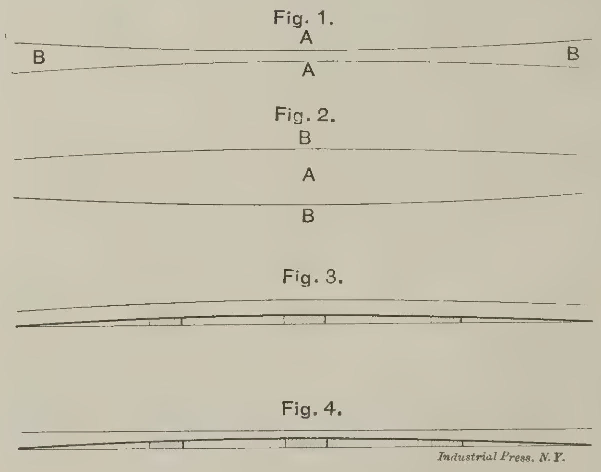
In operation, a punching was placed in one of the holes *R* and the disk moved around by hand until it was opposite and below the hole in the stripper plate. The left hand then allowed the index lever *N* to engage the respective slot in the disk, and the foot of the operator brought down the ram of the press, thus perforating the punching. Another punching was then placed in the hole next to that in use, the index lever disengaged, and the disk moved around a quarter of a turn so as to bring the new punching under the perforating punch. In doing this the punching that had been perforated remained in the disk and was moved around until it came over the hole *S*, in the die; then, as the punch descended, a pin fastened in the holder pushed it through the die and it fell into a box below. It will be seen that this arrangement saves a great deal of time, as it is unnecessary to take the punching from the die and it permits the operator to employ any lost time in placing punchings in the front part of the disk while those under the punch are being perforated.

New York City. FRANK GREINER.

PLANING CURVED SURFACES.

Editor MACHINERY:

By this title is meant the planing, not the milling of curved surfaces that are not circular in contour, the forming of which is known as radial planing. The matter in hand pertains to the formation of long thin pieces with perfectly smooth surfaces, convex or concave in the direction of their length on an ordinary, movable bed, planing machine, and without any special tools or attachments.



Planing Concave and Convex Surfaces.

Suppose that the average connecting rod and coupling rod for locomotives has too little vertical stiffness, especially at high speeds, and too little sidewise flexibility. As, since the days of Matthew Baldwin and his "spherical crank pin" (which really was "barreled" in a spherical curve, to enable locomotives to turn a corner with grace and facility) about the only way of giving a main rod or a side rod any leeway laterally is to give the pin "shake" in the brasses; the laterally flexible rod may be one way out of the difficulty under which all roads labor—and which I may add used to be a specialty of the Baltimore & Ohio Ry. between Baltimore and Washington.

Not that lateral flexibility is the main desideratum, but vertical stiffness is, and that can only be got by widening, or thickening the rod. But even "fish bellying" the rod adds some to the weight, if the rod is of even thickness, and it is desirable to avoid that and even further lighten the rod.

Where the rod is parallel in width (i. e., not fish bellied) a good way is to mill or forge out the center so as to leave the piece of I-cross section.

As the metal along and near the neutral axis is of little or no use in giving vertical stiffness (although it is as good as any as regards laterally stiffening the beam-like member) this I-section is a capital good thing and would be very much better if forged instead of milled; but we have not got that far yet. To mill out all but a flange on each edge and leave a fish-bellied portion of less thickness than the rest (that is, to have an I-cross section of varying height and uniform thicknesses) is not yet a milling nor a planing possibility; and the flanges give lateral stiffness. Now if we will make the top view of the rod as in Fig. 1 and the side view as in Fig. 2, and ease off gradually between the stub ends of the rod proper, we will have an ideal rod.

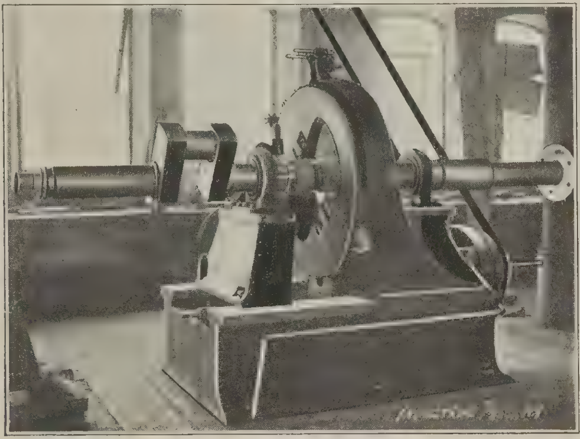


Fig. 1. Crankpin Turning Machine, Front View.

The faces *A A* may be planed or milled, for that matter, on a slab miller. The piece is strapped down at the ends and blocked up in the center, so that it comes to the bed as shown in Fig. 3. Then a planer cut is taken off the convex face, and the piece reversed so as to give another convex face, only the blocking must be higher than for the first operation. When through, the piece has two faces which are concave in the direction of their greatest length. The sketches are purposely exaggerated and simplified. To plane such a piece, thinner at the ends than in the center, strap it down in the center and block it up at the ends. Robert Grimshaw.

Hanover, Germany.

NEW CRANKPIN TURNING MACHINE.

Editor Machinery:

The photographs, Figs. 1 and 2, show a new crankpin turning machine which has recently been erected at the engine works of Messrs. Richard Pohle & Co., Ltd., Riga, Russia. It has been placed on the market by Emil Capitaine, Frankfort-on-Main, Germany, and was exhibited at the Dusseldorf Exhibition last year.

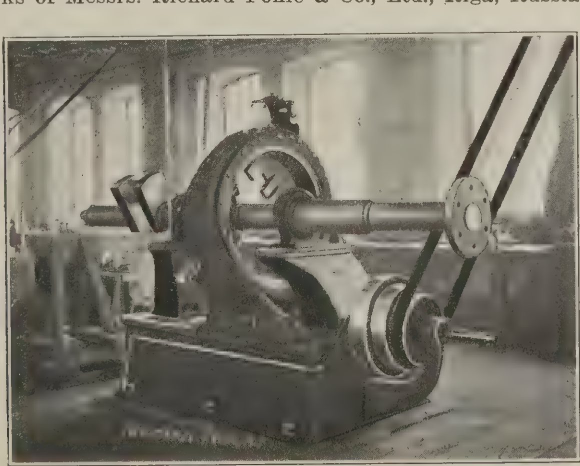

Fig. 2. Crankpin Turning Machine, Rear View.

It is well known that most crankpins are not cylindrical when turned in the usual manner in a common lathe, especially when the crankshafts are of large dimensions. Lately it was necessary to turn a number of crankshafts for some 350 horse power engines for the electric station at Vladuvistok, Siberia, and one of these machines was designed for the purpose, being capable of turning cranks up to 10 inches in diameter and 24-inch stroke. It consists of a bed in box form planed on the upper side, upon which are two brackets fitted with adjustable bearings and vernier scales. The first bracket has also a setscrew attachment for adjusting the crank arm. Between the brackets is the head frame which can be moved longitudinally along the bed. A ring revolves in the head and on the periphery of the ring is cut a 180-tooth gear. This ring is also connected with a disk made in two halves, each having guides, feedscrew attachment and one tool holder. Each half can be moved independently for turning the insides of the cranks. While turning the crankpin itself the whole head frame with ring and disk is moved automatically along the bed. The machine is belt-driven, having a three-cone pulley mounted on the head shaft, which can slide longitudinally in the axle boxes. Six different speeds are provided for, three by running with belt direct, and three by using the intermediate gears. A. Wind.

Riga, Russia.

FACE MILLING.

Editor Machinery:

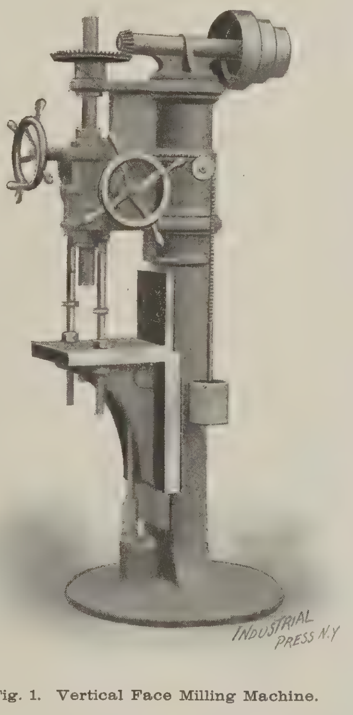

Fig. 1. Vertical Face Milling Machine.

The rapid and economical milling of large quantities of thin pieces is a problem that has been very satisfactorily solved at the U. S. Armory by the vertical milling system that is here described. The Pratt & Whitney Co. build a special drill press, illustrated in Fig. 1, that is admirably adapted to this class of work, but an ordinary drill press may be utilized by placing a jack under the table so as to prevent springing. The table and head must line up very accurately and be retained in that relation in order to obtain satisfactory results. The milling is performed with the face mill shown in Fig. 2, which fits the spindle of the drill. This mill is about 6 inches in diameter and has a pilot *A* which fits the center hole *B* in the milling fixture shown in Fig. 3. In making this mill the distance between the teeth must be less than the length of the pieces, otherwise they will be pulled out of the fixture when they are being operated upon. Oil is fed onto the work by pouring it on top of the mill, whence it runs down through the numerous holes *CCC*.

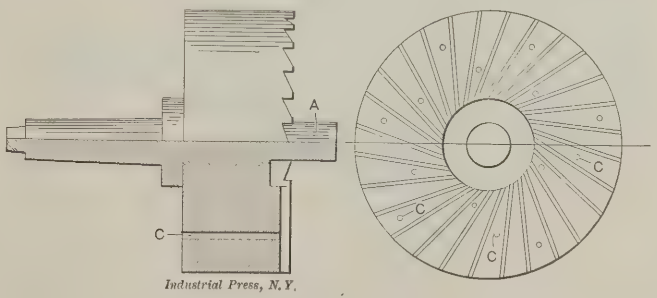

Fig. 2. Face Mill.

The milling fixture is made on the principle of a drill jig with a leaf *D*, which is hinged at the pin *E*. The top of the base is ground true with the bottom of the legs. The base is a permanent fixture to which may be attached different leaves to suit the size and shape of the pieces to be milled. These leaves are planed on top and bottom and are screwed and doweled to the hinge, a special jig having been made for this purpose. The leaves have as many openings in them as the space will allow; with irregular pieces one row is usually all that can be used, but with small, regular pieces, as shown in the drawing, two or more rows may be employed. In making these openings, which must be a good fit for the pieces they are to hold, we first make a hardened templet having a hole of the required shape. This is clamped to the leaf and the holes are drilled out and then profiled, using a mill that has a shank of the same diameter as the cutter. This shank acts as a pilot pin and the templet guides the cutter so that it is possible to mill all but the sharp corners and very little hand work is required. The holes may all be located at the same distance from the center of the leaf by fastening the templet to a piece having a pin to fit the center hole *B*.

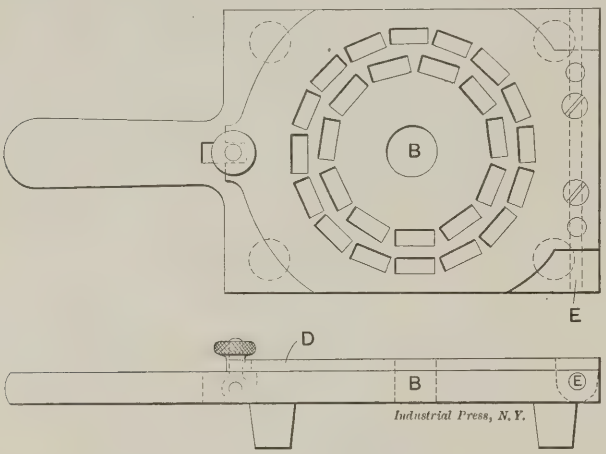

Fig. 3. Fixture for Face Milling.

To operate the fixture, fill the openings with the pieces to be milled and place the fixture under the mill, then feed the mill down onto the work. The pressure of the cutter keeps the work in place. When pieces are to be milled on both sides, after one side has been milled the leaf with the work in place is removed from the hinge, turned over and replaced and the second side is milled in the same manner as the first.

Springfield, Mass. C. H. Wilcox.

ON THE SUBJECT OF FRICTION.

Editor Machinery:

We so often read statements in advertising literature regarding the reduction or abolition of friction that some of our unmechanical friends might conclude that friction is our worst enemy, or at least a necessary evil. It is, however, more necessary than evil for, though the thought rarely enters our minds, it is nevertheless true that without friction every engine in the country would immediately go to pieces and, also, we should be unable to walk a single step. Now, like all phenomena in nature, friction is the more useful to mankind as he learns to make use of it in the proper manner for each purpose. Lack of ability or judgment in doing this has frequently produced failure. Friction is the worst enemy of the perpetual motion fiend, but it is the friend of the primitive savage who could not build his fires without it. If the reader has never yet attempted to produce a fire by rubbing together two pieces of wood he had best try the experiment, though, like one of Jules Verne's characters, he will doubtless become warmer than the wood.

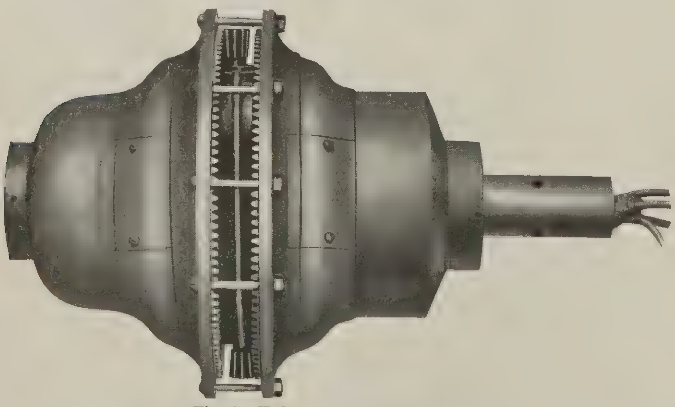

Fig. 1. Holson Couple-gear Motor.

There are some peculiarities about friction that should be better understood. One of these is the rule that the total amount of friction is independent of the area of contact. This is often interpreted literally or, rather, other factors arising from changes in the bearing area are ignored. Sometimes an increase in bearing area, by reducing the pressure per square inch, permits better lubrication with a resulting decrease in friction; whereas in other cases, as where adhesion or atmospheric pressure are active, an increase in bearing area may increase the total friction. Such results are not antagonistic to the general laws of friction but are the results of other elements entering in and modifying the result. The necessity of proportioning the amount of friction to the requirements has furnished ample opportunity for the exercise of inventive power and numberless are the arrangements and devices that are used to reduce friction on the one hand and to increase it on the other.

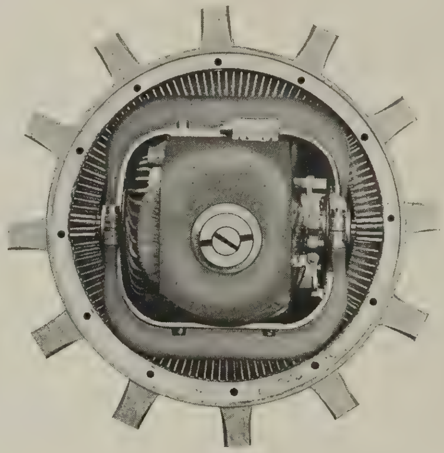

Fig. 2. End View with Casing removed.

For reducing friction we have ball and roller bearings, pivots, jeweled bearings and bearings floating in mercury or magnetically supported; while to increase friction substances having a high coefficient of friction upon each other are employed, or such a substance as sand, in railroading, is inserted between the surfaces. It is also in railroad work that "traction increasers" are used in which the friction is increased by placing additional weight upon the drivers. There is, where it can be practiced, no better way of reducing frictional losses than to do so by judicious design, not simply of the bearings themselves, but of the working parts in relation to each other.

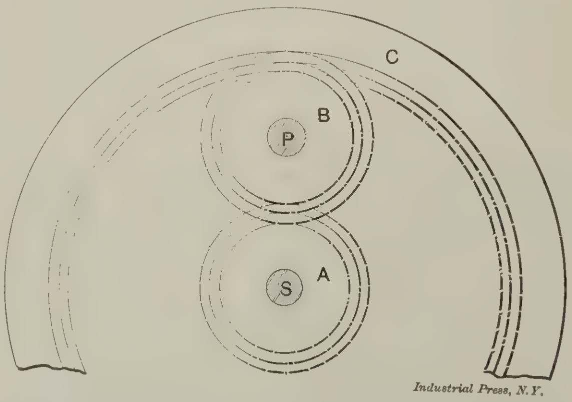

Fig. 3. Arrangement of Gearing in Old Windmill.

One of the best mechanical devices of this order that has come to the writer's notice is the Holson "couple-gear" motor, used on motor vehicles, and illustrated in Figs. 1 and 2. Fig. 1 shows each of the two pinions engaging one of the large bevel gears, while in Fig. 2 a view at right angles to that in Fig. 1, the hub is shown with the outer half, containing one of the large bevel gears, removed to show both of the pinions. It will be seen that power is taken from both ends of the armature shaft, dividing the pressure due to driving between both bearings; and incidentally the driving member, or vehicle wheel in this case, is driven equally at two diametrically opposite points. A couple is thus produced by the driving pinions so that there is no friction in the bearing due to its being driven. An accurate test of this device shows it possesses a very high mechanical efficiency.

Quite another arrangement of gearing is illustrated in Fig. 3 and was used in a windmill. In the drawing, *S* is the wheel shaft carrying the pinion *A* which drives the internal crank gear *C*, through the pinion *B*, with a reduction of about 4 to 1. At the first glance there may not seem to be anything unusually unmechanical in the arrangement as here shown but when the writer was asked to examine this windmill, on the farm where it was in use, the proportions did not appeal to him very strongly. The design was such that pinion *B* was quite small and the stud *P* upon which it ran was also small and short. Besides this the manner in which the gear transmitted its power placed its bearing under twice as much pressure as that on its teeth so that, roughly figured, the pressure on the bearing was found to be so great that proper lubrication was impossible and the mill was soon condemned for that reason.

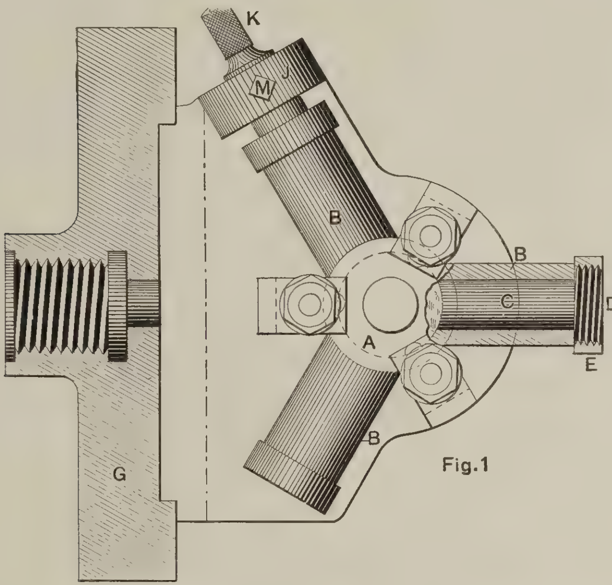

Fig.1

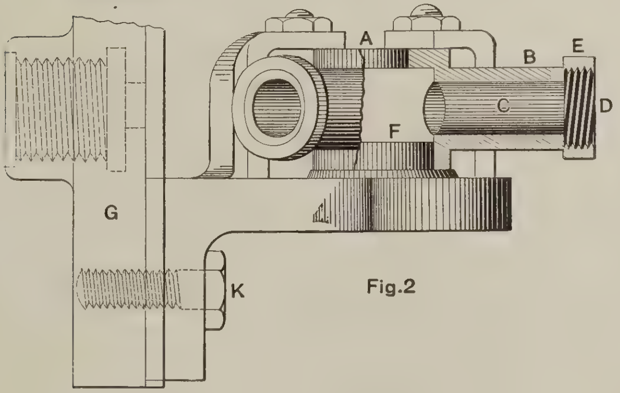

Fig.2

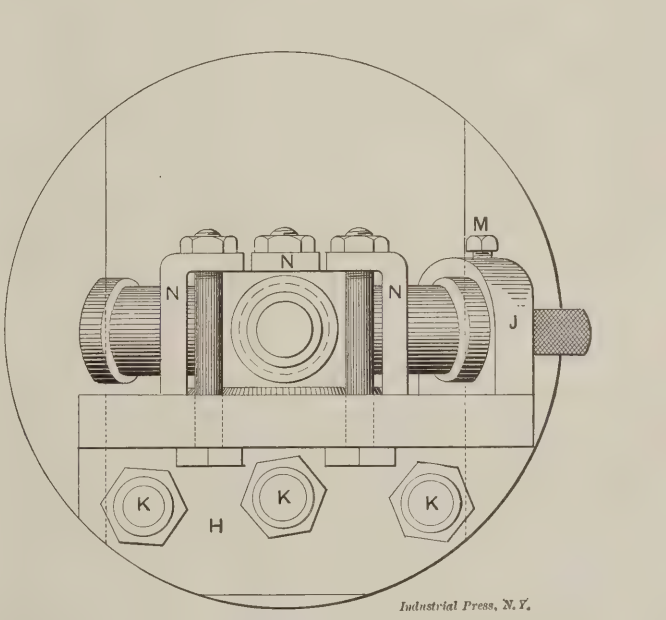


Industrial Press, N. Y.

Fig.3

Fixture for Chucking Gasoline Engine Cylinders.

This subject of reducing friction by arrangement of moving parts as well as by good design of the bearing is far too broad to be given full discussion in the limits of a single article, but the two devices here shown, one a success and the other a failure, serve to illustrate the principle.

Grand Rapids, Mich. CORNEIL RIDDERHOF.

A SPECIAL CHUCKING FIXTURE.

Editor MACHINERY:

Not long ago while visiting a manufacturing and jobbing shop, the writer saw the chuck illustrated in Figs. 1, 2 and 3, which contains some points of interest that might be adapted to the rapid production of any work of a character similar to the pieces for which this chuck was designed. The casting for holding which this chuck was made was, as will be seen, of rather unusual shape. It formed a triple cylinder for a high-speed automobile engine which was being manufactured in the shop. It had three cylinders, *BBB*, which were required to be bored out and reamed to size at *C*, turned on the outside at *E*, and counterbored and tapped for plugs at *D*. The portion indicated by the letter *A* was the hub. The centers of all three cylinders had to be on the same plane and spaced so as to form exactly the same angle with each other.

The construction and use of the chuck will be seen by reference to the three views shown in the illustration. *G* is a faceplate, turned and finished to screw onto the lathe spindle and channeled down the face to allow of locating the angle plate *H* which is fastened to it by the cap screws *KKK*. The hub of the casting was first held in another chuck and bored out on the inside and finished on the outside to gages. This preliminary work formed the basis for the accurate accomplishment of all of the succeeding operations. The work was then located centrally on a boss *F*, formed upon the bracket *H*, so that the three cylinders would come approximately central. For clamping the three straps *NNN* were used; while the indexing was accomplished by plug *K*, Fig. 1, whose locating part was hardened and ground to fit the finished bore of the cylinder and also the reamed hole in the lug *J*.

When using the chuck, a casting was first clamped somewhat loosely upon the angle plate *H*, being located centrally by the stud *F* which projected upward about ¼ inch. A plug, which for a distance along its length fitted the reamed hole in the lug *J* and for the rest of its length fitted loosely in the cored holes in the cylinders, was inserted, through the lug, into one of the cylinders. The clamps were then tightened and the machining proceeded. First the outside of the cylinder was turned at *EE* and finished to gage, after which the steady rest was brought up and adjusted so that the finished portion ran true in it. This was followed by the boring and reaming which were done by first using a bar with an inserted cutter, then a shell-rose reamer, and finally a one-bladed reamer for finishing. After reaming the counterboring and tapping were done. Now the clamps were loosened and slid back, the work removed from the angle plate—the temporary plug having, of course, first been removed—and the casting relocated with the finished cylinder in line with the lug *J*. The plug *K* was inserted, through the lug, into this cylinder which it fitted perfectly. The setscrew *M* was tightened, thereby holding the plug securely in place, after which the clamps were secured and the second cylinder was bored, reamed and tapped as had been done with the first. After this the same method of procedure was followed for finishing the third, or remaining cylinder. TUBAL CAIN.

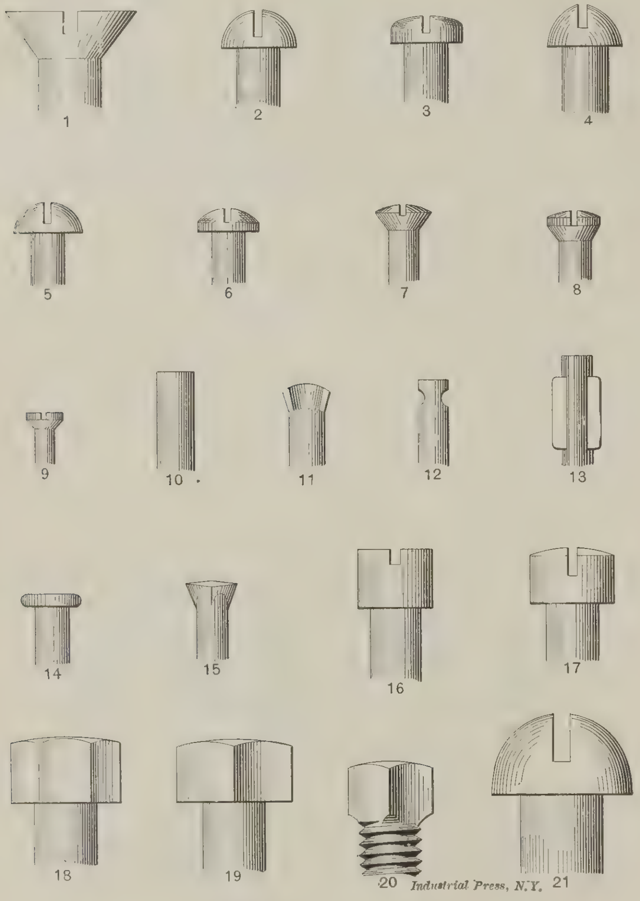
SCREW HEADS.

In the division of screws into classes the head forms an important part, and the name of the head is in most instances the method of distinguishing between the different classes of the same kind, as *round head* wood screws or *flat head* machine screws. The most common kinds of heads are easily learned, but even these are often a source of confusion to the young man beginning the business, while the styles of head not commonly seen in the hardware stock are a mystery to all those who have not had especial reason to learn them. The following brief description of each may help to fix the differences in the minds of those not already acquainted with the different styles.

1. Flat or countersunk head, used on all flat-head wood and machine screws, and on flat-head stove bolts. The top of the head is flush with the surface when applied.

2. Regular round head, used on round head wood screws and stove bolts and on machine screws. The head rests upon the surface of the object to which it is applied.

3. Regular round head used on machine screws larger than 5-16 inch diameter. This also is above the surface when applied.



Forms of Screw Heads.

4. Regular round head used on piano screws only. This differs from the round head used on wood and machine screws in the fact that it is higher.

5. A new round head used on piano screws only. This head has a larger base than the ordinary round head to give it a greater binding surface.

6. Fillister head used on piano screws. This head has also a large base to hold firmly to the surface upon which it rests. This screw is used in the piano action.

7. Regular oval head used on wood and machine screws. In application the edge of the head is flush with the surface, the slightly oval top rising above it, to give a better finish.

8. Oval head improved. Applied in the same manner as No. 7 and having the effect of giving a heavier or stockier head of the same diameter and surface contour as the regular oval. Used largely by gunmakers in attaching the plates to the locks of guns.

9. Head used on butt plate wood screws and damper block piano screws.

10. Headless, made with either wood or machine screw thread. These are used in castings where they are set into the piece cast with the screw protruding. Customers also buy them in this way and fashion the head into any special shape desired. Often furnished with heads slotted, and in use driven with top below the surface.

11. Pinched head used in castings with either wood or machine screw thread. The shape of the head keeps the screw from turning in its place.

12. Grooved head used in castings with either wood or machine screw thread. The groove is formed by pinching the rod and holds the screw fast in the casting.

13. Winged head, either wood or machine screw. When this is used a hole is first bored into the wood to receive the head and it is then driven to place, with the screw protruding, as in base knobs. The hole is the same diameter as the body of the screw. The wings keep the screw from turning.

14. Round bung head, used with wood or machine screw thread. Screws with this head are used in various ways. Many of them are used in the balls of curtain pole fixtures, being soldered into the ball.

15. Square bung head, used with wood or machine screw thread, in castings.

16. Flat fillister head, used with machine and cap screws. Used in machinery, usually with the head set in flush with the surface, in places where one part of the machine slides upon or passes over another.

17. Oval fillister head used on machine and cap screws. This is often countersunk the same as the flat fillister head, leaving the round above the surface for the finish, but is also used with the entire head above the surface.

18. Hexagon head used upon cap screws and machine bolts, and turned with wrench.

19. Square head used upon cap screws and machine bolts, and turned with wrench.

20. Square head used on set screws. The head of a set screw is always of the same diameter as the body of the screw and the thread is cut to the head. These are made with a variety of points, such as round, flat, cup, cone, hanger pivot, flat pivot, round pivot, etc., all shown in the Screw Department catalogue.

21. Button head used upon cap screws. It is slightly higher than the regular round head used upon wood and machine screws.—*From Circular of P. and F. Corbin Co.*

PUNCHING SEAMLESS TUBES—PORTABLE BORING MACHINE—SENSITIVE FEED DEVICE FOR DRILL—NOVEL ROTARY PUMP.

The recent improvements on the line of the London, Brighton & South Coast Railway in England comprise a bridge over the tracks of the London & Southwestern Railway which is remarkable for having one span in which the girders are 150 feet long from the centers of the column supports. The construction is of the single triangulation or N type with the upper boom curved.

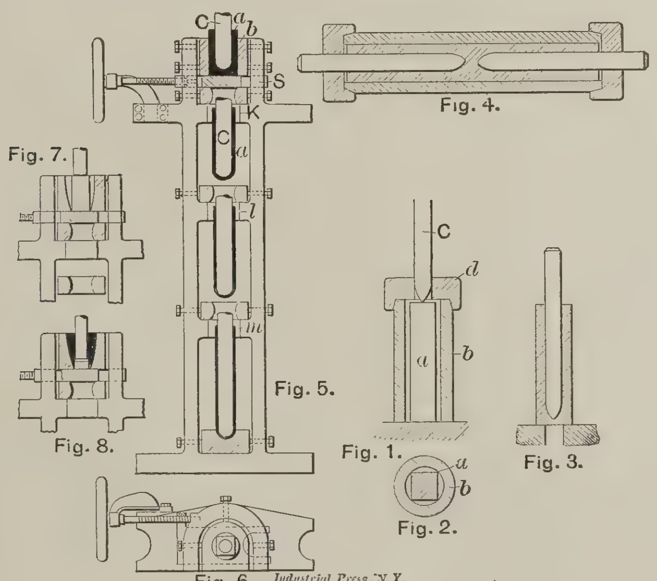
A rule recently published in the *Scientific American* for finding the power of windmills, is as follows: Find the square area of the slats in the wheel in the plane of revolution. This may be assumed to be the same as that of a circle of the diameter of the wheel. Multiply the area by the cube of the velocity of the wind in feet per second. The product divided by 4,000,000 gives the horse power. Example: What is the horse power of a wheel 12 feet in diameter in a wind blowing 15 miles per hour? Area of the wheel equals $12^2 \times .7854 = 113$ square feet. 15 miles per hour is a velocity of 22 feet per second. $22^3 = 10648$ which multiplied by 113 and the product divided by 4,000,000 gives 0.3 horse power.

A factory has been started at Hoslund, Norway, by C. G. P. DeLaval, of cream separator and steam turbine fame, to exploit his electric process for the extraction of zinc from the ore. The process consists essentially of an improved electric furnace which is not only adapted to the reduction of zinc ores, but many other ores. The gist of the improvement consists of means for the continuous introduction of the ore to the furnace and means for preventing the finely-crushed material being scattered about by the gases generated by the intense heat. The difficulty in separating the volatile gases from the pulverized ore that is thrown about by the violent chemical processes incident to the great heat has been heretofore one of the chief obstacles to the use of the electric arc in the reduction of certain ores.

The property of a vacuum by which a negative condition enables the atmospheric pressure to produce a positive result was formerly a great mystery to mankind. The Greek philosopher, Aristotle, the pupil of Plato and the teacher of Alexander the Great, explained the rising of water in a pump and similar manifestations of atmospheric pressure "because Nature abhors a vacuum," and it was nearly two thousand years until the time of Galileo—by whom the phenomenon was logically demonstrated as being caused by the weight of the air. And it would be not beyond belief to find that the true meaning of Galileo's discovery had not yet percolated through the skulls of all present-day gentlemen who make some pretensions to knowledge of physics and kindred sciences. But, nevertheless, we can scarcely repress a smile, strive as we may, at the naive remark of a prominent member of New York City's fire department, who, when asked at the trial of Edward Croker (late chief of the fire department), to define a vacuum, is alleged to have said "a vacuum is an inch of nothing."

PUNCHING OUT SEAMLESS TUBES.

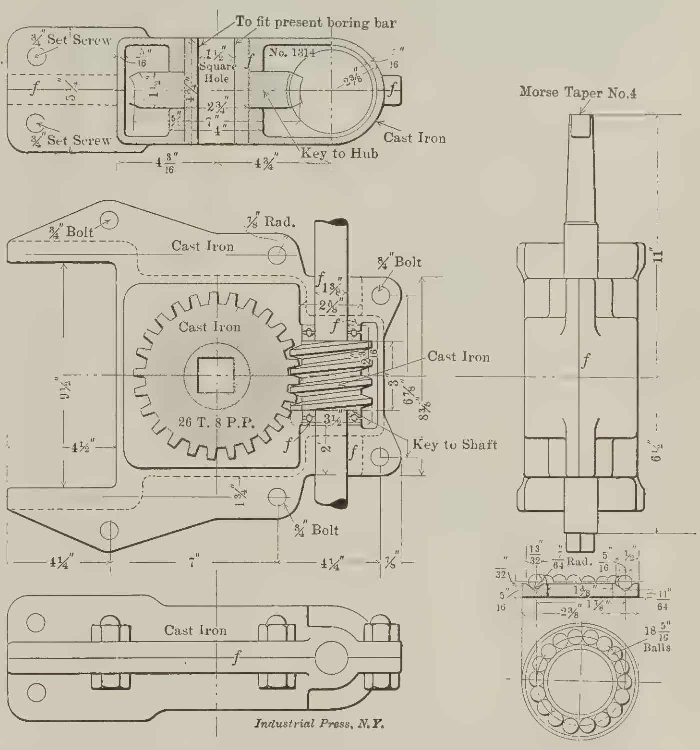
Apropos of the interest that is now being manifested in the United States in the manufacture of hollow axles and the method of producing them, a description of the method employed in the town of Montbar for making seamless tubes of circular section by punching them from square bars may be in order. The process is one of punching and die forging simultaneously. To get a tube of circular cross section, there is introduced into the mold a matrix, or die, *b* (Figs. 1 and 2), a square bar *a*, heated to cherry red, and of such dimensions that its diagonal equals the diameter of the cylindrical die, this having the object and result of exactly centering the bar which is to be expanded in the punching process. The cap *d* serves as a guide to the punch *C*, which latter has the diameter of the required bore of the tube. The calculation of the minimum quantity of metal necessary to give a tube of a given diameter is very simple.



Industrial Press, N. Y.

Thus, for a tube of one inch external diameter the punch must have a diameter of 0.603 inch for the metal just to fill the mold. This gives walls of 0.1985 with thickness. Where thicker walls are desired, for a given external diameter, the bar must evidently have its corners truncated or its sides rounding so that there will be less space between the bar and the mold, and the area of the punch must just equal this space. For a thinner tube, the sides of the bar may be concave. The punch does not go all the way through; the plug left at the bottom (see Figs. 3 and 4) must be drifted out or otherwise removed. For long tubes, two punches are employed, working in opposite directions as in Fig. 4.

The friction of the bar on the die is so great that the pressure of the punch on the bar is comparatively low. Figs. 5 to 8 show in principle but not in detail a machine for making tubes from an ingot *a* of any desired cross section. This is first stamped by the punch *C* in a die *b* closed by a sliding piece *S*, which can be used to close the bottom of the die, by means of a screw and handwheel. The preliminary punching having been effected, the piece *S* is withdrawn and the punch continues its course, driving the metal through a series of dies *X*, *l*, and *m*. Another way is to use a punch-shaped matrix of special form, shown in Figs. 7 and 8.



Industrial Press, N.Y.

Fig. 9. Portable Worm-driven Boring Machine.

The precision attained by this work is remarkable and the polish surprising. Shrapnel are made, with a thickness of wall of only 2 millimeters or 0.08 inch "scant." For very long tubes the short tubes resulting from the punching are drawn further in dies, without being allowed to get cold; they will stand three redrawings without reheating. When the wall is not more than 3½ millimeters or 0.14 inch thick, cold drawing on a mandrel suffices. It is not necessary to heat beyond a cherry red.

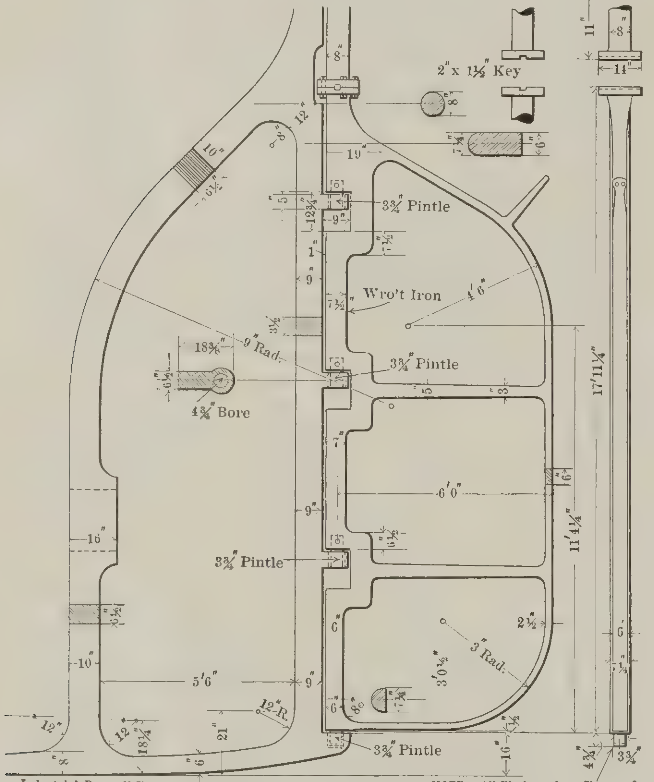
In the first experiments made in Germany, the hydraulic plungers had a diameter of 0.50 meter and a stroke of 1.10 meter or 20 inches diameter, 44 inches stroke, and with 90 atmospheres pressure, tubes were produced up to 60 millimeters or 2.364 inches diameter. At present the same press works at 180 tons pressure and produces tubes up to 240 millimeters or 9.46 inches diameter. In Dusseldorf there are several such presses at work, making gun barrels, etc., at one quick pressure. The limit of exactitude of diameter or of thickness is one-tenth of a millimeter or four thousandths of an inch.

In Dusseldorf there are made by this process boiler tubes, steam pipe, and all sorts of tubes, hollow axles, shells for cannon, cannon barrels, and reservoirs for compressed gases, up to a pressure of 250 atmospheres. The pressure exerted on the material in manufacture condenses it and increases its tensile strength; at 500 atmospheres the reservoirs tear but do not burst. The steel employed must have a tensile strength of from 41,000 pounds to 129,000 pounds per square inch and a coefficient of elongation of 15 to 30 per cent., both of which are increased by the process of manufacture.

Hanover, Germany. *Robert Grimshaw.*

PORTABLE WORM-DRIVEN BORING MACHINE.

The portable worm-driven boring machine shown in Fig. 9 is one that was made some two years ago by the Chicago Shipbuilding Company for boring the holes in stern-posts for rudder pintle bearings. It consists of a hollow cast-iron frame made in two parts and tightly inclosing a worm and cast-iron wormwheel of 26 teeth, having a square hole through the hub for the reception of the square boring bar or the head of a reamer. The frame is made with two opposing jaws having setscrews by which the device can be securely clamped to the rudder post or other work when in use. The worm is also made of cast iron, and its thrust is taken by ball bearings. The feature of ball bearings is an essential one as it not only greatly increases the mechanical efficiency, but reduces the causes for heating. The motive power is connected by means of a Morse No. 4 taper socket fitting the end of the worm shaft. Since the worm is single thread and the number of teeth in the wormwheel is 26, it is obvious that the leverage of the driving motor is greatly multiplied, making it possible to use a motor of comparatively weak torque to drive a heavy cut.



Industrial Press, N.Y.

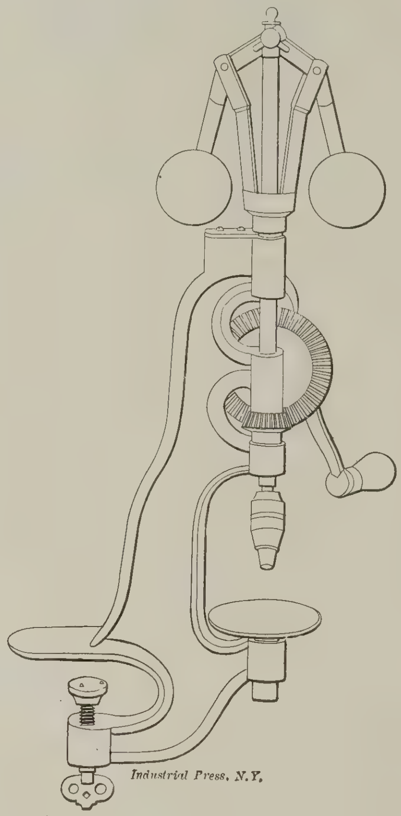
NOTE: All Pintles to have Sleeves of Seamless Brass Tubing 3¾" I. Dia. x ¼" thick. Bearings to have ¼" of Babbitt outside of Brass Sleeve.

Fig. 10. Stern Post and Rudder for which Portable Boring Machine was used.

The particular job for which the rig was designed, is shown in Fig. 10, being the working drawing of a stern-post and rudder for (four) vessels built by the company. The pintle holes in the stern-post are, in this case, 4¾ inches diameter and 5¼ inches deep while the pintles are only 3¾ inches diameter. The difference in diameter is made up by a brass sleeve ¼ inch thick with which each pintle is bushed, and a babbitt lining ¼ inch thick in the stern-post. The device is also used for boring the sockets for the pintles, in the rudders. It is, of course, applicable to a large range of other work in shipyards and general manufacturing plants where portable apparatus is used.

INGENIOUS SENSITIVE FEED DEVICE.

The feed device of the hand drilling machine shown in Fig. 11, is a somewhat ingenious English adaption of the steam engine centrifugal governor principle, the drill spindle being moved downward through a limited distance by the outward tendency of the balls, the same as the valve stem of a fly-ball governor. In effect it forms a sensitive feed device in which the pressure developed between the point of the drill and the work depends on the speed with which the machine is driven The balls also act as a flywheel to keep the motion steady. When the hole is drilled and the machine is stopped the drill automatically lifts out of the hole as the balls drop. One obvious disadvantage of this principle is that the pressure of the feed is in inverse ratio to the size of the drill, provided, of course, each size of drill is driven at its proper cutting speed. For small hand drilling machines, however, in which the range of drill sizes is narrow, this objection is of little weight.

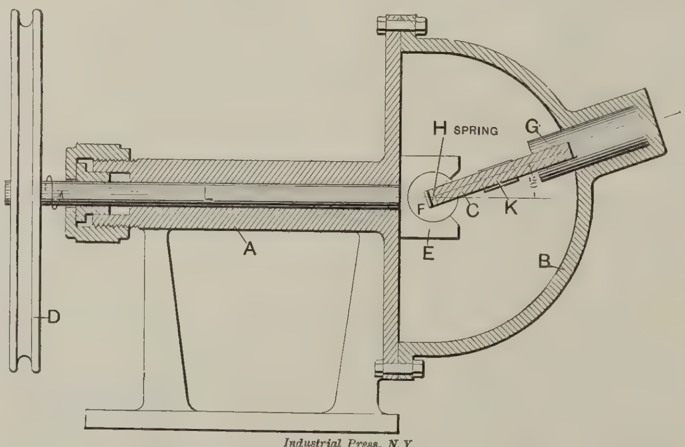


Industrial Press, N.Y.

Fig. 11. Sensitive Feed Device.

NOVEL PUMP.

The *Horseless Age* recently described a novel, so-called rotary pump, invented by A. Butin and manufactured by the well-known automobile concern, De Dion & Bouton of Puteaux, France, presumably for automobile purposes. Although referred to as a rotary pump, it is really an oscillating piston pump, the piston being semi-circular and oscillating in a hemispherical case. But, because of the peculiarity of construction which makes the plane of oscillation rotate with piston, it is possible to dispense with inlet and discharge valves. This is because one port acts constantly as a suction port and the same applies, of course, to the discharge port, as will be seen further on. The case *B*, Fig. 12, is secured to the end of the base casting *A* so as to form a water-tight joint. The shaft *L* transmits motion to the oscillating piston *C* through the medium of the crosshead *E*. This piece is bored throughout



Industrial Press, N.Y

Fig. 12. Novel Form of Rotary Pump.

its length to receive the small rocking cylinder *F*, and it is slotted along one side for the piston *C*. The cylinder *F* is grooved to receive the piston and a flat spring *H* is laid in the groove to keep the piston constantly against the inner wall of the case. A bearing for a short shaft *G* is bored in the case at an angle of 20 degrees with that of the shaft *L*. The inner end of the shaft *G* is slotted to receive the outer edge of the piston *C*. Two ports for suction and discharge are provided in the case, oppositely situated. One of the ports is shown at *K* directly beneath the piston *C*. In this position which is the maximum angle made with the driving shaft, both ports are closed by the edge of the piston.

The operation is as follows: the crosshead *E* and disk *C* divide the chamber formed by the casing *B* into two compartments, which are constantly varying in volume as the disk rotates, one decreasing in volume while the other increases. In the position the disk occupies in the drawing the upper compartment has a minimum volume and the lower a maximum volume, and as the disk continues to rotate, the compartment which is now the upper constantly increases in volume for a half a revolution of the disk. During the entire time this compartment is in communication with the suction port and water is drawn into this compartment equal to the increase in volume. When the compartment has reached its maximum volume it is closed to the suction port and opened to the discharge port by the motion of the disk. During the next half revolution of the disk the volume of the compartment considered constantly decreases, and, as the compartment is open to the discharge port during this half revolution, the water is forced out through this port.

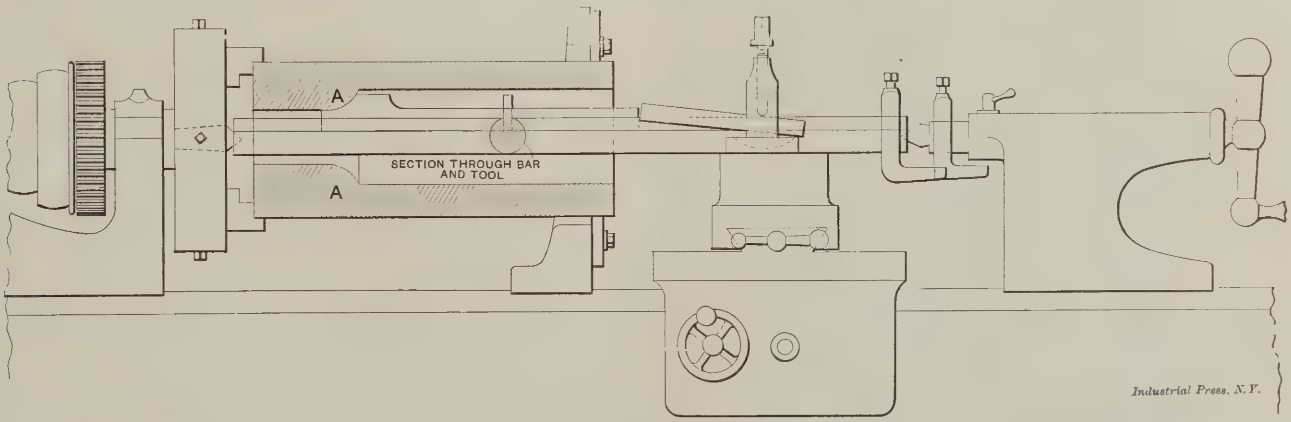
CONTRIBUTED NOTES AND SHOP KINKS.

BORING A ROUND SHOULDER.

G. Trueger sends us a description of a job that he recently had to do, and the method by which it was done may serve as a suggestion for accomplishing a number of jobs of a similar nature which are often encountered. On the inside of a cylinder it was necessary to round a shoulder that was about 12 inches deep, as shown at *A* in the sketch. It was found that this could not be done with an ordinary tool held in the toolpost, owing to the spring and chatter of the tool, so the arrangement illustrated was devised. The casting was first bored and reamed in the usual manner being held in a lathe chuck with the outer end supported in the center rest. A 1½-inch shaft was centered and a keyway, 5-16 inches wide and ⅝ inches deep, was cut its entire length. This shaft was placed on the lathe centers and prevented from turning by using two dogs on the tailstock end. The cutter consisted of a piece of tool steel of suitable width to just slide freely in the slot of the bar and shaped on the front end to the required radius of the corner. It was of sufficient length to extend out in front of the hole and was fed up to the work by a bar held in the toolpost. The results of this boring were very satisfactory, the corners being round and very smooth.



A CONVENIENT SCRATCH GAGE.

M. H. B. sends the accompanying sketch of a scratch gage which, he says, is better adapted to all kinds of work, around circles, close to corners and shoulders, etc., than any other that he has seen. The head is a steel block with a V-groove on one side and holes through it, both lengthwise and crosswise, to receive the bar which is secured in either position by the gib and screw as shown in the figures. By reversing the bar, as in Fig. 2, the tool is made capable of its closest work into corners, etc. The scratch point is a square, flat piece of hardened steel beveled off on the outside corners and fastened by a button head screw passing through its center and binding it to the end of the rod.

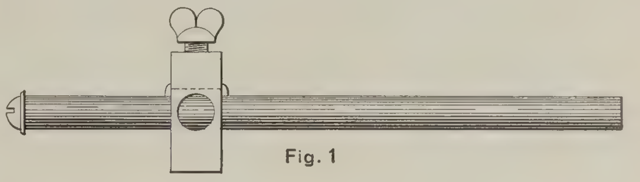


Fig. 1

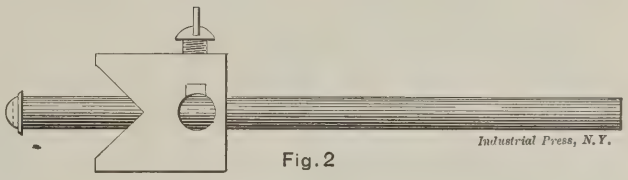

Fig. 2

SCRIBING A CENTER LINE ON WORK HELD IN THE INDEX CENTERS.

It is often required to scribe a center line on gear blanks, or similar work, held in the index head and the following method, contributed by G. G. P., will be found an easy and accurate way of doing this. Set the scriber on the surface gage as near as possible to the height of the center of the index head and scribe a short, fine line on the face of the blank. Then index half way around and make another line on the same side of the blank as the first and if the scriber was set central with the head the two lines will coincide, forming a single line. If the scriber was not set central the two lines will be a short distance apart and equi-distant above and below the center so that, by setting the scriber midway between these two lines and trying again as before, a center line can be quickly and accurately made. Now by indexing one-quarter of the way around this center line will be brought exactly on top and central so that the center line on the cutter can be set to it.

If the cutter has no center line, make two lines which shall be equi-distant each side of the center, by setting the scriber a little above or below the center of the head and making one line, then indexing around and making another line on the same side of the work as the first. Now if we index one-quarter of the way around it will bring these two lines on top and in central position so that the cutter can be set midway between them. When the scriber has once been set at the exact height of the center of the head it is well to scribe a line on some part of the head, which will aid in setting at any future time.

* * *

A writer in the *Electrical Review* gives a formula for a solder to be used as a protection to telephone apparatus, which melts at a temperature of 160 degrees. It consists of lead, 2 parts; tin, 4 parts; bismuth, 7 parts; and cadmium, 2 parts.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

1. A. S. C.—Is there any less expensive metal or alloy used as a substitute for platinum for electrical purposes?

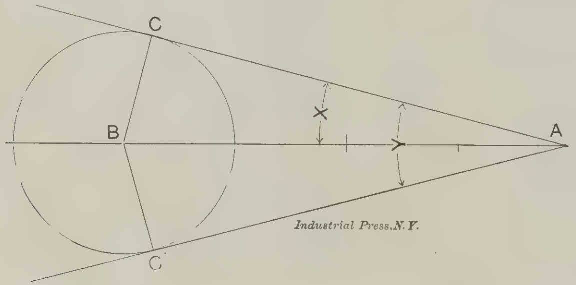
A.—There is a compound, imported from Europe, called "latinum" that is largely employed by telephone makers in the place of platinum for contact points. The price is $13.00 per ounce, and as it is but one-half as heavy as platinum, the actual cost is about one-third as great.

Another substitute for platinum, used for an entirely different purpose, is "platinite," which is an alloy of nickel and steel. It is possible to make this compound in such proportions that its coefficient of expansion is equal to that of platinum. For this reason it can be used in the place of platinum in the manufacture of electric lamps. It has been the custom to use short sections of platinum wire in incandescent lamps because, up to a few months ago, it was the only metal known having the same coefficient of expansion as glass. As stated, "platinite" is now used to some extent for the same purpose.

---

2. W. S. C.—Will you please tell me the angle of the sides of an Acme standard screw thread and explain how it can be laid out for making the thread cutting tool?

A.—The angle included by the sides of an Acme standard thread is 29 degrees. To lay out this angle, set the spacers to any convenient length and lay off four spaces on a straight line, as AB. At the end of the fourth space draw a circle having a radius equal to one of the spaces. From the starting point, A, draw two lines tangent to this circle and these lines will make each an angle of 14½ degrees with the line AB, or, in other words, will include an angle of 29 degrees. In proof of this: In the triangle ABC, $AB = 4 \times BC$. Therefore the sine of the angle $X = \frac{1}{4} = .25$, while the sine of 14½ degrees is .2504, showing that the angle is an extremely close approximation to 14½ degrees and the entire included angle Y is approximately 29 degrees.



---

3. H. W.—Will you please tell me how to cut a right hand thread on one end of a chuck screw and a left hand thread on the other end so that both ends will start evenly in their nuts? 2. In milling slots on a taper reamer please explain how it should be set so that the sides of the lands will be parallel?

Answered by J. T. Giddings, East Providence, R. I.

A.—Scribe a line on the blank parallel with the axis and mark each end on this line where it is desired that the screw should start. Having the lathe geared up for the required lead, take up the backlash as by pulling the belt by hand. Suppose, first, that we are cutting a V-thread, right hand. Set the tool or work so that the point of the tool crosses or intersects the starting point on the scribed line, then, after cutting the right hand thread, shift the tumbler gears for reversing the direction of feed, turn the screw end for end in the lathe and, feeding toward the tailstock, set the tool so that it will cross the starting point at the other end of the screw. If this is accurately done it is obvious that both threads will start on a line parallel with the axis as required. If a square threaded screw is to be cut the leading side of the tool may be set to cross the starting point for the right hand thread and the following side should cross the mark for the left hand thread. If the stock from which the screws are made is long enough so that both screws may be cut without reversing the piece end for end in the lathe, the leading side of the tool may in both cases cross the starting points, provided the right hand thread is the one nearest to the tailstock of the lathe.

The nuts may be threaded in a similar manner. When threading the left hand nut in the lathe it may be conveniently done as follows: Have the inside thread tool bent around in the opposite way to that in which it is usually used and cut the thread with the lathe spindle running backward, the lathe carriage feeding toward the headstock. Then for both right and left-hand nuts the leading side of the tool may cross the starting points, and for the left-hand nut the tool can be seen when starting its chip.

2. Having decided upon the number of flutes, find the length of chords for circles for both the large and small diameters of the taper. This may be conveniently done by reference to the data sheet furnished with the Engineering Edition of MACHINERY in Feb., 1903. which gives the length of chords, for a diameter of 1, for all divisions of a circle up to 100. Multiply the values given in the table by the diameters of the large and small ends respectively and thus obtain the length of chords at each end. From these results subtract the required width of land and this will give the width of the groove in the reamer at the large and small diameters respectively. Then cut the groove in the small end nearly to the required width for a short distance, lower the table and move the large diameter of the reamer under the cutter and make a groove of nearly the required width for a short distance on this end. Then set the bottom of both grooves at the same height, by moving the spiral head through an angle. (Assuming the reamer to be held in a chuck in the spiral head or in centers on a special fixture which goes in the spiral head for milling tapers.)

The required angle could be obtained either by surface gage, the adjustable dial for knee screw, or it may be calculated as follows: Obtain the difference in height of the grooves, the axis of the reamer being horizontal, by means of the dial, then divide the difference by the length of the taper. For example: Suppose the difference in height is ¼ inch in a length of 6 inches. $.25 \div 6 = .04166$, and this is the tangent of the angle required. By means of a table of natural tangents we can then find the angle which, in this case, is 2 degrees and 23 minutes or approximately 2 1-3 degrees, which is the amount that the spiral head should be raised.

---

4. E. E. E.—I should appreciate your best receipt for bluing steel. The steel has a nice finish and is not hardened. I want to get a nice blue for color.

A.—We do not know of any better way than the usual one of heating in sand or charcoal. The following description of the process is as clear as any that we have seen. It is taken from the instruction papers on shop practice issued by the International Correspondence Schools, Scranton, Pa., which contain many similar items of value to the shop man. "Polished work made of iron or steel may be given a beautiful blue color by heating it in hot sand, in wood ashes, or in pulverized charcoal. The substance in which the article is to be blued may be put into an iron kettle that is placed over a fire. The substance must be constantly stirred while it is being heated in order that the whole may be brought to an even temperature. The article or articles to be blued must be absolutely free from grease if an even color is desired. They may be placed in a wire basket or may be suspended by wires and then immersed in the heated substance until the desired color is obtained. A light blue color can be obtained by heating in sand or in wood ashes, but a dark blue color requires the article to be heated in pulverized charcoal. The brightness of the color depends largely on the finish—the higher the polish the more brilliant the color which will be obtained. The substance in which the heating is done should be just hot enough to char a dry pine stick. By this manner of bluing, a piece of work having thick and thin parts can be given an even color all over."

5. J. R. writes: Will you kindly inform me how to galvanize in an inexpensive way? I wish to galvanize round or flat wire and have it come out clean when finished.

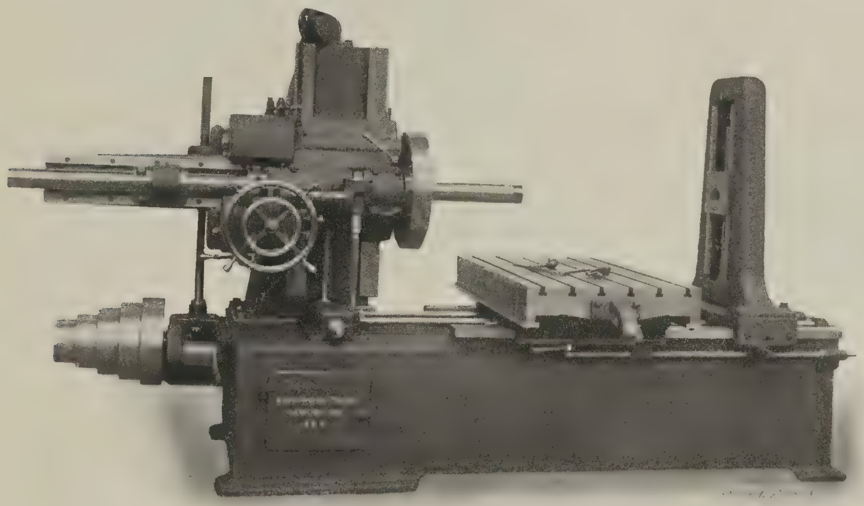
A.—We refer this to our readers for reply.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

HORIZONTAL BORING, DRILLING AND MILLING MACHINE.

The "precision" horizontal boring machine which has just been brought out by the Lucas Machine Tool Co., Cleveland, Ohio, is designed with a special view to accuracy and permanence of alignment, the lack of which has been the principal objection to the knee type of machine. These points are attained by making the spindle adjustable vertically instead of the table, thus moving the constant instead of the variable load. The advantages of this construction will be apparent. This construction permits of the use of a deep box bed carrying a table at a fixed height, this bed being much better able to resist the disturbing forces due to the cut and the weight of the work than the overhanging knee supported on screws.



Horizontal Boring, Drilling and Milling Machine.

To further insure against flexure, the bed is designed to rest on three points. Special attention has also been paid in the design, to arrange so that all operations can be carried on within range of the operator. The head is counterbalanced and is provided with a power elevating device as well as hand adjustment. The spindle is driven by an internal gear of large diameter and is powerfully back-geared. It is provided with both quick and slow hand motions which can be obtained instantly without throwing in any clutches or friction devices. The spindle may be fed 48 inches by two settings of 24 inches each.

The outer support for the boring bar is geared to raise or lower with the spindle, connection being made by a rod under the saddle, and an adjustment being provided whereby it can be corrected from time to time should it be required. The back rest is provided with means whereby it can be conveniently adjusted to any point along the bed and is made to be readily removed, when not required, without disturbing any of the working parts.

The gear feed box is provided on the head and is equipped with a reversing mechanism. The motion from this feed box can be readily converted to feed the spindle longitudinally, the table transversely, and the head vertically, the latter two feeds being milling feeds. The table is provided with automatic cross feed of 34 inches. The application of the cross feed to the table and the vertical feed to the head adapts this machine to a large variety of milling work. The elevating screw for the head and the table cross-feed screw have dials reading to thousandths.

The table is 30 x 48 inches, allowing a maximum distance from its top to the center of the bar of 26 inches and a distance from the spindle to the backrest of 5 feet, 6 inches. The machine is belt driven by means of a 3½-inch belt running on a five-step cone.

THE "HAMILTON" ENGINE LATHE WITH UNIVERSAL SCREW-CUTTING ARRANGEMENT.

The Hamilton Machine Tool Co., Hamilton, Ohio, have recently made extensive improvements in their engine lathes and are now placing on the market a new line of these machines in sizes from 14 to 28 inch swing and any length of bed. The headstock and tailstock, as well as the carriage and apron, have all received careful attention and have been redesigned and constructed to meet the requirements of the most advanced shop practice. The cross feed screws have micrometer adjustment and the tailstock spindle is graduated in inches for convenience in drilling. The apron mechanism is so arranged that it is impossible for the leadscrew and feed rod to be engaged at the same time, thus preventing breakages from this source. The longitudinal feed is powerfully friction driven, and all feeds are reversible from the apron. The leadscrew is used only for screw cutting, the turning feed being driven from a separate rod, and is not, therefore, liable to excessive wear.

The leading new feature of these lathes is the universal screw-cutting and feeding arrangement—an improved system of mounted gearing—giving a full range of screw pitches or feeds without removing a single gear, enabling the operator to change from one feed or thread to another almost instantly. This mechanism is illustrated in detail in Fig. 2 and is shown as applied to the 26-inch lathe in the half-tone, Fig. 1. It is not an attachment in the strict sense of the word but is in reality an integral part of the lathe. By its use any one of 48 different feeds or screw pitches are made available in but a few seconds.

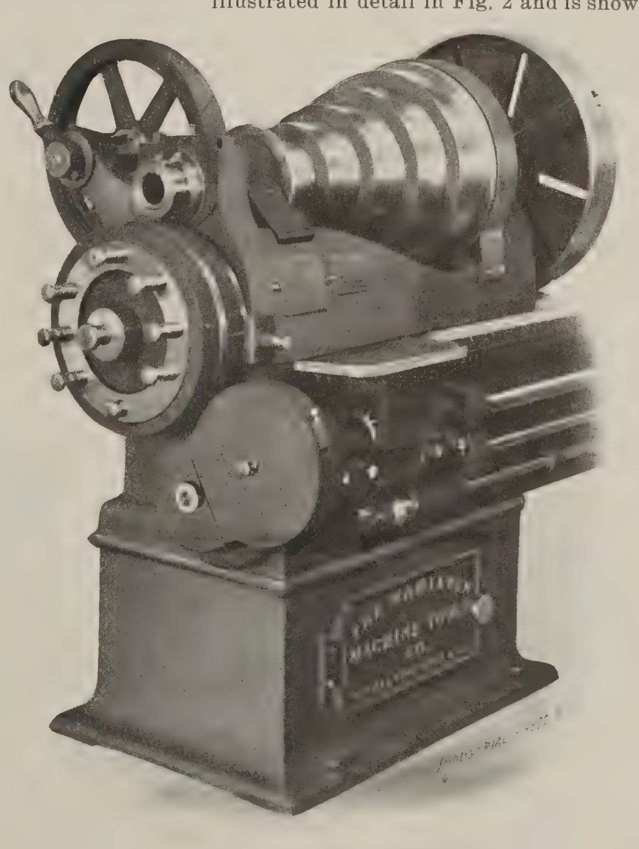


Fig. 1. Screw-cutting Arrangement of "Hamilton" Lathes.

As will be seen in the line drawing, the spindle gear *B* transmits the motion through the compounding gears *C* (of which only two are engaged at the same time), through the center pin *E*, to the driving gears *F*; these drive the lower clutch change gear *G* and connecting clutch gear *L*, which transmit the motion through the intermediate gear *M* to the leadscrew gear *P*. The circular gear box *J* may be rotated so as to bring any of the eight mounted clutch change gears *G* in mesh with the intermediate gear *M*. The reversing mechanism *R* is controlled from the front of the lathe apron by means of the reversing rod *V*. *S* is the leadscrew and *T* is the feed rod. The mounted clutch gears *G* are entirely independent of each other and are arranged so that only the one in use can be engaged. No adjustments are necessary in changing from one thread or feed to another.

leadscrew, 16 additional threads, from 2 to 7 may be obtained, and by using the 20-tooth slip gear, still another 16 threads from ½ to 1¾ are obtained, thus affording a total range of 48 threads or feeds. On this size of lathe the ratio between the feeds and threads is 8 to 1, and on the other sizes it is in proportion. To secure any desired feed it is only necessary to reduce it to the corresponding thread, by dividing by the ratio as given in the index, and set up the machine accordingly. These lathes are designated by the manufacturers as their style "A," in order to distinguish them from the regular pattern or style "B" lathes, having the ordinary loose change gears for screw cutting.

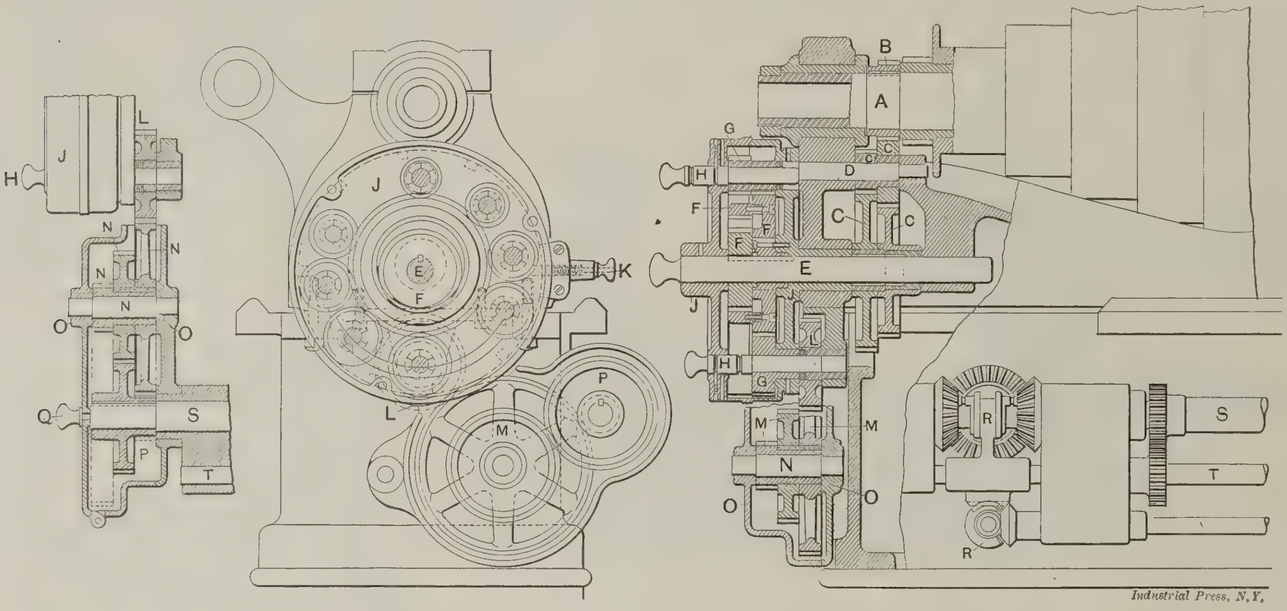

Fig. 2. Detail of Screw-cutting Arrangement used on "Hamilton," Style "A" Lathes.

Fig. 3 shows a *facsimile* of the index plate used on this, the 26-inch lathe. The words "in" and "out" in the column under "center pin" refer to the position of the sliding shaft *E*, in the center of the circular gear box. Under "screw" is given the required leadscrew change gear; three of these gears are provided, and they can be instantly slipped on or off as required. The "box numbers" are stamped on the circumference of the circular gear box and designate the different mounted clutch change gears *G*; the box should be rotated until the "box number" called for is opposite the pointer, when it is instantly secured in position by a spring locking pin; this brings the required "box" gear into mesh with the connecting clutch gear *L*, to which it is connected by simply pushing in the handle or knob *H* with which each "box" gear is provided. The knob on the gear in mesh is always at the lowest point of the circular gear box, and the arrangement is such that it is impossible to push in the wrong knob, thus preventing any error from this source. Referring to the index plate, it will be noted that if we employ the 80-tooth gear on the leadscrew, 16 different threads from 8 to 28 per inch may be cut without removing a single gear, the changes being made while the lathe is in motion, by simply rotating the circular box and setting the center pin as called for in the index. By placing the 50-tooth slip gear on the

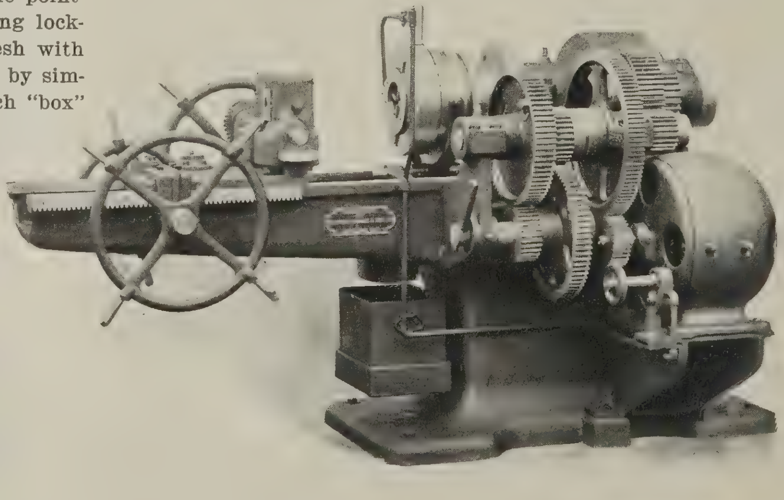
A NEW ELECTRICALLY-OPERATED BOLT CUTTER.

The Reliance Machine and Tool Co., Cleveland, Ohio, have just brought out a new bolt cutting machine which is a decided departure from what has hitherto been their standard type of machine. This is the 3-inch bolt cutter that is shown in the accompanying photograph, and it is equipped with a Crocker-Wheeler motor and controller. A new and distinctive feature is found in the method of driving the spindle or shaft, the driving gear of which is located centrally between the bearings of the spindle instead of being at the extreme end thereof. A system of compound gearing makes it possible to obtain greater power without having an unduly large driving gear. This method of driving the head spindle eliminates all torsion and produces a smoother and more rapid cut without chatter.



Rear View of Electrically-driven Bolt Cutter.

The oil and chips which work through the hollow spindle are no longer a cause of trouble by falling upon the belt and pulley. The working parts are all easily accessible and the floor space has been reduced by the compact design of the machine. In the belt-driven machines, a four-step cone pulley replaces the gear that is shown in the cut meshing with the motor pinion.

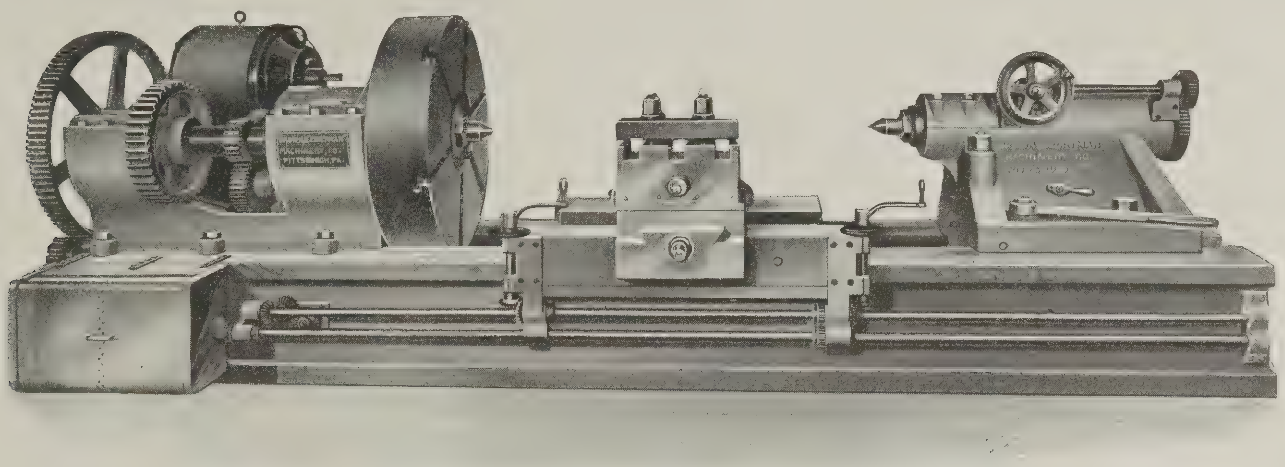
A NEW 42-INCH FORGE LATHE.

The Brown & Zortman Machinery Co., Pittsburg, Pa., have just placed on the market the new 42-inch forge lathe that is illustrated in the accompanying half-tone. This lathe is arranged to be driven by a 25-horse power variable speed motor or by a 4-inch belt running on a five-step cone pulley. Five speeds are thus available and by changing a gear on the end of the motor or cone shaft, five more speeds are obtained. The gearing is in the ratio of 1 to 84, and terminates in a broad internal gear in the faceplate by which the spindle is driven. A large and a small cathead are provided which are fastened to the faceplate and used in lieu of dogs for driving the work.

The tailstock is clamped to the bed by six binding bolts and is also provided with a latch which drops into a slot in the bed and thus keeps the tailstock from sliding back. A hand wheel and gear arrangement is provided to facilitate the movement of the tailspindle in and out of the tailstock.

The carriage has no hand movement along the bed but has three feeds, available by lever at the apron. These feeds can be changed from one to the other instantly while the machine is in operation. The feeds are .189, .354, .664 inch, and then by changing the gears .134, .251 and .469 inch per revolution of the spindle. Quick movement is furnished to the carriage when it is to be moved a considerable distance, and at other times the coarse feed is available. The feed is driven by gears in the headstock which in turn drive a screw, inside of the bed, running in a long, solid, bronze nut which is fastened to the carriage. This screw is supported in bearings planed into every cross tie in the bed and the thrust in either direction is taken upon large ball bearings. The carriage is furnished with an upper block that has three grooves for securing tools, 2½ × 3 inches, and which allows of a hand movement of the tool longitudinally. When the variable speed motor is used the carriage is provided with a controller lever by which any speed forward or backward can be obtained at once.

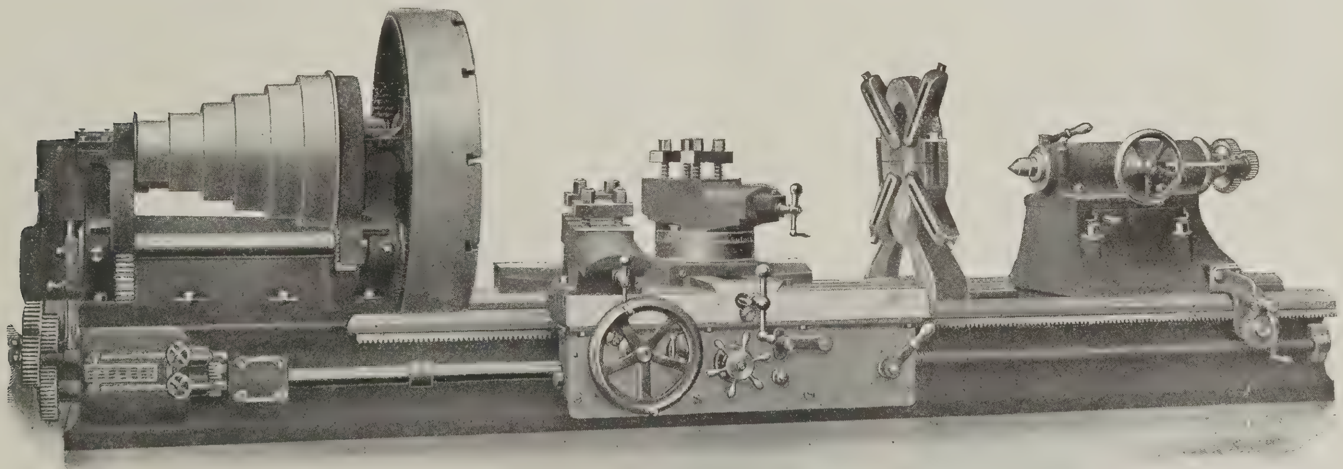
The lathe, when mounted upon a 20-foot bed, has a capacity of 10 feet between centers and weighs about 38,000 pounds. Any length of bed may be furnished, each additional 2 feet of length adding about 1,450 pounds to the total weight.



Brown & Zortman 42-inch Forge Lathe.

SIXTY-INCH "AMERICAN" SCREW-CUTTING LATHE.

The American Tool Works Co., Cincinnati, O., have just brought out the new 60-inch screw-cutting lathe illustrated in the accompanying half-tone. This tool is equipped with improved rapid change gear mechanism which greatly increases its capabilities as a rapid handler of heavy work. This mechanism is located on the head end of the bed and consists of a clutch device, of new design, through which seven changes for feeding and screw cutting are rapidly available without the removal of a gear. Then, by changing a single gear on the stud, seven additional changes are provided, the quadrant being so designed as to obviate the readjusting of the entire train of gears to each new change gear. Nine change gears are ordinarily furnished, thus providing a total of 63 changes of threads and feeds. Each of these changes is indicated on the index plate located on the front of the gear box. By the simple movement of a hand wheel, a pointer is brought directly above the desired thread or feed. This will indicate the number of the change gear that is to be placed on the stud and also automatically arrange the gears in the gear box for cutting any thread or feed desired. The range of threads is from one in eight inches to 16 per inch.



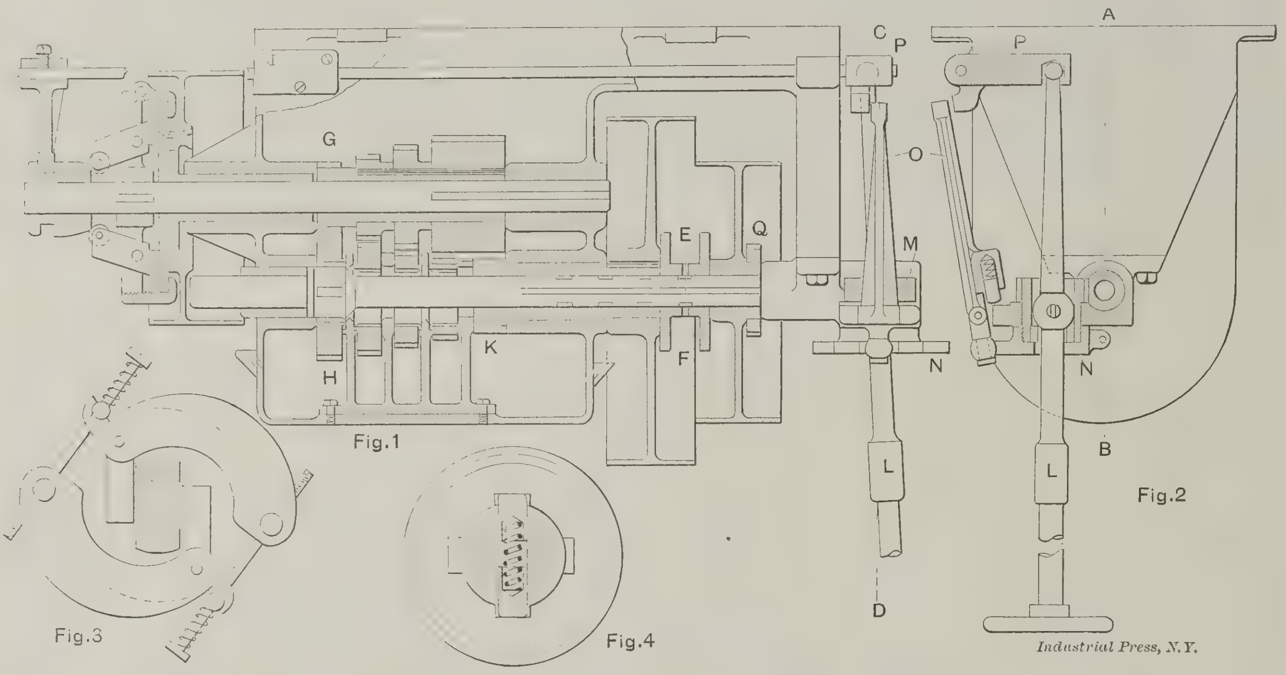
American Tool Works Co.'s 60-inch Screw-cutting Lathe.

The lathe can be arranged for left-hand screw cutting by means of a tumbler reverse plate which is mounted on the end of the headstock, so that it is not necessary to interpose an idler gear as formerly and no gears are ever disarranged by this method.

The bed is of drop V pattern, of such construction as to secure the greatest rigidity. The headstock is massive and the driving cone is mounted on a spindle of its own, entirely independent of the main spindle, and is powerfully geared. The carriage is very heavy, especially in the bridge, due to the drop V bed, and has double apron extending its full length. The compound rest is fitted with taper gibs and provided with power cross and angular feeds.

THE "SCHELLENBACH" VARIABLE SPEED PLANER COUNTERSHAFT.

While much has recently been accomplished in the development of the variable speed countershaft for use with machine tools in general, a countershaft for the exclusive use on planers, combining with variable speed drives a constant return and provision for elevating the cross rail, has, up to the present we believe, been lacking. The demand for such a countershaft has been met by the "Schellenbach" variable speed countershaft, illustrated by the accompanying drawings and half-tone photograph, which is the product of the National Machine Tool Co., Cincinnati, Ohio. This countershaft provides for four cutting speeds, ranging from 20 to 50 feet per minute and a constant return speed of 70 feet per minute.



Industrial Press, N.Y.

Figs. 1 to 4. Details of "Schellenbach" Variable Speed Countershaft.

Referring to the illustrations, the pulley shown at the left takes its power from the main line as in the ordinary countershaft. It is operated with the usual sliding bush and fork, engaged and disengaged by the shipper rod which passes entirely across the main frame and connects with the lever, at the lower end of which will be seen the handwheel by which it is moved back and forth. The method for obtaining the changes of speed will be understood by reference to the drawings, Figs. 1 to 4. The upper cone of gears is made of forged steel and is fitted as a unit for convenience in assembling. The largest gear of the upper cone meshes with a sleeve pinion, *K*, which passes through and takes its bearing in the casing. It has keyed to it the pulley which drives the return stroke of the planer platen. Thus it will be seen that the return speed is always constant and is not influenced by the four gears, with large bore, which rest in receptacles normally out of mesh with their mates above. These gears are keyseated, as is shown in Fig. 4, which is a section on the line *G H*, and receive the flat tool steel keys which are fitted into a slot cut through the enlargement of the lower shaft. These keys oppose each other with the aid of springs which are side by side. The casting, which supports the lower cone of gears, by their hubs which rest in counterbored receptacles, is bored to fit the enlargement of the lower shaft and serves to depress the keys as the enlarged portion containing them passes through. The lower shaft is splined to receive the smaller pulley which controls the cutting speeds.

Cut into the shaft are notches spaced to correspond with the gears which make the changes. The two pulleys, as shown in Fig. 1, are separated by a flange casting the inside of which on the line *E F*. The casting referred to is also splined to turn with the lower shaft and contains latches which mesh into the notches above referred to. Fig. 3, which is a section on *E F*, shows this centrifugal lock, which is a simple and sure means of making it impossible to mesh the gears when running at a high speed. The lever *L* is ball-seated into the gear *M*, and serves the purpose of revolving this gear as well as operating the friction pulley as before mentioned. The gear *M* has a cam *N* attached to it and this cam operates the lever *O* and forms a locking device which makes it necessary to release the friction pulley before a change of speed can be made, and if such change is only partly made the friction pulley cannot be connected. A glance at Figs. 1 and 2 will readily show how this is accomplished by means of the parts *N*, *O* and *P*.

The pulley *R*, in Fig. 5, is used for elevating the rail and is driven through a short shaft upon which is a gear that meshes with the gear *Q*, Fig. 1. This elevating pulley shaft may be extended to suit conditions and a regular hanger used to support it. The device throughout is provided with thorough facilities for oiling and a drip pan is cast on either end of the gear casing under the shafts to catch the oil and return it inside of the casing. The gears may run in an oil bath if preferred.

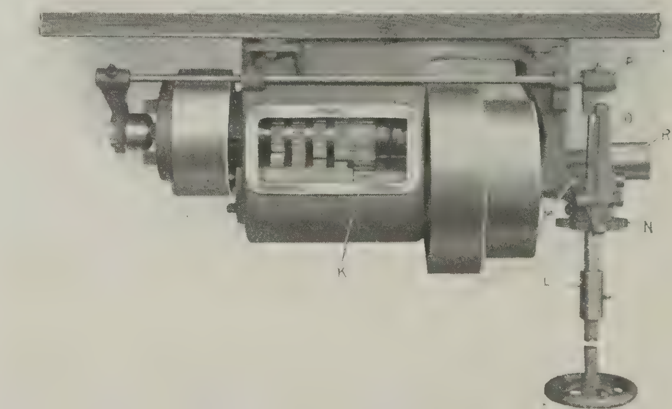


Fig. 5. "Schellenbach" Variable Speed Planer Countershaft.

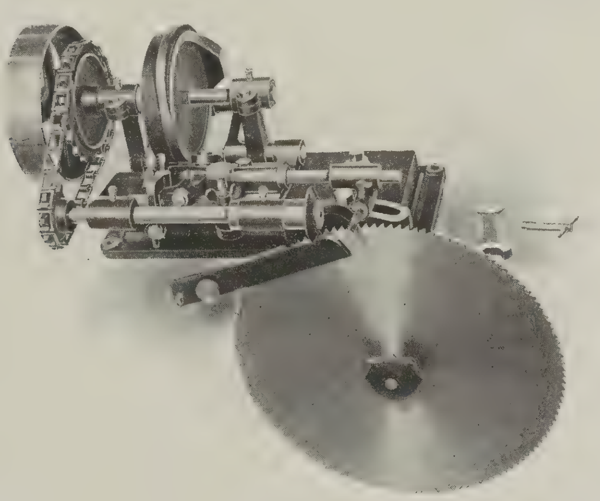
When desired the friction driving pulley may be omitted and a coupling provided to receive a motor shaft, thus making a simple and direct method for using a constant speed motor.

AUTOMATIC SAW FILING MACHINE.

The accompanying cut illustrates a machine that is designed for truing up and filing circular, band and hand saws by power and thus obviating the tedious hand work ordinarily required for this purpose. The machine uses a rotary file about 2¼ inches in diameter, having a cross section suitable for the work. Two forms of file are usually required, the one for rip saws having an angle of 50 degrees, and that for cut-off saws having an angle of 60 degrees. The file is carried by a rocker arm, and a spacing gage, provided with hardened steel finger and adapted to drop into the tooth space, is also carried by a slide on the rocker arm. A cam motion is arranged to automatically lift the file clear of the teeth, move the gage forward, drop it into a tooth space, bring back the file to normal position and then drop it into the next tooth space. This space gage is normally held firmly into the tooth space by spring pressure and holds the saw against any longitudinal movement, while the file may be readily adjusted toward one side or the other of the tooth space if the latter is uneven. The guide clamp is provided to hold the saw blade and at the same time permit it to be readily slipped through.



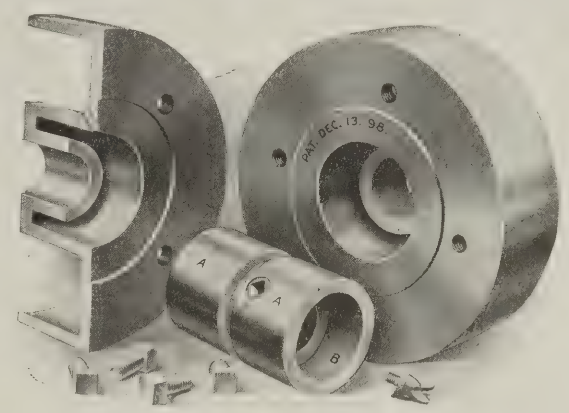
Automatic Saw Filing Machine.

To control the depth of cut of file an adjustable screw is provided in the rocker arm, allowing the latter to drop only to a predetermined distance and hence allowing the file to cut only to the desired depth. These two features, the spacing gage and the depth gage, make it possible to true up unevenly-filed or toothed saws, and once a saw is true it can be filed without further attention. Means are provided for setting the saw at any unusual angle of hook and at any bevel of teeth up to 30 degrees. Adjustment is also provided for varying the position of the file with reference to the spacing gage while the machine is in operation. This machine is adapted, by use of an interchangeable saw-carrier, for filing band saws and for hand saws. It has a capacity for filing circular saws up to 22 inches in diameter and ½-inch teeth, band saws up to ½-inch teeth and 1½-inch width of face. It will also file as large as 1-inch teeth on the points, when the gullet can be filed out at a separate operation. This machine is the product of the Rotary File & Machine Co., Brooklyn, N. Y.

THE "NELSON" LOOSE PULLEY.

Of all appliances used in connection with the running parts of machinery, none have been the source of greater annoyances than the loose pulley. On this account numerous devices have been produced to insure proper lubrication and prevent the pulley from sticking to the shaft. Most of these consist of a network of oil grooves, a multitude of drilled holes or the use of a bushing of wood, babbitt or other anti-friction material. The trouble with a great many of these devices is the lack of sufficient bearing surface for the hub of the pulley. While capillary attraction between the shaft and the sides of the bore of the pulley would naturally tend to preserve a thin film of oil entirely around the shaft, the load on the pulley produces so great a pressure per square inch of bearing surface that the film of oil is forced out and metal-to-metal contact ensues and causes trouble.

A loose pulley that is somewhat out of the ordinary construction and in which the above trouble has been obviated is the "Nelson" loose pulley, which is illustrated herewith. In this case the pulley does not run directly on the shaft but upon a sleeve or bushing, *A*, which is firmly clamped to the shaft by headless setscrews. This arrangement furnishes a large bearing surface for the hub of the pulley and thus reduces the pressure per square inch to such an extent that the film of oil continually surrounds the sleeve and permits the pulley to run upon the oil without any actual contact with the sleeve. Oil is held in an oil chamber formed in the bushing and from this reservoir it is thrown by the action of centrifugal force onto the bearing surface. The great advantage of this method of lubrication is, that as the speed of the pulley increases, and more lubricant is demanded, the centrifugal force likewise increases, thus adequately suiting the supply to the demand.

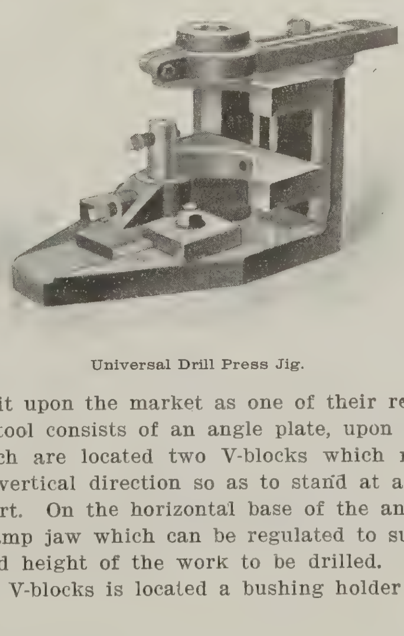


Details of the "Nelson" Loose Pulley.

The pulley is made in halves which fit over the bushing and their hubs, form a guard that is proof against dirt or dust from without and the escape of oil from within. A continual supply of clean oil is thus insured, and when once the reservoir has been filled the pulley may be run indefinitely without attention. To replenish the oil supply it is necessary only to remove a small thumb screw and fill the oil chamber from an oil can. These pulleys have been thoroughly tested for a period extending over five years and, having proved satisfactory, are now being placed upon the market by the Wilmarth & Morman Co., Grand Rapids, Mich.

UNIVERSAL DRILL PRESS JIG.

In view of the difficulty experienced in holding in an ordinary vise, cylindrical pieces such as pulleys, journals, cones, cams, etc., the Bayldon Machine & Tool Co., Jersey City, N. J., designed and constructed the drilling attachment here illustrated and so successful has it proved that they have now placed it upon the market as one of their regular products. This tool consists of an angle plate, upon the vertical side of which are located two V-blocks which may be adjusted in a vertical direction so as to stand at any required distance apart. On the horizontal base of the angle plate is a sliding clamp jaw which can be regulated to suit both the diameter and height of the work to be drilled.



Universal Drill Press Jig.

Above the V-blocks is located a bushing holder which may be moved in and out to accommodate varying diameters of work but always remains in line with the center of the V-blocks. This holder is for carrying steel bushings that act as a guide for the cutting tool, which may be a rose reamer, an ordinary twist drill, a four-lipped drill or a boring bar. Bushings can be furnished for any diameter of drill or bar up to 3½ inches in diameter. The capacity of this tool ranges from pieces 7 inches in diameter and 6½ in length, down to those 1½ in diameter and 1 inch long.

A NEW MILLING MACHINE FOR HEAVY WORK.

The Henry Hess Machine Co., Philadelphia, Pa., have just brought out a new type of slab milling machine that is especially adapted to all kinds of heavy work where it is desired to produce flat surfaces quickly and cheaply. This machine is capable of taking a cut equal to the greatest width between the housings, 30 inches, and carries cutters up to 15 inches in diameter. The platen, as ordinarily furnished, has a working capacity of 8 feet, and may be increased, if necessary, by increments of 2 feet. The cutter is driven by a worm of steep pitch which is, in turn, driven from a two-speed overhead countershaft with cone pulley. The cutter itself terminates at the driving end in a large flange, which is bolted to a corresponding flange upon the driving arbor. The drive is therefore from a diameter equal to or larger than the diameter of the cutter employed.

The outer end of the cutter is supported in a bracket mounted upon the same cross rail that carries the driving head, and when two pieces are being milled side by side an intermediate support is introduced between the two pieces of work. The cross rail may be raised or lowered by power and has micrometer adjustment for depth of cut. Provision is made for driving the spindle at eight speeds, from a minimum of 6 revolutions per minute to a maximum of 36. The platen has both hand and power feed, and a quick return by power. The rate of feed is controlled by a small hand-wheel, which is placed near the operator, and may be varied from .5 inch to 30 inches per minute, twelve changes being provided for. The net weight of this machine is about 52,000 pounds.

NEW TRADE LITERATURE.

The Ray Automatic Machine Co., Cleveland, O. Circulars treating of the "Vulcan" steel annealing box and "Vulcan" putty for annealing, with directions for using. Also folder treating of the manufacture of automobile parts such as hoods, fenders, radiators, tanks, mufflers, etc., with illustrations of same.

The Webster & Perks Tool Co., Springfield, O. Circular of grinding and polishing machinery. The 1-inch bench grinder, the 1¼-inch self-oiling bench grinder, the improved No. 1 and No. 2 self-oiling, buffing and polishing lathes, are shown. Also a 1-inch grinder on a pedestal.

Wm. Pilton, Hamilton, O. Descriptive circular of parallel ruler attachments, which may be attached to any form of drawing boards or tables, for office, school or home use. Also circulars describing an instantly adjusted drawing table, and a draftsman's new handy reference table.

Hammacher, Schlemmer & Co., New York. Catalogues Nos. 185, 187, 188 and 190. These are supplementary lists of the various classes of goods catalogued. The first of these treats of hand screws, bench screws, clamps, etc.; the second of wood carvers' tools and accessories; the third, of miter boxes, trimmers, etc.; and the last, of files and rasps.

The Ingersoll-Sergeant Drill Co., 26 Cortlandt Street, New York. New drill catalogue No. 43, the first of a series of catalogues which will illustrate and describe in very complete form all classes of Ingersoll-Sergeant machinery. The cuts and descriptive matter are nearly all new and the catalogue itself is an unusually handsome product.

The Loop-Lock Machine Co., Waltham, Mass. Price lists of the No. 2 bench and No. 3 special milling machines and attachments, and of No. 3 bench lathes and attachments. Also illustrated circulars of No. 2 bench milling machine, No. 3 automatic internal grinding machine and of No. 3 bench lathe, new model, and attachments for same.

The Etna Manufacturing Co., No. 253 Broadway, New York. Special illustrated circular describing their new clock spring-tempered back, hack saw blades. They state that the blades are manufactured by their new process, whereby the tooth edge only is left hard, while the back is drawn to a clock spring temper, permitting the saw to bend without kinking or breaking readily, and thereby giving the user full efficiency until the teeth are worn out.

The Peerless Rubber Mfg. Co., 16 Warren Street, New York. Catalogue No. 58 of "Peerless" spiral piston and valve rod packings. "Rainbow" packing is described, which is especially adapted for very high pressure, being vulcanized in a higher degree of heat than it ever comes in contact with in a joint. The "Eclipse" sectional rainbow gasket is also treated, as well as the different styles of packings for various purposes, and seamless rubber belting, steam hose, etc. This catalogue will be sent to any one upon application.

The Berlin Construction Co., Berlin, Conn. Catalogue 1903 giving 40 illustrations of steel-frame construction work done by this company. This includes machine rooms, factories, foundries, bridges, etc., and the cuts give an excellent idea of the great variety and good quality of the work done. A partial list of the company's customers also appears. The company have a complete modern structural steel plant, and their shops are operated throughout by electricity and compressed air. The branch offices are at New York, Boston, and Newark.

The North Penn Iron Co., North Penn Junction, Philadelphia, Pa. Bulletin "W" No. 705, treating of the steam locomotive cranes manufactured by this company. These cranes are useful in yards, as any irregular area can be covered with them, and they can be used as a locomotive for moving freight cars for transporting heavy work from one building to another. These steam cranes are especially useful in plants where electric power is not available. An illustration shows a 10-ton crane, with half cab or roof. Full cab can be furnished if desired. The cranes are made for standard track gage of 4 feet 8½ inches.

Pratt & Whitney Co., Hartford, Conn. Standard 6 x 9 booklet just issued of the company's bench lathe, 10-inch toolmakers' lathe, 13-inch engine lathe, and 14-inch gibbed carriage engine lathe. The book contains 67 pages and is fully illustrated with excellent half-tone plates. The first thirty-seven pages are taken up with a description of the 7 x 32-inch bench lathe, described in detail and illustrations are given of more than thirty of the various attachments which may be furnished with the lathe, giving an adequate idea of the great diversity of work for which this machine is adapted. The 10-inch toolmakers' lathe is also carefully described, and illustrations are given showing the application of the collets and split step chucks to the spindle. Two views of the 14-inch lathe show the standard lathe, and the lathe with pan bed. A number of important attachments for this lathe are also shown. These include the relieving attachment for relieving straight, taper and spiral taps and milling cutters, draw-back collets, step chucks and closers and expanding arbors. While these lathes perhaps are not applicable to rough shop use, anyone who cares for good machines or who has to do accurate work will appreciate them.

MANUFACTURERS' NOTES.

The foundry and machine business formerly conducted by the Robert Poole & Son Co. has been merged into the Poole Engineering & Machine Co., and will be continued under this corporate name.

The Ray Automatic Machine Co., formerly at Cleveland, O., have removed to corner Front Street and First Avenue, Berea, O., where they have increased facilities for manufacturing their line of automatic nut machines, cold punched nuts, etc. They state that the rates of freight from Berea are the same as from Cleveland.

E. Horton & Son Co., Windsor Locks, Conn., have recently completed an addition to their works which triples their capacity. They have installed a number of special machines and discarded all the old tools, bringing their plant up to date in every respect. The Horton Co. build a complete line of chucks, including every kind made.

The Springfield Tap & Die Co., Springfield, Vermont, have incorporated a number of features in their product which adds to its value. Their patent relief ensures excellent results, and their improved method for threading does away with many of the inaccuracies which taps have heretofore been subject to. Their sizes are guaranteed to run uniform, which is a feature that every mechanic will appreciate.

The Brown & Zortman Machinery Co., Pittsburg, Pa., have opened an office and store room at the Bourse, Philadelphia, under the charge of R. G. English, where they will be glad to see all their Eastern friends. They will have constantly on the floor both Colburn boring and turning mills and Universal saw tables, as well as a full line of modern machine tools of standard manufacture.

The D. E. Whiton Machine Co., New London, Conn., have just completed a new foundry, 60 x 100, which will add greatly to their facilities. The building adjoins their works and is high and well lighted, and will be equipped with all the modern foundry appliances. They have also built a four-story L-shaped addition to their works, 80 x 85, extending along the railroad track and giving them unexcelled facilities for receiving and shipping goods.

The Abrasive Material Co., of Philadelphia, have made two more additions to their already extensive plant—another new kiln, and a recent installation of new machinery for making their pressed emery wheels. The present abrasive emery wheel is made by the vitrified process, and by reason of its fast, free cut has given great satisfaction in all classes of grinding. The makers, however, realize the need of special wheels for special purposes, and have decided to place on the market a pressed wheel that will, for its special work, equal those made by the vitrified process.

The Ingersoll-Sergeant Drill Co., 26 Cortlandt Street, New York, who have placed a line of pneumatic tools on the market, report immediate recognition of the excellence of the Haeseler "Axial Valve" hammers, upon comparative tests with other tools. Among the latest purchases of these tools are: Niles-Bement-Pond Co., Ramapo Iron Works, MacPherson Switch & Frog Co., Creswell & Waters Co., Warren Foundry and Machine Works, Chicago, Rock Island & Pacific R. R.; Brown Hoisting and Conveying Machine Co., Howard Iron Works, International Boiler Works Co.

Roth Bros. & Co., manufacturers of dynamos and motors, have recently moved to 27-29 So. Clinton Street, Chicago, Ill., where they have more than doubled their floor space and have added machinery for the more efficient handling of their work. They have fitted all their machines with individual motor drive. Some have the motor directly connected while others have single belts—the lathes for instance, which are driven by their electric countershafts, or motors with a back-geared shaft upon which is mounted the cone pulley. The controller, of the reversible style, is also hung from the ceiling and operated by a rod connecting with a splined shaft on the lathe, which rod is in turn operated by a handle which travels with the lathe carriage. Coarse changes of speed are obtained by shifting the belt, and intermediate speeds, through the controller.

The Standard Welding Co., Cleveland, O., inform us that a very interesting test has recently been made, at a large bicycle factory, of two bicycles—one built entirely of seamless tubing made by the Standard Welding Co., and the other, with ordinary seamless tubing. The wheels were put to test on a vibrating machine with the result that the bicycle of ordinary tubing went to pieces after a continuous run of only 36 hours, while the bicycle built with the "Standard" seamless tubing stood up over 72 hours, thereby demonstrating its strength to be twice as great as that of the cold-drawn tubing. The "Standard" tubing is made from stock of uniform thickness, and the welding, which is done by electricity, makes every section of the tube of equal strength, and the product much more uniform than is possible with the cold-drawn tubing.

Thos. H. Dallett & Co., Philadelphia, Pa., have lately been reorganized and incorporated as the Thos. H. Dallett Co., with officers as follows: President, Thos. H. Dallett; Vice-President and General Manager, Ernest C. Bliss; Secretary and Treasurer, E. C. Clay. W. H. Van Sickel, lately New York representative of the Under-Feed Stoker Co., of America, and formerly identified with the pneumatic tool industry, is Superintendent. The company will greatly extend and enlarge the capacity of their plant, located at York Street and Sedgley Avenue, and while continuing the manufacture of their well-known belt and electrically driven portable drills, deck planers, etc., will devote especial attention to the production of "Dallett" pneumatic tools. Their works are equipped with the latest and most improved machinery.

MACHINERY.

October, 1903.

A SCREW PROPELLER PLANING MACHINE.

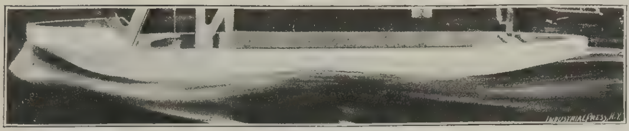

Fig. 1. Model of a Ship's Hull under Test.

THE machine of which an illustrated description is published herewith, is entirely novel in conception and design and in the work that it performs. It was designed for planing the blades of screw propellers, to be used for experimental purposes, and will accurately finish helicoidal surfaces of any desired pitch, within reasonable limits and with the pitch either uniform or variable. The machine was built for the United States Government by the Builders Iron Foundry, Providence, R. I., and is now in use at the Washington, D. C., Navy Yard as an adjunct of the experimental model-testing basin located there, where models of vessels are tested to determine their performance at various speeds.

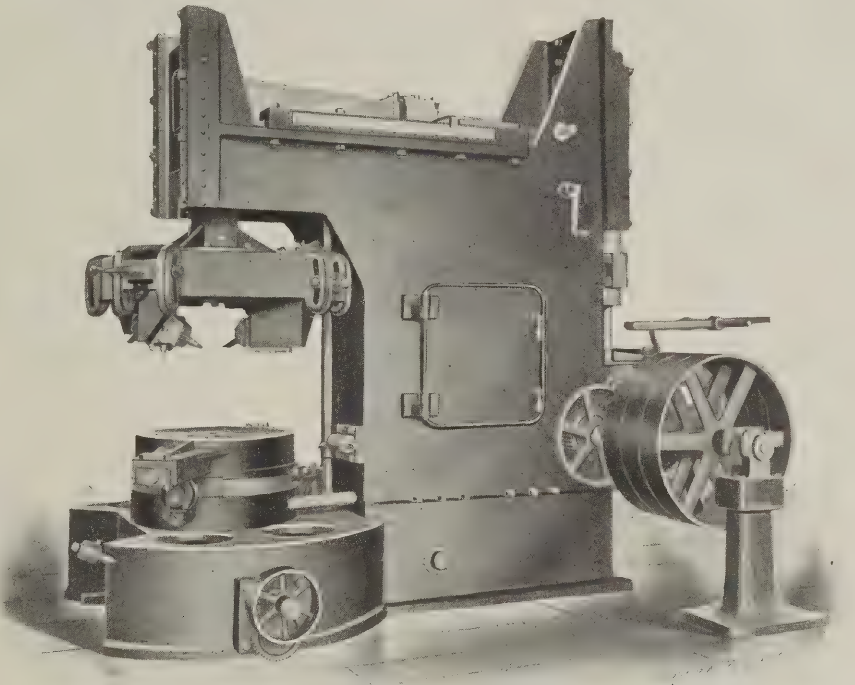

Fig. 2. Propeller Planer for Machining the Blades of Propellers for Experimental Purposes.

The experimental model basin was completed between two and three years ago, and tests upon models of ships of various types have since been regularly conducted. The building in which the basin is located is 500 feet long, and 50 feet wide, while the water surface of the tank is 470 feet long. The basin is spanned by a bridge which travels on carefully leveled tracks at the side of the basin and is driven by electric motors fitted with the Ward Leonard system of control, which permits an almost infinite variety of very uniform speeds. The model to be tested is placed in the water below the bridge and attached by a flexible connection to brackets extending below the bridge. The brackets support a dynamometric apparatus by which the resistance of the model is automatically recorded upon a drum placed on the platform above for the different speeds at which it is towed. The models are made uniformly 20 feet long and coated with smooth, white enamel. The process of making the models involves the use of several complicated special woodworking machines. As a result of one of the first series of tests changes were made in the lines of a model which were such an improvement that had the vessel been constructed along the old lines instead of in conformity with the new, it is estimated it would have required 2,000 horse power more to have propelled it at its maximum speed of 19 knots an hour than was required with the vessel as constructed.

The propeller models which the planing machine was built to produce are to be tested in connection with ship models in the experimental basin. Tests upon screw propellers have previously been conducted, either with full-sized propellers on full-sized ships—which is at best a slow and very expensive process—or with small propellers made to rotate in a fixed position in a tank of water, and driven by an electric motor or other power outside of the tank. Tests of the latter description have recently been carried on at the naval academy at Annapolis, and have been productive of good results, although the information to be derived from them is necessarily comparative rather than specific. Results that will supply definite data for a designer to work with can only be obtained by testing a propeller in connection with the hull of a ship, where there is always motion of the water around the stern, relative to the hull, which affects the action of both ship and propeller. It is proposed to test the propellers made on the planing machine by equipping a model hull with them and driving the propellers with electric motors, which will enable the power absorbed and the speed of rotation to be accurately determined; and from the results derived from such tests the performance to be expected from propellers and hulls on similar lines, but of full size, can be closely calculated.

The general features of design of the planer were outlined by the Navy Department and were original with Naval Constructor D. W. Taylor. The details of construction, however, were left with the builders and were worked out by Mr. F. N. Connet, mechanical engineer of the Builders Iron Foundry. The planer operates on rough bronze propeller castings of two, three or four blades, ranging from five inches to 24 inches in diameter and will finish both the fronts and backs of the

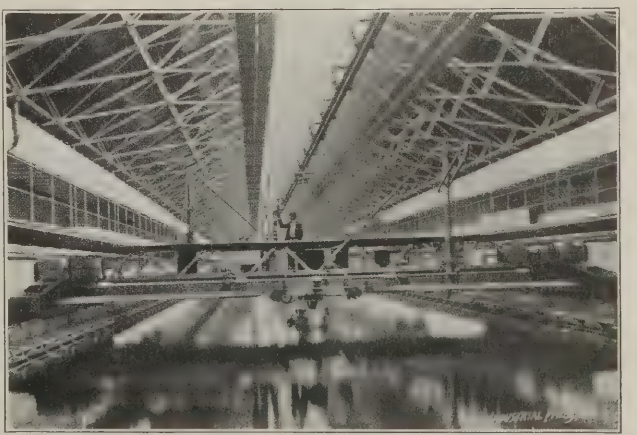

Fig. 3. The Marine Experimental Basin, Washington Navy Yard, where Screw Propellers are to be Tested.

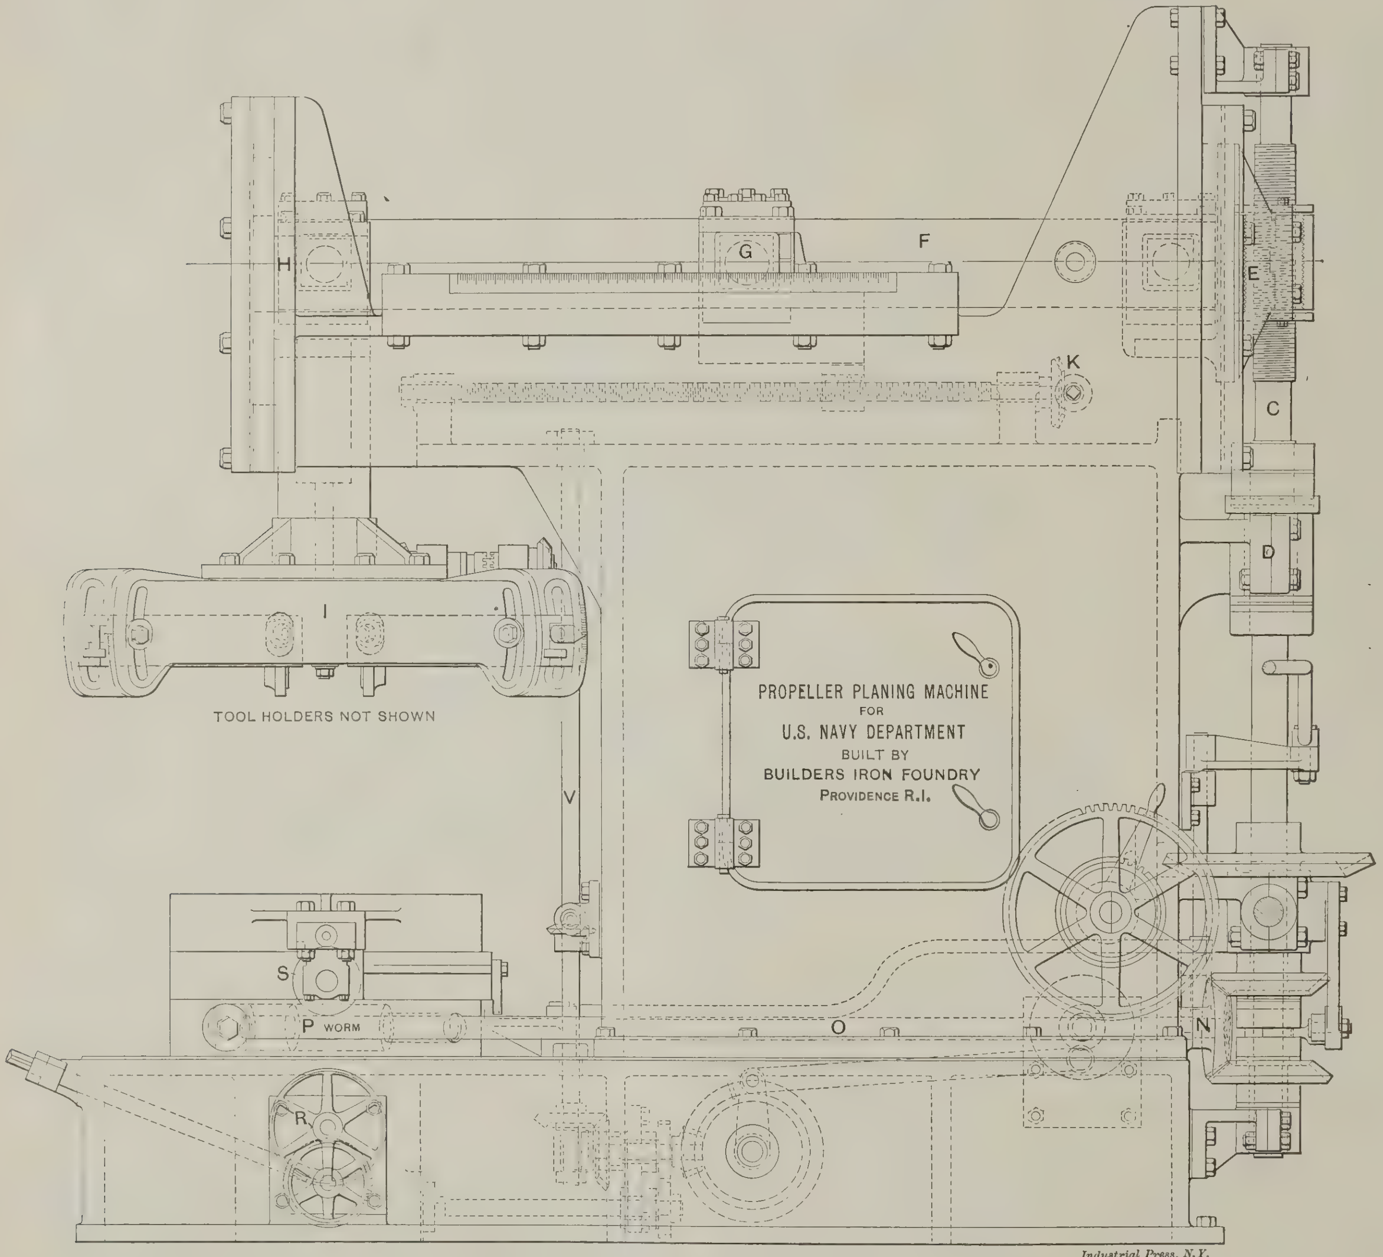
blades. The cutting is accomplished by diamond-point or round-nose tools, the tools and work being given such relative motion as to cause the surface of the blade to have the required pitch and form. The propeller is mounted, with its axis vertical, upon a horizontal table, which has a reciprocating rotary motion about its vertical axis. The cutting tools are carried by a cutter head, which has a reciprocating motion in a vertical direction, timed to correspond with the motion of the table. Provision is made for varying the extent of the travel of the cutter head, relative to the motion of the table, by this means varying the pitch of the surface being planed. The machine is driven by a shifting-belt mechanism, similar to a planer of the usual type, the shifting mechanism, in this case, being controlled by dogs clamped in a T-slot on the periphery of the table. Both the cutter head and the table are operated by the same shifting belt, and the feed for the tools is operated by a planer feed mechanism, with friction clutch.



Industrial Press, N.Y.

Fig. 4. Side Elevation of Propeller Planer.

In Fig. 2 on the first page is a side view of the machine and in Fig. 4 is a side elevation indicating many details of construction. The two subsequent views, Figs. 5 and 6, show details of the mechanism at the rear of the column and on the opposite side from Figs. 2 and 4. The belt pulleys are three in number, 30 inches diameter and 5-inch face, the two outside pulleys being loose and the middle one, *A*, in Fig. 6, is tight on its shaft and transmits motion through the bevel gears, *BB*, to the vertical driving shaft, *C*. This shaft consequently changes its direction of rotation with each reversal of pulley *A*, and the reciprocating motions of both cutter head and table are derived from it.

At the lower end of the driving shaft are bevel gears, *L* and *M*, Fig. 6, loose on the shaft, but either of which may be set in motion by a clutch which is splined to the shaft. These gears mesh with a third bevel gear, *N*, Fig. 4, and transmit motion through the shaft, *O*, to a worm, *P*, and worm-wheel, which drive the table, and give it its reciprocating motion. The object of the two bevel gears and clutch on the driving shaft is to reverse the direction of rotation of the table, relative to the motion of the driving shaft, so that either right- or left-hand propellers may be planed.

At the upper end of the driving shaft is a double-threaded screw, 3½ inches diameter, ¾ inch lead, which runs in an adjustable bronze nut, forming part of the crosshead, *E*. This crosshead is connected with the walking beam, *F*, Fig. 4, by a sliding and pivoted joint, and the walking beam, at its opposite end, is similarly connected with another crosshead carrying the tool head *I*. It is evident that in the production of the surfaces of a propeller blade the motions of the blade and tool are entirely analogous to the motions of the corresponding parts when thread cutting in a lathe. That is, for a propeller of uniform pitch, the propeller must rotate uniformly and the tool must advance uniformly, just as the work turns uniformly and the carriage and tool post advance uniformly in the case of the engine lathe. In the propeller planer the driving shaft has a uniform rotary reciprocating motion, received from the driving belt, as we have already seen, and this is reproduced in the motion of the table through the bevel-and-worm-gear connections. The design of the walking beam, also, is such as to give a uniform advance and return to the cutter head, this being accomplished by the crosshead at each end, guided in a straight, vertical line, in connection with the walking beam, which is so arranged that each end slides in a block pivoted to the crosshead at that end. This arrangement maintains a constant ratio between the lengths of the two arms of the walking beam, whatever the angle of inclination, and the motion of the cutter head thus accurately reproduces the motion transmitted by the screw at the upper end of the driving shaft, *C*.

The walking beam is a steel forging of rectangular cross section and has an adjustable fulcrum consisting of a trunnion block which can be clamped to the walking beam at any desired position along its length. This block has two trunnions supported in boxes carried by a casting which can be adjusted to any desired position by means of a crank, *K*, Fig. 4, a pair of bevel gears, and a screw. The adjustment of the position of the fulcrum varies the distance traveled by the cutter head, *I*, for each inch of travel of crosshead, *E*; and as the travel of crosshead *E* is always relatively the same as the travel of the table, it is evident that adjustment of position of the fulcrum of the walking beam enables propellers of various pitches to be planed. To facilitate setting the machine, the frame adjacent to the walking beam is graduated and indicates where the fulcrum must be set to correctly plane a propeller of given pitch. The maximum movement of crosshead *E* is 8 inches and the movement of the cutter head can be varied from 1 inch to 12 inches.

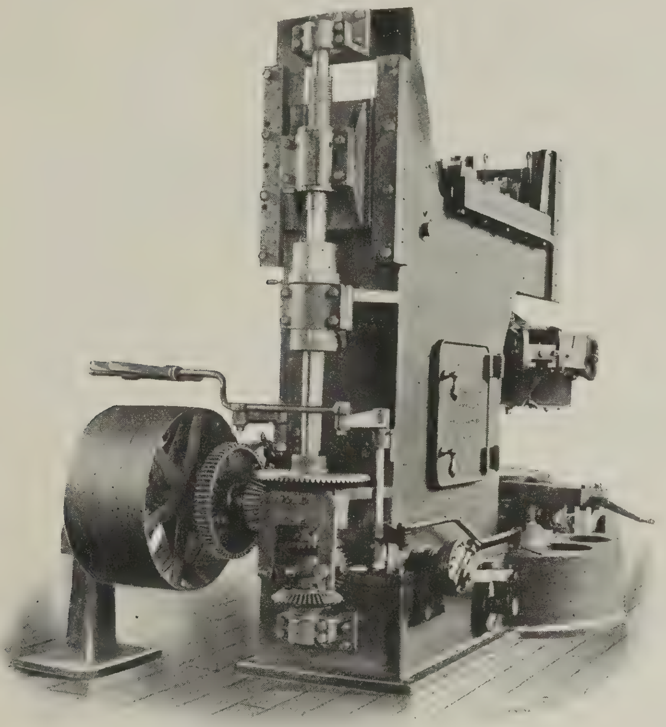


Fig. 5. View showing Feed and Driving Mechanisms.

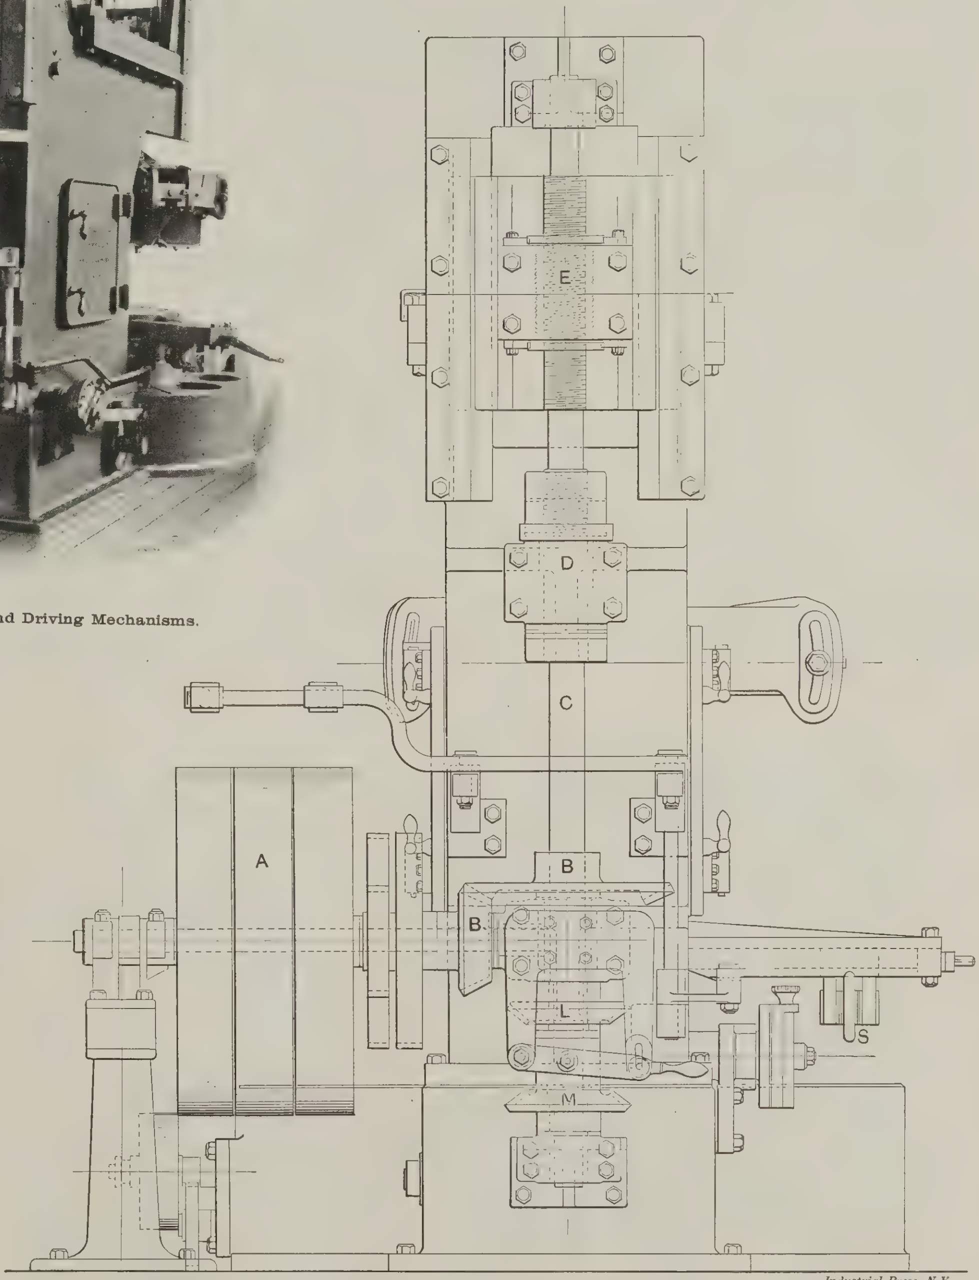

Industrial Press, N.Y.

Fig. 6. Rear Elevation of Propeller Planer.

The work table of the machine is 27 inches in diameter and is arranged so that it can be raised or lowered either by hand or by power, to bring the work into position for machining. The gearing for this purpose is shown at *R*, in Fig. 4. Provision is also made for the automatic lifting of the table while the machine is in operation, through the use of two cam surfaces, bolted to the base of the machine, on diametrically opposite sides of the table. By raising the table during the downward, or cutting stroke of the tool, the effect is the same as though the cutting speed of the tool were changed, thus allowing the propeller to rotate a greater or less amount, according to the shape of the cam, for every inch of travel of the tool, and producing a propeller of variable pitch. By laying out suitable cams any desired variation in pitch can thus be obtained. There are two horizontal arms, extending radially outward from the table, as shown clearly in the half-tone illustrations, each of which carries a sliding block supporting a steel roll. These rolls ride up and down on the cam surfaces as the table reciprocates, alternately raising and lowering the table. Provision is made for feeding the rolls out or in along the radial arms, their motion keeping pace with the out or in feed of the cutting tools; and by making the cam with a surface of changing curvature, different pitches can be employed for the inner and outer ends of the propeller blades.

In Fig. 7 is a view of the under side of one of the cutter heads. This head has four radial slots or channels, in each of which are slides or ways that carry the tool heads. The cutter head is designed for planing either two- or four-bladed propellers, and there is a second head having three radial slots spaced 60 degrees apart, for planing three-bladed propellers. The specifications for the machine called for the feeding of the tools in a radial direction in a horizontal plane, and also the ways on which the tool heads traveled should be capable of being swiveled up to 10 degrees in either direction with the horizontal, the object being to provide for propellers having "rake" to the blades. The slides are pivoted at their inner ends and are clamped in position by two bolts at their outer ends. Each tool head carries a tool post attached to a swiveling apron, similar to the tool heads of planers and shapers, and two sets are furnished, one right-hand and one left-hand, for cutting right- and left-hand screws, and all of them have adjusting screws for vertical adjustment of the tools.

The feeds for the tool heads are derived from a central stud gearing with feed screws which extend radially one for each slide. The feed screws have universal joints at their inner ends to allow motion to be transmitted when the slides are tilted above or below the horizontal. The central feed stud derives its motion from the bevel gear seen on the outside of the cutter head at top of the engraving, Fig. 7, and this gear in turn meshes with a gear on the splined feed shaft, *V*, in Fig. 4. At the lower part of Fig. 4, the gearing connecting this feed shaft with the ratchet wheel operated by the friction feed mechanism of the planer is shown by dotted lines. The cam rollers on the table arms also derive their feed motion from the same device.

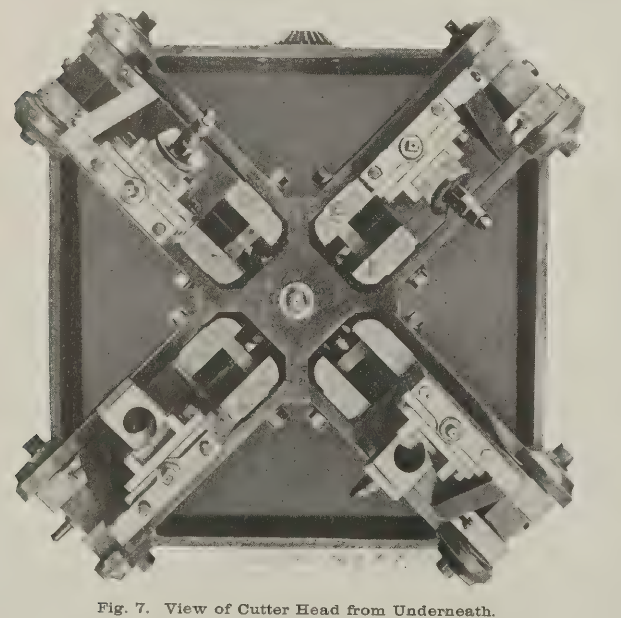

Fig. 7. View of Cutter Head from Underneath.

The machine is back-geared and is belted to a countershaft driven by an electric motor. It weighs about 10 tons, is 8 feet 10 inches high, 4 feet 10 inches wide, and 8 feet 3 inches long. It works to the entire satisfaction of the government officials and the builders.

Without doubt the installation of the propeller planer will result in the carrying out of many important and much-needed experiments upon screw propellers, and apparently we have started upon an era of scientific investigation in marine propulsion, and problems connected with it, which will give designers much better data to work with than any which now exist.

THE NEW SPRINGFIELD RIFLE, ADOPTED BY THE UNITED STATES GOVERNMENT.

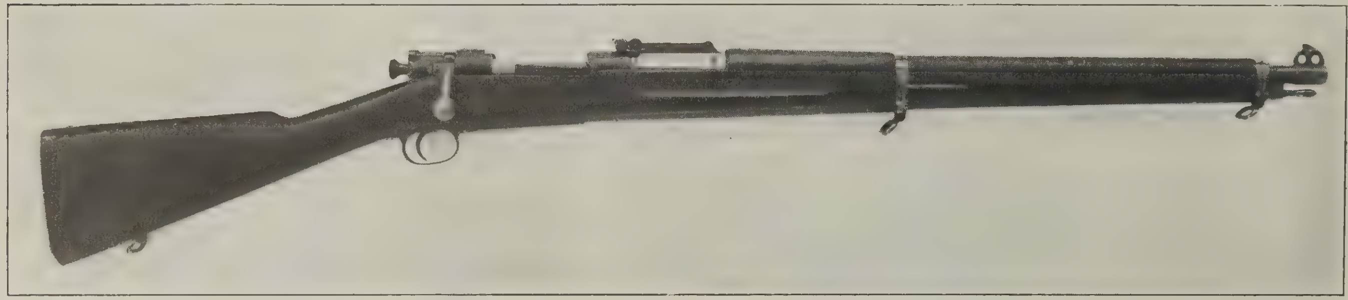

Fig. 1. The New Springfield Rifle—the best Army Rifle in the World.

The new Springfield rifle, model 1903, which has been adopted by the United States Government in place of the Krag-Jorgensen rifle, is a shoulder arm that, to date, is said to be without an equal in flatness of trajectory and penetrating power. Shooting at a range of 1,000 yards the maximum ordinate of the trajectory is only 20.67 inches high. That is to say, in a distance of 3,000 feet the parabolic path of the bullet curves upward less than 21 inches above the straight line connecting the muzzle and the point of impact. The initial velocity of 2,300 feet per second gives the projectile a penetration of 54.7 inches of white pine, the target being composed of 1-inch boards, 1 inch apart and located 53 feet from the muzzle. Since the energy required to penetrate the fleshy part of a man's body is about equal to that required to penetrate a 1-inch pine board, it follows that the new rifle theoretically has the power to mow down fifty-five men in a line at a distance of 53 feet from the muzzle.

The accompanying comparative table from the *Scientific American* gives the principal data for the new rifle, the Krag-Jorgensen which it displaces, the Mauser, and the German military rifle. The weight of the new weapon is 1.17 pounds less than that of the Krag-Jorgensen, but perhaps the greatest advantage is its short length, being only 43 inches as compared with 49 inches, the length of the latter. This length, which is slightly greater than that of a military carbine, will enable the arm to be used by both the cavalry and infantry, and it is expected that it will be adopted by the Navy Department as well, thus equipping all branches of the service with the same weapon and using the same ammunition.

NEW SPRINGFIELD MAGAZINE RIFLE COMPARED WITH THE KRAG-JORGENSEN, THE MAUSER, AND THE GERMAN MILITARY RIFLE.

Maximum ordinate of 1,000 yards trajectory, feet.	20.67	25.8	24.47	23.73

Because of the general use of smokeless powder which has not only greatly widened the danger zone, but made close encounters practically impossible, the evolution of the military rifle will undoubtedly eventually end with the total discarding of the bayonet; in this gun it is reduced to a mere pike or rod bayonet. This rod normally lies underneath the barrel in the position ordinarily occupied by a cleaning rod or the ramrod of the old muzzle-loader. When required for action the rod bayonet is pulled part way out until a catch engages a circumferential groove.

The magazine holds five cartridges. Loading the magazine is effected by means of a clip holding five cartridges in a row, which is over the magazine with the breech open. Pressure downward forces the cartridges into the magazine where they

Fig. 3. Sectional View, showing Details of Breech Mechanism.

take the position shown in the cross section view at the left of Fig. 3. The clip is discarded when the filling of the magazine is completed, the forward movement of the bolt throwing it to the ground. The gun can be used as a single-loader by cutting off the magazine.

The construction is simple and strong. Two lugs are provided on the bolt, instead of one, to resist the breech pressure. The location of the magazine does not impair the balance of the arm, and, being entirely concealed, it does not detract from the appearance. In fact the lines of the new gun are nearly as pleasing to the eye as those of some sporting rifles. The barrel is only 24 inches long and is entirely incased in a wood sheath, the object of which is to prevent the heating of the barrel, due to rapid firing, interfering with the handling of the piece. The uniform protection of the barrel also prevents unequal radiation and consequent deflection of the barrel which would result in inaccurate shooting. The barrels are turned so as to make the exterior perfectly concentric with the bore, and the seating of the barrel in frame is a detail that has been carefully worked out. Further description need not be given here, but suffice it to state that the details of design and manufacture have been planned with the view, so far as possible, of obtaining the maximum accuracy and efficiency in one type of weapon that shall be adapted to all branches of military and naval service. The new gun is to be manufactured at the government arsenals at Springfield, Mass., and at Rock Island, Ill., for the present at the rate of about 350 per day.

* * *

A STUDY OF ALLOYS SUITABLE FOR BEARING PURPOSES.

In an elaborate article, in the *Journal of the Franklin Institute* for July, Mr. G. H. Clamer discusses the advantages and disadvantages of various compositions and alloys for bearings, and especially alloys for railway journal brasses. He also quotes the results of many tests on various compositions made on an Olsen testing machine designed by Prof. Carpenter of Cornell University.

Upon close examination we find that there are but few metals available for bearings. They are copper, tin, lead, zinc and antimony. While other metals may be introduced in greater or less proportions, the five mentioned must constitute the basis for the so-called anti-friction alloys. The combinations of these metals now used may be grouped under the two heads of white metal and bronze. Bronze is the term which was originally applied to alloys of copper and tin as distinguished from alloys of copper and zinc; but gradually the term "bronze" has become applied to nearly all copper alloys containing not only tin, but lead, zinc, etc., and no sharp lines of demarcation exist between the two.

White metals are made up of various combinations of lead, antimony, tin, copper and zinc, and may contain as few as two elements, or all five. Bronzes are made up of combinations of copper, tin, lead and zinc, all of them containing copper and one or more of the other elements. The essential characteristics to be considered in any alloy for bearings are composition, structure, friction, temperature of running, wear on bearing, wear on journal, compressive strength, and cost.

It is utterly impossible to have one alloy reach the pinnacle of perfection in all the above requirements, and so it is important to study the possible compositions and determine for what purpose each is adapted. It has been shown that a bearing should be made up of at least two structural elements, one hard constituent to support the load and one soft constituent to act as a plastic support for the harder grains. Generally speaking, the harder the surfaces in contact the lower the coefficient of friction and the higher the pressure under which "gripment" takes place. It would seem for this reason that the harder the alloy the better; and it was with this idea in mind that the alloys of copper and tin were so extensively used in the early days of railroading. A hard, unyielding alloy for successful operation must, however, be in perfect adjustment, a state of affairs unattainable in the operation of rolling stock. For this reason the lead-lined bearing was introduced and the practice of lining bearings has now become almost universal in this country.

While the harder the metals in contact the less the friction, there will also be the greater liability of heating, because of the lack of plasticity, or ability to mold itself to conform to the shape of the journal. A hard, unyielding metal will cause the concentration of the load upon a few high spots and so cause an abnormal pressure per square inch on such areas, and produce rapid abrasion and heating.

The bronzes will, generally speaking, operate with less heat than softer compositions, while the softer metals will wear longer than the harder metals. In the matter of wear of journal, however, the soft metals are more destructive. Particles of grit and steel seem to become imbedded in the softer metal, causing it to act upon the harder metal of the journal like a lap. High-priced compositions are being used that have but little resistance to wear compared with cheaper compositions, and low-priced alloys are in service that are not cheap at any price. It is generally conceded that soft metal bearings cause a marked decrease in the life of the journal, and yet they have many marked advantages, as we shall presently see.

Bearings Containing Antimony.

Lead and antimony: These metals will alloy in any proportion. With increase in antimony the alloy becomes harder and more brittle. It has been determined that when this is made of 13 parts antimony and 87 parts lead the composition will be of homogeneous structure. If there is a greater proportion of antimony, free crystals of antimony appear, imbedded in the composition; and if less than 13 per cent. there appear to be grains of the mixture itself imbedded in the lead as the body substance.

According to one writer an anti-frictional alloy should consist of hard grains, to carry the load, which are imbedded in a matrix of plastic material, to enable it to mold itself to the journal without undue heating. Such a condition would be met in a lead and antimony alloy having above 13 per cent. antimony; but it is not advisable to use in any case more than 25 per cent. antimony, as the composition would be too brittle. The same writer claims that alloys having from 15 to 25 per cent. antimony are the best adapted for bearings. The author of the paper under review, however, does not agree with this, and says that alloys containing below 13 per cent. antimony can likewise be said to consist of hard grains consisting of the composition itself, imbedded in the softer material, lead, as mentioned above. He says: It has been my experience that, although the friction may be higher in such alloys, the wear is greatly diminished, and where pressures are light, causing no deformation, this is a great advantage. I have seen many instances in service where alloys between 15 per cent. and 25 per cent. were greatly inferior to alloys between 8 per cent. and 12 per cent., owing to their frequent renewal due to wear. It will perhaps be interesting to hear that the Pennsylvania Railroad Company, at the suggestion of Dr. Dudley, their chemist, have adopted the 13 per cent. antimonial lead alloy as a filling metal for bearings in order to obtain the best results.

In a general way my own work in the subject has confirmed the opinion that lead is the best wear-resisting metal known, and that with increasing antimony, or increasing hardness and brittleness, the wear becomes more marked. This is due to the splitting up of the harder particles.

The friction, as we may naturally expect, becomes less with increase of antimony, and the temperature of running likewise diminished when running under normal conditions; but the harder the alloy, the more difficulty is experienced in bringing it primarily to a perfect bearing, and the greater the liability of heating through aggravated conditions. The wear on the journal one would naturally expect to be decreased with increasing hardness; but this journal wear is in all probability not due so much to the alloy directly as it is to the fact that the softer metals collect grit, principally from the small particles of steel from the worn journal, and, acting as a lap, cause rapid wear. With the harder metals these particles are worked out without becoming imbedded.

The cost of the lead and antimony alloy is the least which can be produced. It can be used in many services where higher-priced alloys are being relied upon mainly for their high cost. It is one of the greatest extravagances of large industrial establishments to use materials that are too good for certain uses, and even perhaps unsuited, under the supposition that they must be good because they paid a good price for them. This fact has no greater exemplification than in the purchase of babbitt metal, and is due to the great uncertainty which exists, not only among consumers, but among manufacturers, many of whom carry on their business much the same as the patent-medicine man.

Lead, Antimony and Tin: I do not wish it understood that antimony-lead is the cheapest alloy to use under all circumstances; not so, for when high pressures are to be encountered, tin is a very desirable adjunct. Tin imparts to the lead-antimony alloy rigidity and hardness without increasing brittleness, and can produce alloys of sufficient compressive strength for nearly all uses. The structure of a triple alloy of this nature is quite complicated, and not yet definitely defined.

The cost of the alloy increases with increase of tin; but for certain uses, where sufficient compressive strength cannot be gotten by antimony, because of its accompanying brittleness, it is indispensable, and will answer in nearly every case where the tin basis babbitts are used.

Tin and Antimony: These are seldom used alone as bearing alloys, but are extensively used for so-called Brittania ware, and in equal proportions for valve seats, etc.

Tin, Antimony and Copper: This combination is what is known as genuine babbitt, after its inventor, Isaac Babbitt, who presumably was the first man to conceive the idea of lining bearings with fusible metal. The formula, which for no arbitrary reason he recommended, is as follows:

Tin	89.1
Antimony	7.4
Copper	3.7

This formula is still considered the standard of excellence in the trade, and has been adopted by many of the leading railroads, the United States Government and many industrial establishments. It is used in the majority of cases where cheaper composition would do equally as well. It is the most costly of all bearing alloys because of the high content of tin.

Tin-Antimony-Lead-Copper: This quadruple combination of metals I will not venture to describe, as it would no doubt take years of study to fathom the complicity of the metallic combinations here represented. Suffice it to say that lead, although of itself a soft metal, renders this alloy, when added in but small proportions, harder, stiffer, more easily melted and superior in every way to the alloy without it, and yet consumers will raise their hands in horror when a trifling percentage of lead is found in their genuine babbitt. This is one of the instances where cheapening of the product is beneficial.

The foregoing represents the more important combinations of alloys of tin and lead basis. These are of far more importance in the arts than the white metals, the main portion or basis of which is zinc.

At various times new combinations of zinc have been proposed, but so far as my knowledge goes, they have not come into popular use for two reasons: First, because of the great tendency of zinc to adhere to iron when even slightly heated. What is technically known as galvanizing the journal is effected under these conditions. Second, because of the brittleness produced under the effects of heat, such as is produced by friction when lubrication is interfered with, and consequent danger of breakage.

Bronzes.

Bronze is the term which originally was applied to alloys of copper and tin as distinguished from alloys of copper and zinc.

Copper and Tin: This, according to our general conception of the word, is a bronze only when the copper content exceeds that of the tin. According to the proportions in which the metals exist, it has widely different properties. In general, the tin hardens when present up to proportions of 30 per cent., or perhaps a little over, and when this limit is exceeded, it takes on more and more the nature of tin until pure tin is reached. From a scientific point of view this alloy is one of the most interesting and has attracted the attention of many investigators, who have spent years of study on it, to learn its various properties and explain its constitution.

The alloys which interest us most, however, are those which are so constituted as to be adapted for bearing purposes. These would be said to contain from 3 to 15 per cent. tin, and from 85 to 97 per cent. copper. The alloy of tin containing smaller percentage of copper is often used as a babbitt metal, but this comes under the class of white metals, which I have already discussed. Bronze containing above 15 per cent. of tin has been recommended at various times for bearings owing to its hardness, but very unwisely, for such a bearing assumes mechanical perfection and perfect lubrication. It has no plasticity of its own, and as soon as the oil film is interrupted rapid abrasion and gripment take place, with hot boxes as the result. The very erroneous idea is still held by many, that to resist wear and run with the least possible friction a bearing alloy must be as hard as possible. It is true that hard bodies in contact move with less friction than soft ones; but the alloy which is the least liable to heat and cause trouble is the one which will stand the greatest amount of ill use; by this I mean an alloy which has sufficient plasticity to adapt itself to the irregularities of service without undue wear. The enthusiasts over hard bearings have even gone so far as to try glass for this purpose, and whereas this substance may give satisfaction on perfectly adjusted light spindles, for example the jewel bearings of a watch, we can readily imagine what would be the consequence if such a trial was made on locomotive or car journal bearings. It is for the foregoing reasons that I have limited the useful bearing alloys of copper and tin to those containing less than 15 per cent. tin, and began my investigation from this point.

The alloys of copper and tin were used extensively some twenty or twenty-five years ago, and were considered the standard for railroad and machinery bearings. The old alloy, known as "Cannon Bronze," containing 7 parts copper and 1 part tin, is still being specified by some few unprogressive railroad men and machinery builders.

COPPER AND TIN, AND COPPER, TIN AND LEAD SERIES.

	Copper.	Tin.	Lead.	Friction.	Temp. above Room.	Wear in Grams.
1	85.76	14.90	.....	13	50	.2800
2	90.67	9.45	.....	13	51	.1768
3	95.01	4.95	.....	16	52	.0776
4	90.82	4.62	4.82	14	53	.0542
5	85.12	4.64	10.64	18½	56	.0380
6	81.27	5.17	14.14	18½	58	.0327
7	75?	5?	20?	18½	58	.0277
8	68.71	5.24	26.67	18	58	.0204
9	64.34	4.70	31.22	18	44	.0130

Copper, Tin and Lead: This composition is now recognized the standard bearing bronze, its advantage over the bi-compound coming from the introduction of lead. The bronze containing lead is less liable to heat under the same state of lubrication, etc., and the rate of wear is much diminished. For these reasons and the additional fact that lead is cheaper than tin, it seems desirable to produce a bearing metal with as much lead and as little tin as possible. The metal known as Ex. B. composition tin 7 per cent., lead 15 per cent., copper 78 per cent., is stated by Dr. Dudley to be the best that can be devised, this being the smallest quantity of tin that will hold the lead alloyed with the copper. By adding a small per cent. of nickel, however, to the extent of one-half to 1 per cent., a larger proportion of lead may be used, and successful bronzes have been made which contained as much as 30 per cent. lead by this process. Such bronzes, containing a large amount of lead, through the addition of nickel, are known in the trade as "Plastic Bronzes" and are a regular commercial article. The table above gives the results of tests on different compositions of bronzes.

* * *

One of the interesting and valuable features of the steam turbine is that there appears to be practically no limit to the size which single units may be built. In fact the larger the wheel the better, since the peripheral speed of both large and small wheels should be about equal, and given the larger wheel, the less, of course, the number of revolutions per minute.

LOUISIANA PURCHASE EXPOSITION.

PRELIMINARY PLANS—THE ENGINEERING FEATURES.

Work has so far progressed upon the buildings and grounds of the Louisiana Purchase Exposition, and the plans have been so far developed, that it is now possible to give definite information upon many of the features of the exposition, with reasonable assurance that they will be carried out as outlined. We present a reproduction of a photograph of Machinery Hall, taken August 10, showing the state of completion, and also an engraving of the latest ground plan of the exposition. Nothing is shown on this plan save items which are either completed or in process of completion or definitely contracted for. As a matter of fact there are a great many features not shown on this plan, which, however, are practically decided on and which will completely fill the apparently unoccupied spaces of the map. For example, the entire section called "The Pike," lying to the north of the Varied Industries and Transportation Buildings, and the sections lying between the Transportation and the English section; and between the Machinery and the French sections and thence southerly to the east of Skinker Road, is devoted to concessions and constitutes the "Midway." Since July 15th practically all of this space has been allotted to concessionaires. To give a clearer and more immediate idea of the general character of the Exposition plan, special prominence is given on the map to the Intramural Railway; and the waterways, the Machinery Building and the Steam, Gas and Fuels Building, called on the ground plan the "Boiler House," are made more conspicuous by cross-sectioning.

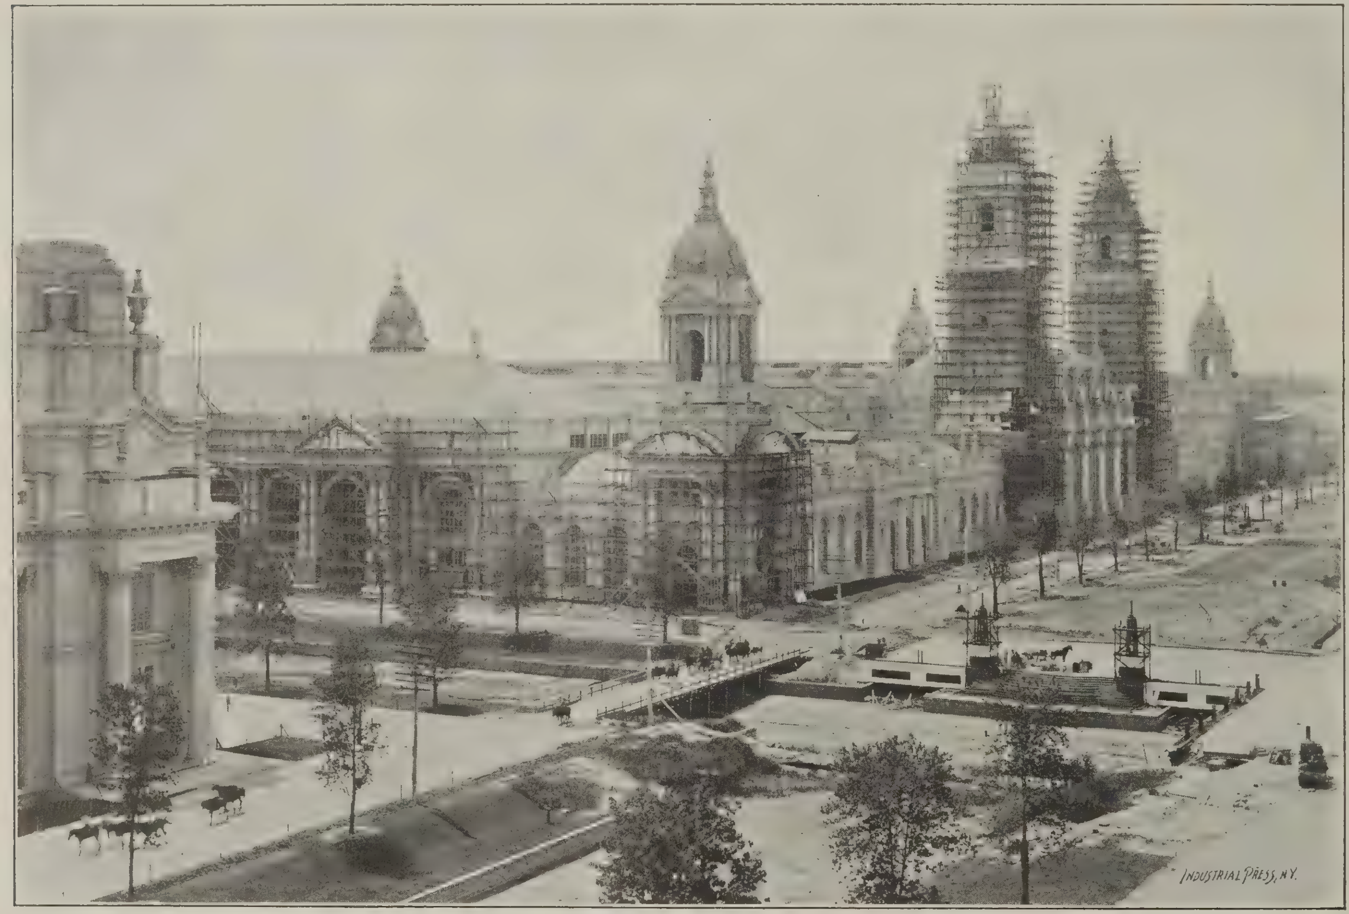

Fig. 1. Machinery Building, now nearly Completed.

With reference to the Intramural Railway, this consists of a double-track trolley road, standard gage and standard type of open cars. The motor equipment and control is furnished by the General Electric Company; the brake equipment and control is furnished as an exhibit by the National Electric Company; the power plant for the operation of the road will be located in the central portion of Machinery Hall and the prime movers in this plant are as follows:

1. A 1,500 B. H. P. Oechelhauser system gas engine (100 R. P. M.) built and exhibited by A. Borsig, Tegel-Berlin, and supplied with gas from a producer plant built and exhibited by Julius Pintsch, Berlin.

2. A 900 H. P. Corliss type steam engine (85 R. P. M.) built and exhibited by the Murray Iron Works Company, Burlington, Iowa.

3. A 750 H. P. modified Corliss steam engine (100 R. P. M.) built and exhibited by the Lane & Bodley Company, Cincinnati, Ohio.

4. A 600 H. P. four-valve steam engine (150 R. P. M.) built and exhibited by the Harrisburg Foundry and Machine Works, Harrisburg, Pa.

The Crocker-Wheeler Company, Ampere, N. J., build the generators, which in every instance are directly coupled to the prime movers and deliver current at 550 volts at the switchboard.

In addition to the foregoing there will probably be included in this Intramural Power Plant a combination which, while not economical in efficiency, will have features interesting to the engineer and attractive to the public. This combination consists of a steam pump built and exhibited by the Jeanesville Iron Works Company, Jeanesville, Pa., which is planned to deliver 1,200 gallons of water per minute at a pressure of 300 pounds, the water being conveyed through a pipe line and delivered against a tangential water wheel built and exhibited by the Abner Doble Company, San Francisco, Cal. This water wheel will be encased in plate glass. It will run at 900 R. P. M., and it is to be directly coupled to a Crocker-Wheeler generator. Incidental features will be a Lombard governor on the water wheel and a Venturi meter measuring the water delivered through the pipe line. The Intramural Power Plant will have its own independent system of boilers, stokers, force draft apparatus, piping, condensers, pumps, etc.

With particular reference to the water ways, the main one consists of a grand basin with lateral lagoons. The water is delivered into this basin from a niche in front of Festival Hall and from fountains in front of two ornate restaurant buildings which flank the Terrace of States. From these three points it flows over cascades and it is to be illuminated by electric lights placed under the lip of each step, which breaks the spill. The water is to be lifted by three centrifugal pumps built and exhibited by the Henry R. Worthington Company. Each pump is planned to deliver 30,000 gallons of water per minute against a total head of 158 feet. Three induction-type motors, each of 2,000 H. P. rating, are to operate the pumps. The magnitude of this feature will be better appreciated by the statement that the total water moved in the Paris Exposition of 1900 was about 4,500 gallons per minute and at the Buffalo Exposition of 1901 about 7,000 gallons per minute, while here in this cascade feature alone we are to move 90,000 gallons per minute. The energy required for the operation of this feature equals the total energy had from the Niagara power plant by the Pan-American Exposition and the total energy used for illuminating the latter exposition. The secondary water system consists of Arrow Head Lake. This lake is to afford an opportunity to illustrate the water dwellings and water life of the Philippines. There is a proposition on foot to afford Messrs. Farcot Freres & Company, St. Ouen-sur-Seine, France, an opportunity to install in the center of this lake a fountain which they claim will project a free jet of water to a height of about 250 feet. As the normal level of the water in Arrow Head Lake is about 40 feet higher than the water level in the grand basin, this jet would have an extreme elevation as above the surrounding country of approximately 300 feet, and when illuminated it should be visible within a radius of from ten to twenty-five miles. Messrs. Farcot Freres & Company furnished the pumps for the water display in the Paris Exposition of 1900. The particular pump which they suggest for this jet is to be driven by electric motor and it is claimed will not require more than 250 H. P. for its operation.

With particular reference to Machinery Hall and the Steam, Gas and Fuels Building, it is very gratifying to note that they will be found near the center of the grounds. The Steam, Gas and Fuels Building is a steel structure covering an area of about 100,000 square feet, and is well adapted for the installation of the class of exhibits which it is to contain. The topics to be covered by exhibits in this building are the storage, handling, preparation and conveying of fuels; the conversion of natural fuels into briquettes; the production of gas for power uses; the purification of water for boiler use; the generation of steam in boilers of both the stationary and marine types; mechanical stoking; force draft, and any subjects relating to steam generation, control and transmission. The management have done well in giving the exhibits so prominent a position, as in all former expositions the boiler house has been a boiler house pure and simple and always tucked away somewhere in the background and removed from a point where the exhibits attracted the attention of the public.

Machinery Hall is practically finished and is said to be the best exhibit building ever constructed. It has good light and air; freedom of vision and long vistas; a floor immediately on the ground level and a foundation soil naturally good. Prime movers and their accessories will occupy the westerly half of Machinery Hall. There will be found there a total of something over 40,000 H. P. of steam and gas engines doing duty and furnishing the power for the operation of the Exposition. Among the most notable units will be the following: An 8,000 H. P. and a 5,000 H. P. steam turbines; a 5,000 H. P. Allis-Chalmers Manhattan type reciprocating steam engine; a 3,500 H. P. Belgian, a 1,750 H. P. and 900 H. P. German, and an 1,800 H. P. American gas engines; a 1.500 H. P. vertical French steam engine giving 330 R. P. M. and working in parallel on arc lighting service with a German tandem compound steam engine of 1,000 H. P. and 94 R. P. M. The full range and ratings will be illustrated in each of the three great groups of prime movers—reciprocating steam engines, steam turbines, and explosion engines. In practically every instance, generators will be directly coupled to the engines. About 80 per cent. of the energy developed will be in 6,600 A. C., three-phase, 25-cycles; this for the general lighting and hydraulic work of the Exposition, but there will also be current of 2,300 volts, 50 cycles, three phase A. C., generated by foreign exhibits and used for the arc lighting, and there will be the 550-volt D. C.—as before referred to—for the

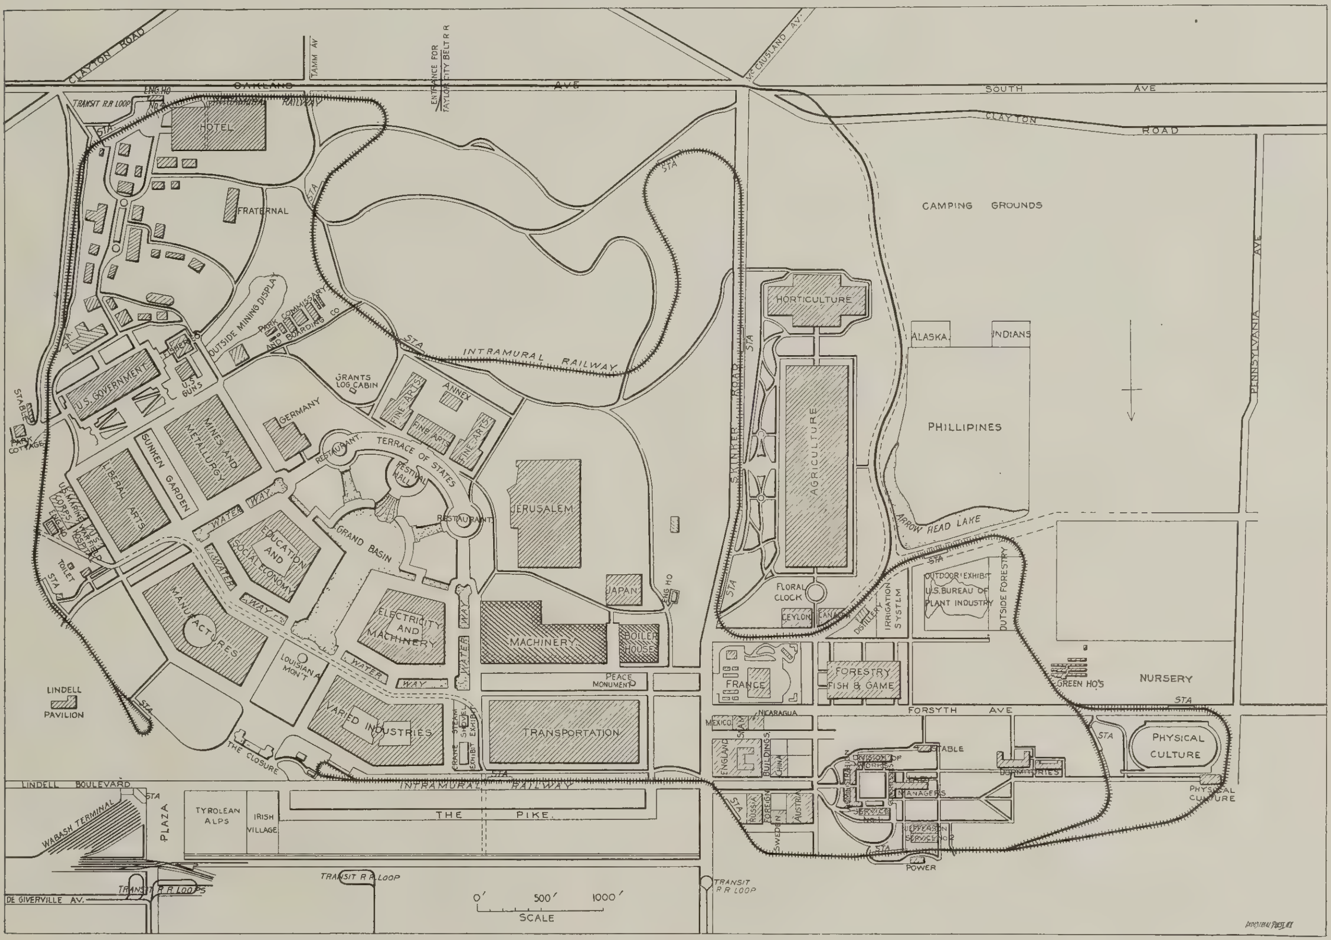

Fig. 2. Plan of Exposition Grounds as now Laid Out.

operation of the intramural road. There will also be minor installations for the generation of both A. C. and D. C. of standard voltages for the motor service of exhibitors in Machinery Hall.

To the east of the engine installation will be an air compressor plant which will furnish the air for the operation of pneumatic machinery and for the locomotives in the Transportation Building. Immediately in this vicinity the pump exhibits will be found and machine tools will occupy the northeast quarter of the building and woodworking machinery and fire engines and apparatus the southeast quarter of the building.

* * *

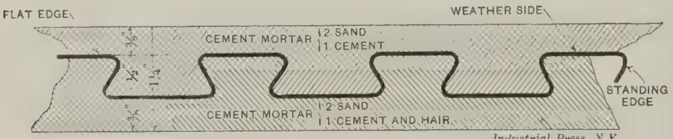
MACHINE SHOP ROOFS,*

WITH DESCRIPTION OF A SPECIAL STEEL-CONCRETE CONSTRUCTION.

One of the largest foundries and machine shops to be destroyed by fire in recent years was that of the Brown Hoisting Machinery Company, Cleveland, O., whose plant burned in December, 1900, but has since been rebuilt on a larger scale and is of more durable construction.

The walls of the main building were of brick, supporting the outer ends of steel trusses, of which the inner ends were supported by unprotected steel columns. The floors of the building were of 2-inch plank, nailed to 4 x 4 stringers, set in 18 inches of cinders. The roof was of plank covered with slate. A corrugated iron covered gasoline tank was in the end of the building and it was in this that the fire started through the carelessness of a workman. Once under way, it spread with such rapidity as to travel the length of this building, and out around a "U"-shaped building to the street in less than seven minutes. As a result the whole plant was destroyed, with the exception of the office building and a small pattern vault, which were accessible on all sides by a 16-foot driveway.

In erecting the new plant, the office building was moved across the street and out onto a vacant lot, where wings were built on each side. The area covered by the "U"-shaped building referred to, and most of the other buildings of the old plant, is now occupied by a single structure 500 x 312 feet. In addition to this a pattern shop and pattern vaults have been erected and a power house, service building, and warehouse are in process of design and construction.



Industrial Press, N.Y.

Fig. 1. Section of Ferroinclave Steel-concrete Roof.

One reason for the rapid spread of fire in the old plant was the wooden roof construction. It was determined that in the new shops this fault should be corrected and an extended investigation of various forms of roof construction was begun, Mr. Alexander Brown, vice-president of the Brown Hoisting Machinery Company, giving the matter his personal attention. In the new works it was considered necessary that cranes should be high enough above the floor to place heavy parts on the top of machines which were 40 or 50 feet high, and before designing the trusses it was necessary to decide on a fireproof roof which should be light and inexpensive. Slate laid on light steel supports would condense moisture badly; ordinary corrugated iron was objectionable for the same reason; roofing tile entailed a large number of purlins, which made the expense of the structural work very high, and also they were not at all suited to the saw-tooth roof construction. This brought the matter down to a concrete roof. The majority of those upon the market had to be made from 2 inches to 3 inches thick to obtain sufficient strength to span 5 feet. To keep the weight down, some concerns recommended the use of cinder concrete with a steel reinforcement. This could not be expected to be permanent on account of the action of the cinders in rusting away the reinforcing metal. In addition to these points, the concrete roofs were very expensive, especially when the cost of the excessive amount of structural work for supporting the roof was added to the cost of the roof itself.

These considerations finally led to the design of a steel-concrete roof which is used on all the new buildings and has now been placed on the market under the name of "Ferroinclave" roofing. A section of the roofing is shown in Fig. 1 and the half-tone illustrations indicate its appearance when completed and under construction and illustrate the method of applying it. It was determined that a cement roof 1¼ inch thick would be sufficient to prevent undue condensation and it remained but to devise a reinforcing material that would have sufficient strength to support a snow load of 30 pounds per square foot. The reinforcing sheet adopted is of corrugated sheet steel, made 10 feet long, 20 inches wide, and ½ inch thick, of No. 24 metal. The corrugations run the long way of the metal and are in the form of a dovetail. As they are wider at one end than at the other, one sheet will shingle edgeways into another sheet.

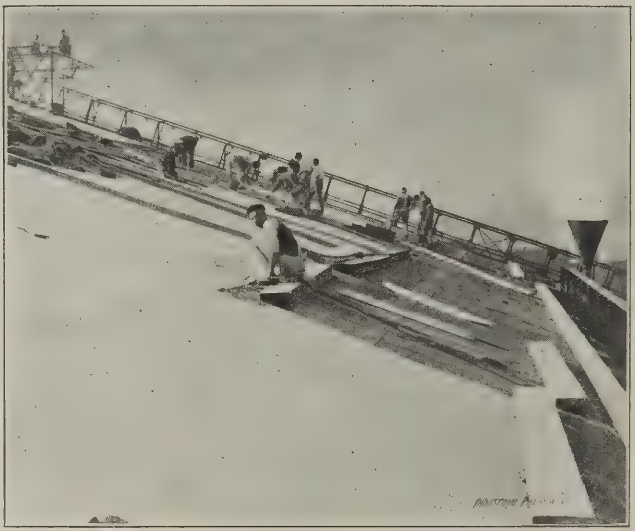


Fig. 2. Applying Cement to the Corrugated Steel Sheets.

The sheets are laid upon the tops of the purlins, spaced 4 feet 10½ inches, and clipped to them in very much the same manner as an ordinary corrugated iron roof is laid. The metal is stiff enough to support the weight of the laborers, who then spread upon the upper side a mixture of two parts of sand and one part of Portland cement. The under side of the roof is coated with a similar mixture, which contains also a small amount of lime and hair. This is put on the under side in the same way that plaster is put on to the ceiling of a room. When the cement has set for about ten days, the upper side is coated with two coats of a special non-drying paint, which renders the roof perfectly water-tight.

In the circular from which we have taken most of the facts appearing in this article, Mr. Edward Atkinson, the director of the Insurance Engineering Experiment Station, says that for years a suitable outside covering for roofs has been sought, adapted for flat roofs, or roofs of half-inch pitch, that should be as durable and safe as the composition roof of tar and gravel and, if possible, lighter in weight. Outside the practice in slow-burning construction, omitting the costly fireproof buildings with roofs of brick, concrete and steel, the roofs of miscellaneous buildings are usually the most unfit and dangerous parts of buildings in respect to the spread of fire. The great Boston fire spread by way of the roofs. The worst type of roof is the pitched roof of boards, laid on joists 18 inches to 2 feet on centers, covered with slate; worse when sheathed and ceiled inside than when not so finished within. The roof of flat section, of boards laid on joists, sheathed underneath, is bad and dangerous. For isolated buildings in the country the roof of boards, shingled outside, is somewhat unsafe and liable to be set on fire by sparks, while it transmits heat readily. On the other hand a roof of matched boards with shingles laid over half inch of lime mortar, is safe, non-conducting, and very durable.

---

*For most of this article we are indebted to a recent report of the Insurance Engineering Experiment Station, Boston. While the description relates mainly to one type of roof, the facts presented comprise a valuable supplement to the articles on shop construction that have appeared in our columns.

Prof. Charles L. Norton, of the Massachusetts Institute of Technology, has submitted samples of Ferroinclave roofing to test and reports as follows:

Under the action of fire against the lower side, the roofing became gradually heated through until at the end of an hour bits of wood were charred upon being placed in contact with the top of the roof. The temperature of the fire was from 1,700 deg. F. to 1,900 deg. F. A few cracks developed on both sides of the slab in less than ten minutes, but none of them penetrated further than to the steel sheet, and no fire came through the slab during the four hours' test.

At the end of two hours the temperature of the top of the roof had risen to the igniting point of wood, but at the end of four hours it had not risen sensibly higher. Upon cooling with a stream of water the roof was found practically intact, except for a softening of the lower surface, and the development of a few fine cracks in each surface—none penetrating more than half way through. The condition of the roof was such that it was still at the close of the test a good fire stop and with a little cement plastering it would have been, in appearance and efficiency, in its original condition.

A second test was made to determine the conductivity of the roof and its liability to cause condensation. Its thermal conductivity or heat-carrying power is nearly six to eight times that of a 2-inch spruce plank, and the condensation or drip on the lower side would be much greater. It is impossible to make an accurate estimate of the amount of this condensation. The experience of a whole winter is needed to settle the matter definitely. I see no reason to question the permanency of the roofing. There is no danger of the steel web being corroded if the cement is properly applied.

To sum up: The roofing is a fire retardant of a high order; is itself incombustible; more liable than wood to cause a drip; durable, strong and light.

In the matter of cost, comparative figures are given for a Ferroinclave roof, a foundry or machine shop roof of ordinary construction, and the cost of an ordinary roof equipped with a sprinkler system for its better fire protection. The items for the Ferroinclave roof are as follows, for a square of 100 square feet, the cost of cementing presumably being at the labor rates prevailing in Cleveland:

	Per Square.
Ferroinclave sheets	$8.50
Fastening clips	.48
Laying Ferroinclave	1.25
Cementing upper side	3.00
Cementing under side	4.00
Water-proofing coating	1.50
Sundries, freight, superintendence, etc.	1.27
Total	$21.00

The items for a roof of common construction are as follows:

	Per Square.
Plank, including nailing strip on purlins	$6.90
Laying	3.00
Painting on under side of plank (two coats)	1.75
Tar and gravel roof	4.50
Apportionment for repairs for tar and gravel roof, on the assumption that the life of this roof is ten years	.45
Total	$16.60

The plank roof coated with tar and gravel will weigh about 10 pounds per square foot. The Ferroinclave roof is about 1¼ inch thick and weighs 15 pounds to the square foot. A snow load for each of 30 pounds per square foot must be provided for, so that the purlins and trusses must be designed to support 40 pounds per square foot of roof in one case and 45 pounds in the other—substantially the same weight. To equip a plank roof with sprinklers is estimated to cost $35 a square, including underground connections, gravity tank, valves, etc., assuming the roof to cover a total area of 124 squares. The cost alone of sprinklers and pipe connections for same would be nearly $7 per square.

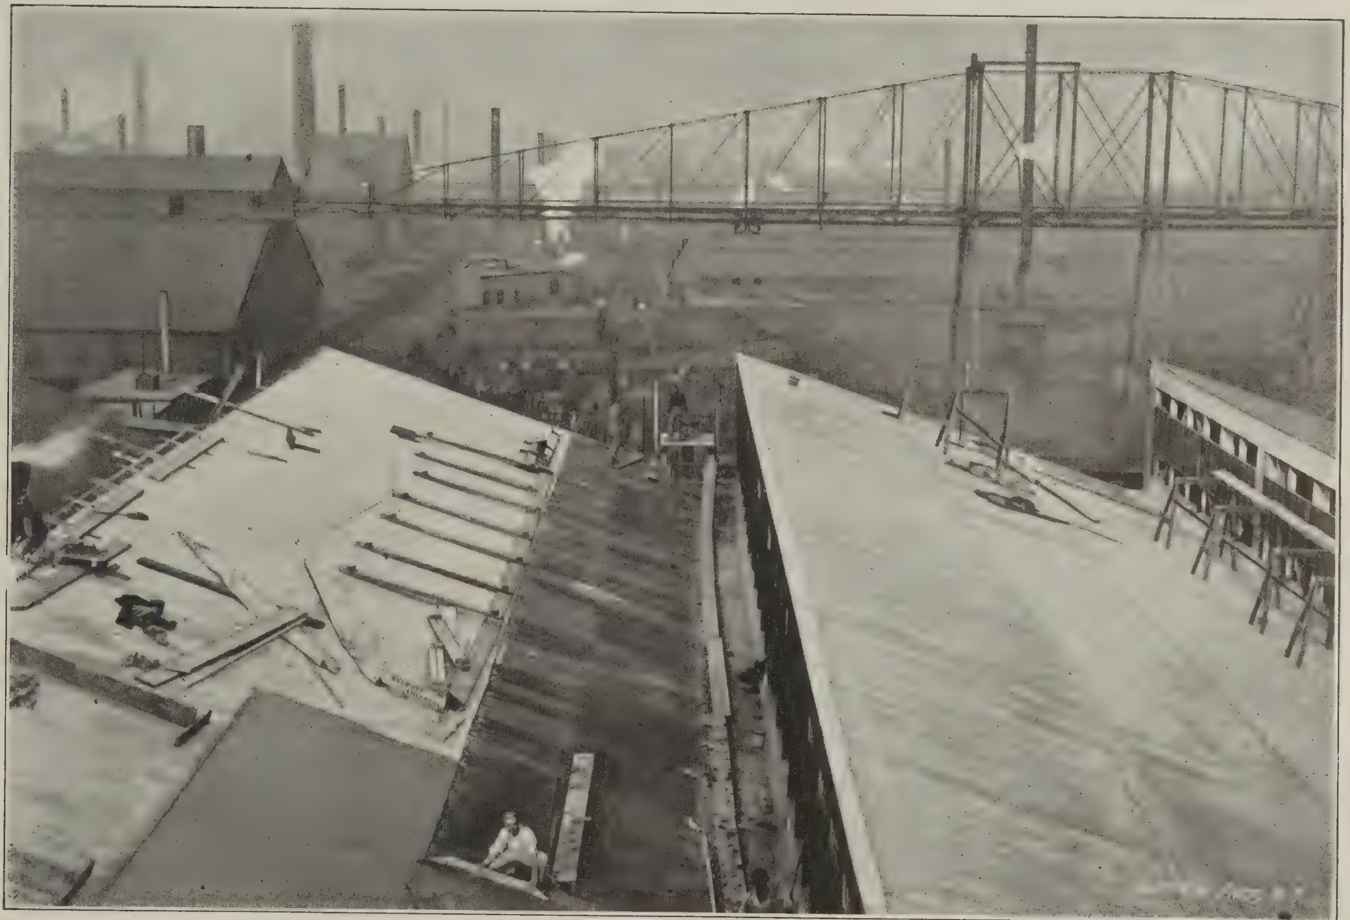

Fig. 3. Part of Roofs of New Shops of the Brown Hoisting Machinery Company, Cleveland—Steel-concrete Construction.

* * *

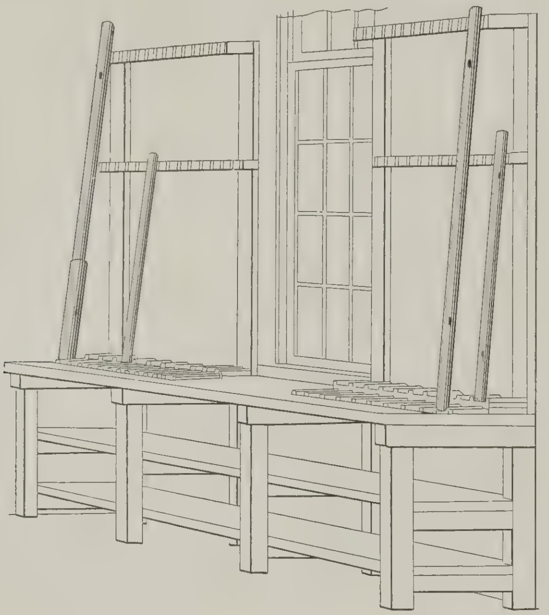
The addition of nickel to steel gives a two-fold advantage: First, it increases the strength and ductility of a steel of given carbon content; and second, permits the use of a higher carbon and therefore stronger steel, because it gives the high carbon steel greater endurance under shock. The characteristics of nickel steel are toughness, great tensile strength, high elastic limit, and the ability to withstand shock.

MACHINE SHOP EQUIPMENT.—2.

THE EQUIPMENT OF THE TOOL ROOM AND STORE ROOM

OSCAR E. PERRIGO.

Before proceeding with the regular text of this article the writer desires in this formal and public manner to heartily thank the many manufacturers who have very kindly sent valuable catalogues, circulars and other printed matter, and even blueprints of their products, as well as letters of approval and good wishes for the success of this series of articles. These favors show emphatically the broad-mindedness of the busy manufacturers and a commendable desire to assist in any effort to spread useful information in reference to mechanical subjects.



Industrial Press, N.Y.

Fig. 1

In the previous article we considered in detail the machine tool equipment necessary in the various departments of the machine shop, and the location of the machines in each group or department, all arranged for convenient supervision and for the ready handling of the stock and the finished parts.

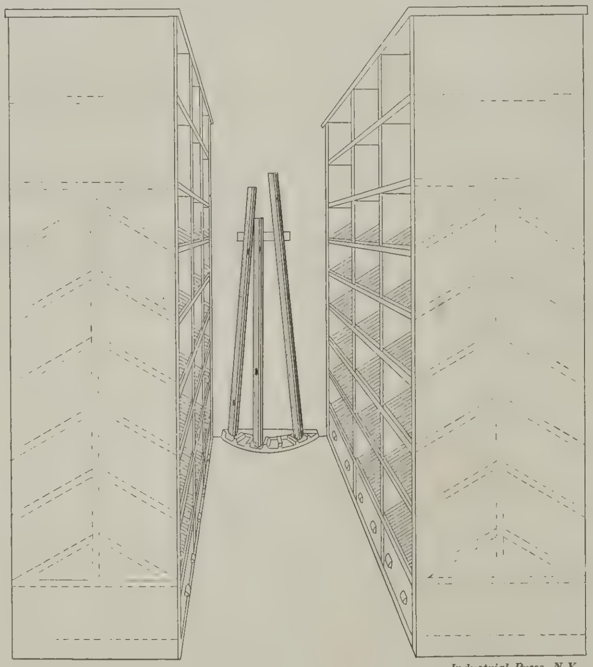
In that article the *machines* in which the work was to be done were considered. In this article it is proposed to consider the *tools* for use in these machines, including a department for making them and proper arrangements for their care, such as providing a place for their safe keeping and regular issue to the shop. It is also proposed to consider, in connection with the store room for tools, the arrangement of the store rooms for the smaller kinds of rough stock, and such purchased parts as are received complete from outside dealers or manufacturers. This plan leads us into the office portion of the building, and consequently a brief explanation of this part of the establishment does not seem out of place, inasmuch as it is, in a purely manufacturing plant, so intimately connected with all the machine shop operations, rather than partaking of the commercial side of the marketing of the product.

The large cut, Fig. 3, accompanying this article, is a plan of the front portion of the machine shop building, showing the relative location of the offices, tool making department, store rooms, etc., and the essential parts of their internal arrangements.

The main entrance to the office part of the buildings is through wide double doors from a large porch and opening into a public space in the portion devoted to office arrangements. The divisions of this portion of the building are clearly shown in the drawings. Upon the outer side are located the superintendent's public and private offices, between which is the stairway leading to the drawing room above, and the necessary toilet conveniences. The public space is separated from the large central space of the general office by a railing, doors opening from both these into the superintendent's public office. The bookkeepers' desks are so arranged that a cashier's window opens into the public space. The timekeeper's desk is surrounded by wire netting, secluding his work from the general work of the office. A door leads into the gateway space, across the large platform scales and into the tool room portion of the building opposite. At one side of this door and as far away from the general work as may be is the telephone booth. A wide hall leads from the central space to the machine shop proper, and divides the private office from the purchased parts store room. This latter is so placed because the purchase, receipt and issue of such stock is more intimately connected with the office work than that of the rooms in the opposite side of the building.

The tool making department is purposely placed away from the general machine shop, as a too intimate connection with it does not seem desirable in practice, while it should be convenient to the drawing room and the pattern shop, which may be reached by the stairs next to the rough stock room, as shown. It occupies the entire front of this square, front structure and is provided with a variety of machines rendered necessary for the making of modern tools and fixtures for properly machining small or medium sized parts. The character of each of these machines is indicated on the drawing. It is also provided with the grinding machines for grinding such tools as lathe tools, planer tools, twist drills, etc. It will be noticed that in providing the machine tools for making jigs and fixtures particular attention is paid to grinding facilities since these are in many cases the best adapted to such accurate work, both as to producing good work and to doing it economically. Large pieces of heavy fixtures may, of course, have to be planed in the planing department, but these cases will seldom occur. The tempering of tools will best be done in the forge shop, the tools being sent there in quantities when possible, rather than to attempt such work in the tool making room with hand forges.

A foreman's office is provided so that he may have a proper place for keeping the records of the work of the department as well as a private room for convenience in making such sketches, plain drawings or details as he may find necessary in carrying out the plans for tool making; these are not always worked out in sufficient detail by the drawing room force, or such as he may wish to devise himself for special work and develop as the necessities for them may arise.



Industrial Press, N.Y.

Fig. 2.

To avoid confusion in the tool making department, a tool store room is provided, where the usual supply of lathe and planer tools, twist drills, taps, reamers, arbors, etc., is kept and issued to the tool-distributing points such as the general room near the engine room and the foremen's offices. In this room are also kept, when they are not in use, the jigs and fixtures necessary for machining small parts, as they can be better cared for here than in the machine shop. The en-

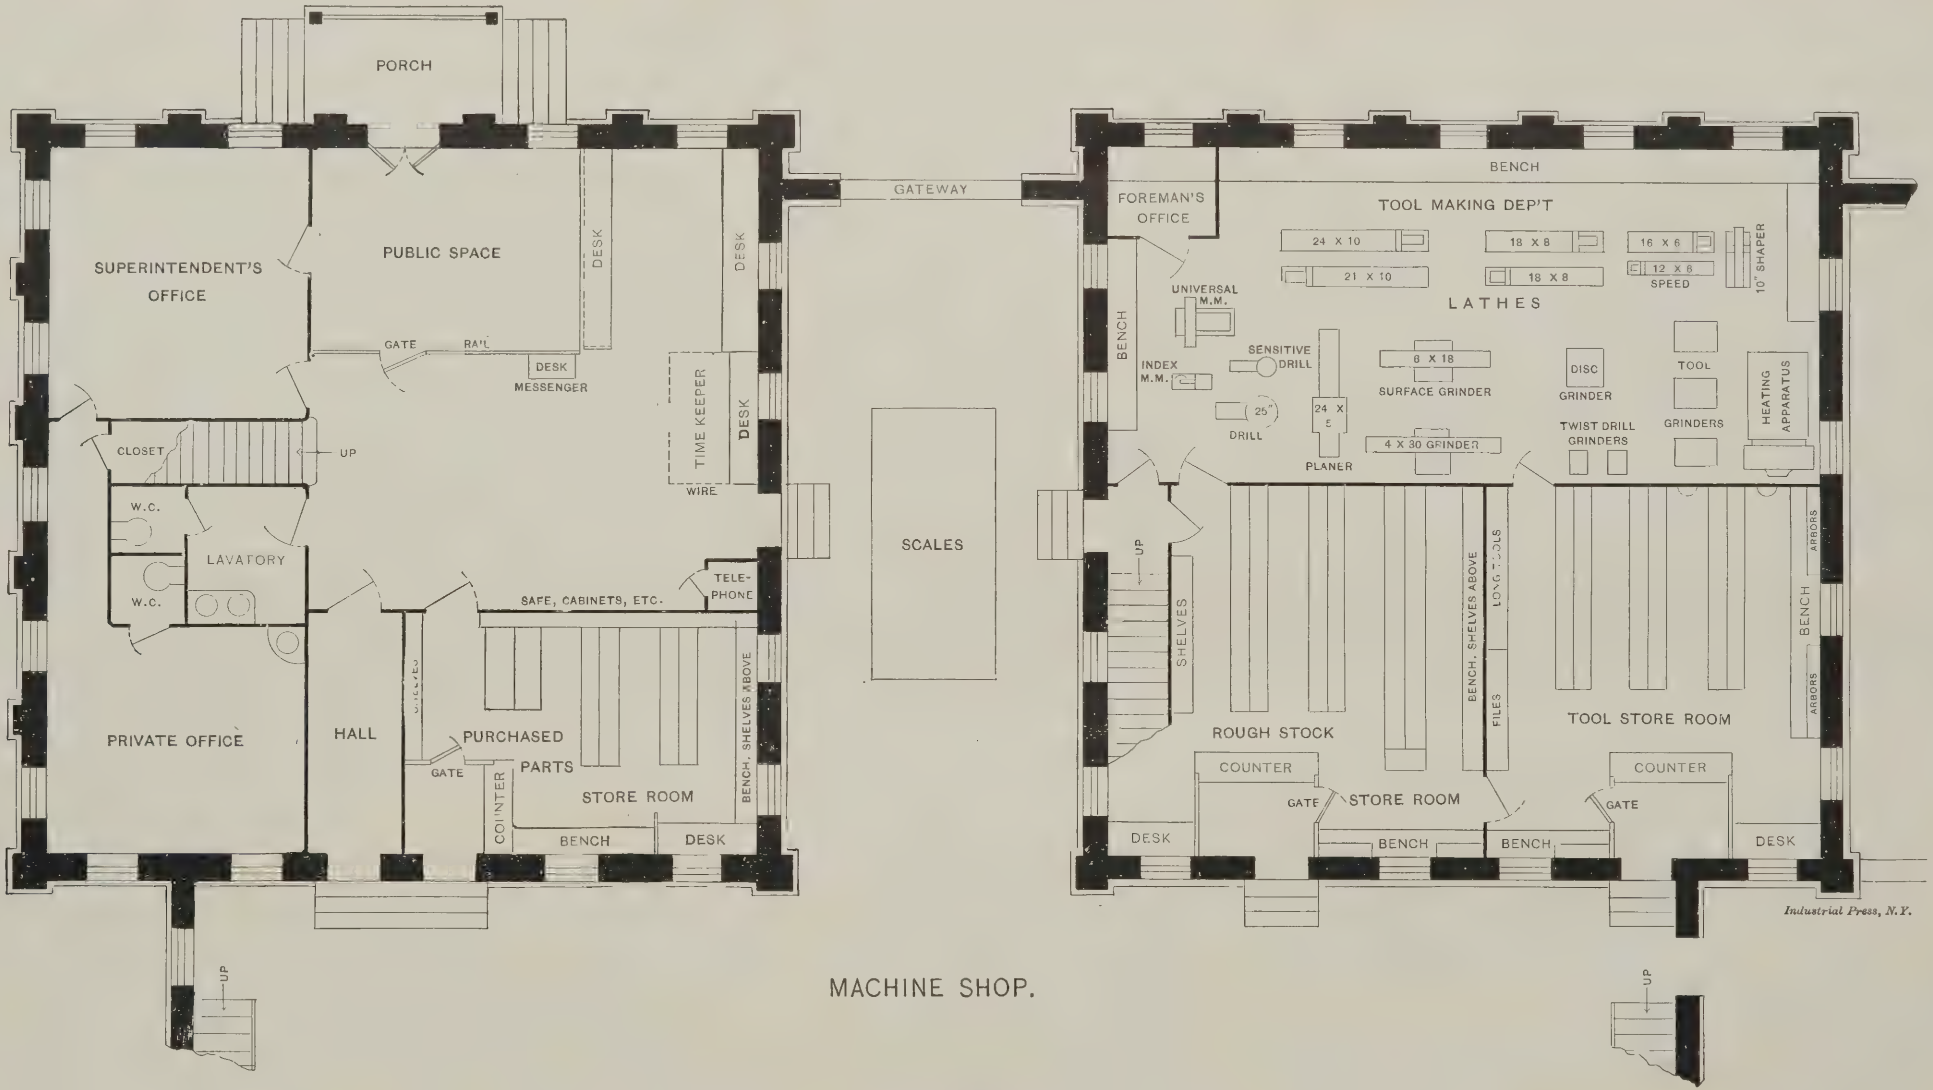


Fig. 3. Plan View of Shop Offices, Tool Room and Store Room, all of which adjoin the Machine Shop.

trance to this room for the workmen is so arranged that he enters a space in front of a counter and has no access to the main space of the room. This will prevent confusion and enable the tool keeper to do his work quickly and properly. To save unnecessary distance in reaching all tools and fixtures the alcoves of shelves are so placed that the alleys all terminate near the issuing counter. At the right is a convenient bench arranged with arbor racks as shown in Fig. 1. These racks will accommodate arbors from four to seven feet in length. The same form of racks may be arranged for any length too long for conveniently placing on the shelves. Beneath this bench are strong shelves upon which may be placed heavy jigs and fixtures. Fig. 2 shows cases of inclined shelves arranged with strips for holding such tools as drills, reamers, short arbors and similar tools, and at the far end another form of arbor rack. This may, if preferred, be arranged similar to the arbor rack shown in Fig. 1. The series of inclined shelves is continued as high as is within convenient reach, and above this point horizontal shelves are provided which will be found convenient for holding jigs, fixtures and similar articles that are seldom used, and not too heavy to be stored at that height. At the base of these cases a series of large drawers is located. They will be found very useful in storing small tools not needed on the shelves, and a variety of such articles as are best kept in such a receptacle until wanted for adding to the regular issuing assortment on the inclined shelves. In Fig. 4 is

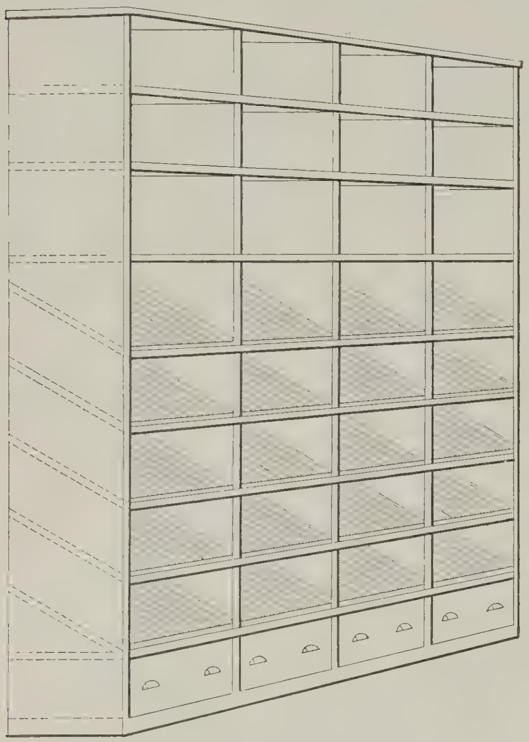

Fig. 4.

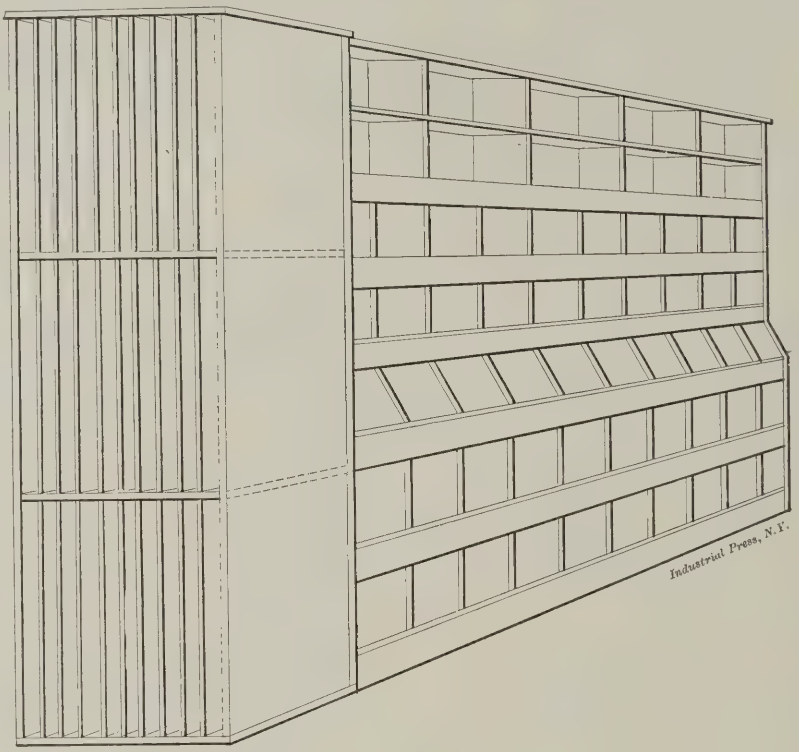

Fig. 5.

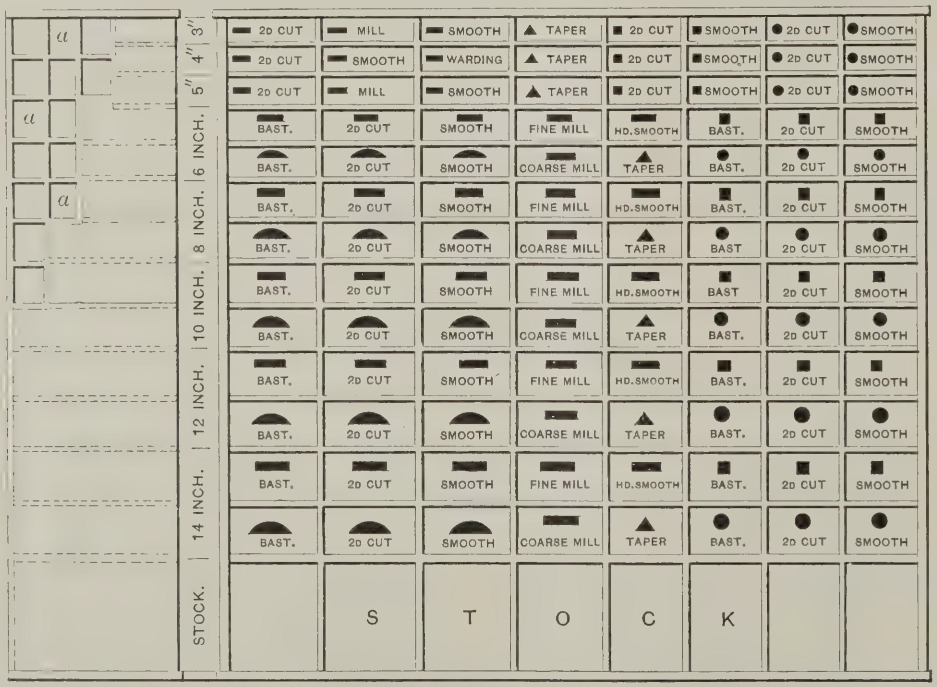
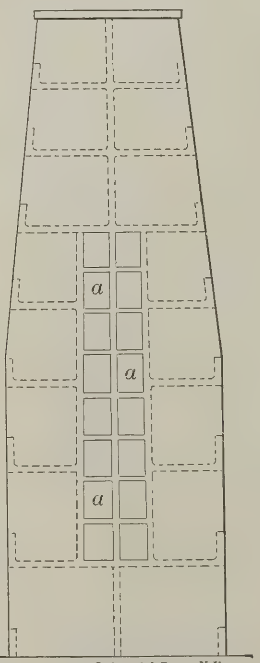
shown a form of case of inclined shelves for longer tools than can be accommodated in the cases shown in Fig. 2. Otherwise the arrangement is the same. The ends of these cases may be conveniently used for the posting of blueprint lists of regular or standard sizes of tools in stock, from which it will be easy to ascertain if a certain tool wanted is kept on the shelves. They may be used as tool check boards, being convenient to the desk and counter. Fig. 6 shows a file case in which a regular system of arrangement of the files of different lengths, cuts and shapes are provided for, so as to make the memorizing of their location easy and convenient. It will be noticed that the smaller files, as the 3-inch, 4-inch and 5-inch files, have each one shelf provided for them, while all of the larger sizes have two shelves to each length, as more different shapes and cuts of these are required. Also, that the coarsest cut is placed at the left and the triangular, square and round shapes follow them toward the right, and that the files of each length are arranged in the same regular order. This arrangement will save much time in issuing files, as well as in distributing stock when it is received. The labels showing the shape, cut and length are placed on the edge of the horizontal dividing shelves, the *shape* being shown as in the drawing. At the base, and below convenient reach in issuing, are compartments for stock. The sizes and shapes of files shown are such as are usually needed in ordinary machine shop work. If a special class of work is done these sizes and shapes would, of course, have to be modified or added to, but the same general plan might be adhered to. As the files at the top of the case are much shorter than those lower down, a waste space will be left in the rear of them. This may be utilized by forming compartments as shown at *aa*, in which drill rods or other similar articles may be placed if such are kept in this room.



Industrial Press, N.Y.

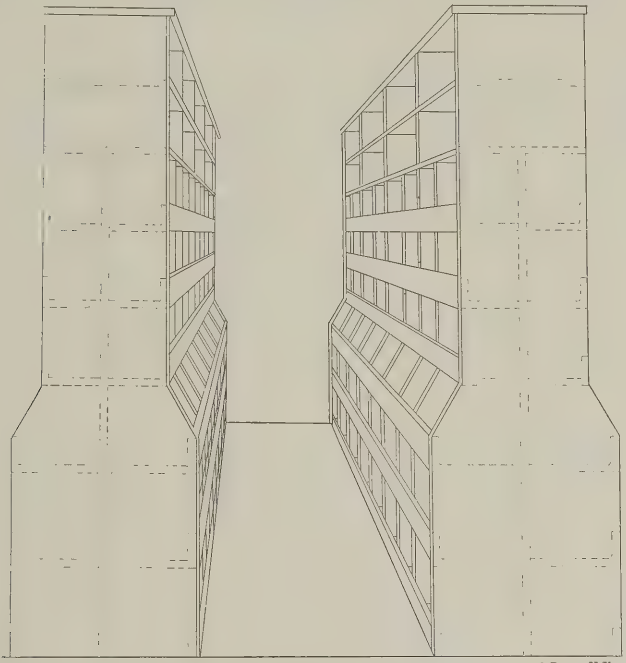
Fig. 6.



Industrial Press, N.Y.

Fig. 7.

From the window opening into the machine shop a system of tool carriers, similar to the cash carriers or the package carriers of a department store, may be run to the tool distributing room near the engine room, to each of the foremen's offices, keeping out of the way of the traveling crane, and to the galleries. These will be very useful in sending in dull tools to the tool department to be ground and in quickly returning the same. Also, in keeping these distributing points supplied with standard tools in proper condition for use. Such a system will soon save its initial cost in the time that would otherwise be spent in carrying these tools, not to consider the many delays in the work, which is usually far more important. Several matters more or less closely related to this subject will be discussed in detail in articles on the management of the work of the establishment.



Industrial Press, N.Y.

Fig. 8.

In the rough stock store room the cases are also arranged in alcoves, and are of the form shown in Fig. 8. These are made wider at the base to accommodate larger articles which are more conveniently handled at this height than higher. The construction is plainly shown in the drawing. At the upper portion plain shelves are provided to hold articles seldom used or of such irregular form as are not convenient to store in bins as arranged below. These may be constructed with a retaining strip at each side, thus forming bins all the way across the case, if the form of the articles stored renders it necessary. In Fig. 7 is shown a modified form of these cases, in which the center portion has formed in it compartments *aa*, in which may be stored round and square cold drawn steel, brass tubing and similar articles, in a safe and convenient manner and without occupying any additional floor space. Fig. 5 shows a case, the front end of which is arranged to hold such articles as sheet brass, copper or vulcanized fiber, in a similar manner to that provided for storing large window glass. This form of construction will be found better than to lay the sheets in a horizontal position, as they can be more conveniently reached, and by providing entirely separate compartments for each thickness, small pieces can be more easily cared for and readily found when wanted.

Wire in coils may be hung upon the walls. It should be so assorted and arranged that all of one material shall be together and that the smallest size is at the top, or at the left of the group.

Various modifications of these plans may be necessary in adapting the arrangements to different conditions and classes of materials to be handled, but in a general way the construction shown will be the most useful, both as to the proper storing and care of the stock, materials and tools, and as to their convenient and consequently speedy delivery when called for.

Cotton waste, or whatever equivalent is used, may be kept in a bin built under the bench, or in a similar one built under the stairs.

A small counter scale weighing up to 80 pounds and provided with a pan for weighing small articles should be provided for the counter.

The purchased parts store room is located in the office portion of the building and is arranged in a similar manner to those just described. All articles purchased outside of the shops and in a complete form to enter into the work, are here received, stored and issued. This will include all kinds of screws, bolts, hardware, belting, belt fastenings, etc. It might include files but they are here classed as tools and put in the tool store room. Oil cans, hand lamps, file cards, emery cloth, grain emery, etc., may also be kept in the tool store room, as being more nearly allied to tools than to either rough stock or purchased parts. For the same reason it might be well to place belting and belt fastenings in this room. Returning to what may strictly be considered purchased parts, the following arrangement of them will be found to be convenient and practical, both for proper storing and for issue. Machine screws should be kept in the original gross packages, on shelves not necessarily over 6 inches in width, and for the smaller sizes 5 inches apart; for the larger sizes about 9 inches apart. For eighty sorts, say from ¼ inch, 6-32 to 2 inch 24-16, and in both round and flat heads, there will be about twenty linear feet of shelving required, exclusive of vertical supports. Setscrews are also kept in the original packages on similar shelves. Thirty-four sorts, from ¼ inch x ⅜ inch to ¾ inch x 2½ inches of both oval and cupped points, will require about twenty linear feet of shelving, exclusive of vertical supports, the shelves to be placed the same distance apart as for machine screws. While the setscrews average larger than the machine screws there are only fifty in a package, against one hundred and forty-four machine screws. Setscrews with V-points, if they are of small sizes, may be kept in the original packages, but if of larger sizes, as for shafting hangers, they are best stored loose in bins. Gib screws, being of the smaller sizes, should be kept in packages or boxes. Round head and hexagon head cap screws of small sizes, say, ¼ x 1 inch to 7-16 x 1¾ inch should be kept in packages on shelves, and will occupy about the same space as setscrews. The larger sizes should be kept in bins holding about five hundred. In arranging shelf space for machine, cap and setscrews it is assumed that there will be at least three packages of each size on hand, which will be sufficient for all ordinary purposes. Special screws are usually made in large lots and are more conveniently kept in bins.

Belting may be placed under the bench at the end of the room. The rolls should be set on edge, between vertical supporting boards, and kept in place by a strip three inches high, placed on the floor in front of the rolls. In issuing belting the roll remains in place and the portion taken off is stretched along the floor and measured to the length required.

Miscellaneous hardware should be kept on shelves, and as it is seldom called for, the higher shelves will be the proper place.

Should the amount of purchased parts be larger in proportion than is here arranged for, the door leading into the general office may be omitted, thus gaining room for one more case and making one more alcove, and a door be cut through into the hall from the space inside the rail. This would add about fifteen to twenty per cent. to the storage capacity of the room.

The desks provided in these rooms should be a fixed top about 44 inches from the floor. Twenty-four inches wide will be ample. The top should be inclined to the front about 1 inch to the foot. Drawers provided with locks are fitted under this top, and below the drawers should be three shelves 12 inches wide, the first 8 inches from the floor and the others 8 inches apart. These will be convenient for storing books, blanks, etc. The space under the counters should also contain similar shelves, but these should not contain articles of regular issue to the shop.

The stock used for building bins and cases should be generally ⅞-inch pine. The divisions in the file case and in the sheet metal case need be only ½ inch thick. It is well to paint all these fittings quite a light lead color, as it is a good wearing color, and should not be so dark as to interfere with ample light. The partitions may be of the same tint up to a line 5 feet above the floor, and above that, including the ceilings, white. The same colors will be proper for the tool making department.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Domestic trade is supplied by the American News Company or its branches.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

OCTOBER, 1903.

NET CIRCULATION FOR SEPT., 1903,—25,183 COPIES.

MACHINERY is issued in three editions—the Engineering Edition, printed on coated paper throughout, each volume comprising 650 or more reading pages and forty-eight 6 x 9 data sheets—price $2.00 a year; the Shop Edition, printed on super-calendered paper, comprising 430 or more reading pages, devoted to practical shop matter—price $1.00; and the Foreign Edition, which comprises the same matter as the Engineering but is printed on thin paper for transmission abroad—price $3.00 a year.

GOVERNMENT EXPERIMENTS.

The propeller planer illustrated in this number is one of a series of very ingenious machines that have been devised by the Navy Department for use in connection with the experimental model tank at the Washington Navy Yard. There is no more important subject for investigation than that of the screw propeller, which this machine makes it possible to investigate. This is particularly true since the advent of the steam turbine in marine work, requiring propellers of unusual design, for high rotative speeds, and concerning which there is but little information available. Thirty-five years ago Engineer-in-Chief B. F. Isherwood carried on an extended series of experiments upon the subject of screw propellers, and his results are standard authority to-day. But since that time government endeavors in this direction have been of a sporadic character and the efforts of individuals have not resulted in a great increase in knowledge upon this subject. What we have gained in the intervening time has come mostly from abroad. In the matter of careful investigation the Germans have led us, and the fruits of these efforts are seen in the tremendous advances in German marine construction. In commenting on this fact Admiral Melville recently made a very frank statement, from which the following is taken:

In all probability England, France and America have each spent more money than Germany in experimental work, but German expenditure, in great part, has taken place before the article is manufactured or the ship laid down, while in the case of some rival powers, at least, the tests and experiments have been conducted instead to discover means of overcoming avoidable defects. The proverbs that "an ounce of prevention is worth a pound of cure," and that a "stitch in time saves nine" are as applicable to-day as they were in the last century. It is for this reason that the preparatory experiments of Germany have been productive of greater results than those of rival powers working in the direction of seeking remedies for existing evils. The rise of Germany as a naval power during the past thirty years has surprised the world. I believe her battleships for their tonnage are the best afloat, because they possess the triple-screw installation of machinery, thus giving the motive power of her larger warships decided economical and tactical advantages. Strangest of all, this excellence in construction is not the result of a progressive series of failures, either in design, construction, or of operation. The success of Germany can be accounted for only by recognizing the fact that study, reflection, and research must have been expended in the preparation of plans, in the building up and the organization of shipyards, and in laying out and carrying on the work of construction. It was the high appreciation of the value of original investigation, coupled with experimental work, that has caused Germany to advance successfully and progressively.

ARE THE CLAIMS FOR EDUCATION MADE GOOD?

A wise man of the West has written a pamphlet which has attracted not a little attention, to show that an academic education, such as given by our best American colleges, is not beneficial to a young man who is to have a business career. In the latter part of the pamphlet the attempt is also made to show that a technical education is also of considerably less value to its recipient than it is commonly supposed to be.

It does not make so much difference where an education is obtained—whether at home, in day school or at night school. Many have obtained liberal educations who have spent very little time behind the walls of a schoolhouse. The main advantage of the school and college, over the home or other method of study, is that the work can be completed more quickly and under proper guidance, with many facilities in the way of apparatus, models, exhibits, etc., that are nowhere available except within the school walls. Hence, an arraignment of college education is really an arraignment of education itsself, wherever obtained, and it is very pertinent to ask, Does it pay?

To the open minded no argument is needed for an affirmative answer, for it is by knowledge, and knowledge only, that advances in the world have come; but if statistics are desired, Prof. Thurston, of Cornell University, has been gathering a little information with regard to the fruits of technical education, which, all things considered, we believe, indicates that education does pay, not only in the satisfaction and pleasure that it gives, through broadened views and better grasp of affairs, but in actual dollars and cents. Prof. Thurston has reports from 1,000 graduates of technical courses, and it is fitting to ask, whether similar returns from 1,000 men who have not had technical training, but who started out at the same time that these various students did, and who were in the same condition and circumstances, would show as good results. This would give a fair test of the question of education and its value, and each reader can form his own conclusion in the matter. Prof. Thurston says:

"A list of one thousand has been prepared for me, tabulated. The average period since "graduation" is about seven years. Of these, so far as reported, one-third are holding positions of independent responsibility; one-eighth are managers and superintendents of work; ten per cent. are teaching in the professional schools and twice or thrice as many are wanted. Ten per cent are designing engineers, planning the machinery of the work shops, the manufacturing establishments, the railroads and the fleets of the country. Several are editors, one-fourth are manufacturers; many are presidents and vice-presidents of corporations, others are treasurers and the balance are distributed throughout the whole system of industries of the country. One-half of these men are not above the average age of 27 or 28 years; and 95 per cent. are not over 35 or 37. Practically all retain their connection with their profession. They commonly realize and fully appreciate their advantages, educationally.

"Of the calls which I have received for men in all grades from the 'captains of industry,' 45 per cent. are for positions worth $750 to $1,000; 15 per cent. at $1,200; 20 per cent. at $1,500; 15 per cent. at $2,000; 5 per cent. at $2,500, and in many cases from two to ten men are sought. The needs are greatest in the highest positions and where men capable of carrying large responsibility and having exceptional executive capacity find their place.

"One of the best gages of the value of these men when well suited to their profession is found in the fact that when these alumni of the engineering colleges are asked if they desire to change their present positions they almost invariably reply that they are well satisfied. Asked at what salary a change would be considered 10 per cent. of these giving definite figures propose $1,000; 30 per cent. $1,500; 30 per cent. $2,000; ten per cent. $2,500 and 5 per cent. in each grade $4,000, $5,000 and $6,000. The ablest men in highest positions usually declined to consider a change of employers or of employment."

THE ST. LOUIS EXPOSITION,

WITH REPRESENTATIVE OPINIONS FROM THOSE WHO WILL AND WILL NOT EXHIBIT.

In another part of the paper is an account of the engineering and mechanical features of the Louisiana Purchase Exposition to be held at St. Louis next year, in so far as plans have been developed and work accomplished. As yet it has not been possible to secure a list of exhibitors or of space allotments in the machinery building, for at this writing assignments have not definitely been made, except in the power department. Enough is known, however, to indicate that there will be a great show of machinery, probably surpassing in quantity that at any previous exposition, either here or abroad; but whether the machinery exhibits will equal in novelty or general interest those that have been seen elsewhere, as for example at Paris or Dusseldorf, we are not prepared to predict, although the management is very sanguine in this regard. From what we can learn we think it doubtful if it will be as representative of American machinery as could be wished; but for the mechanic and engineer not familiar with European practice, it will probably present more interesting features than any American exposition since the Centennial of 1776, because of the large assignment of space already made to foreign exhibitors, who will show machinery more or less new to Americans.

Machinery Hall is a very large building, and at the outset it was supposed that it would be ample for all requirements; but as the case now stands it is stated by a representative of the department of machinery at St. Louis that it would have been possible to have filled a much larger building and that there are now more applications for space than can be allotted.

In spite of this fact, it has been evident to us that there was a very noticeable apathy among American machinery manufacturers, especially in the machine tool trade, with respect to the St. Louis exposition. Lately more interest has apparently been aroused, largely, we judge, because of the considerble number of exhibits which have been secured from abroad through the enterprise of the management. The most important of these are of steam and gas engines, with boilers and gas producers, to the extent of 40,000 horse power, in itself a most important power installation, and one of general interest to people in this country.

Some manufacturers who have had experience at expositions, but without direct returns in the way of business, have felt that it was "crowding the mourners" to ask them to spend the time and money necessary for a display at St. Louis so soon after the expositions at Paris and Buffalo, and have frankly so stated in letters to us. On the other hand, many have secured good results from exhibits and are even enthusiastic over the opportunities this show will present for the extension of their business interests. These and other views have come to us in one way or another; and to arrive at some conclusion in regard to the sentiment among the trade, particularly the machine tool trade, we addressed a circular letter to a list of the American machinery exhibitors at Paris and Buffalo. In this the conditions as we found them were stated and we asked for opinions as to direct or indirect results from previous exhibits and also if the firm addressed was to exhibit at St. Louis. We believed that a general expression of views on this subject would be of benefit to many individual manufacturers. It has been well demonstrated that to secure the best returns a display of machinery should be a "live" exhibit, with machines turning over, and that the firm must be represented by competent salesmen and capable attendants, in order to secure results commensurate with the cost of the installation. The vital question in regard to all of this is, Does it pay? And only those who have "been there" are competent to give the answer.

Eighty-three replies were received to our letter, from firms who exhibited at Paris or Buffalo, or both, and their replies may be classified as follows:

83 exhibited at Paris or Buffalo.

43 of these have decided to exhibit at St. Louis.

28 have decided not to exhibit at St. Louis.

12 are still uncertain.

22 of those who will exhibit believe that past exhibits have been profitable.

21 of those who will exhibit are not sure about results, but are going to St. Louis, either because their competitors will be there or because on the whole an exhibit is believed to be a good advertising proposition.

We have not attempted to publish extracts from all of those heard from, but in what follows are representative expressions of opinion giving as fair a resumé of the sentiment of the trade as we are able to prepare. In the first group of "Those who will exhibit" it will be noted that some state the direct returns from past expositions have been satisfactory, while others are not so sure of this, but believe in a general way that returns have come indirectly and that it is a paying proposition. A few will exhibit from "patriotic motives" and we suspect a good many because competitors are to be there. In classifying this group, we find, as stated above, that 22 out of the 43 were definitely assured of direct returns from their exhibits at Paris or Buffalo.

Those who will Exhibit, because they believe Exhibits Pay.

We will exhibit at St. Louis with a "live" exhibit, as our experience at Buffalo was a very satisfactory one in both direct and indirect returns.

As a general proposition, we believe Fairs pay. We were exhibitors at Paris and Buffalo; Paris did not pay us; we think Buffalo did.

We did not have an exhibition at Paris, but did have one at the Pan-American exposition, to which we have traced some very good results. On the whole we feel satisfied with our exhibition and the results thereof.

The Buffalo exposition proved a very profitable advertising medium for our machines, and we believe we were fully justified in making the expenditure. It is our intention to exhibit at St. Louis and we shall have a "live" exhibit so far as possible.

Our exhibits in the past have brought us sufficient direct business to warrant the expense we have been to. We do not believe that a small exhibit pays, and unless we can have sufficient space we prefer to stay out.

Are pleased to say that we obtained direct and indirect results from the exhibit at Buffalo, such as we feel justified the expense incurred. It is our opinion based on our experience, that an attractive exhibit, properly looked after, and the missionary work done, and foundation laid for getting increased and new business, properly followed up thereafter, are sure to bring satisfactory results.

As regards our Chicago and Paris exhibits, we recall having received direct returns from the former, but the results from the latter were more a matter of publicity and advertisement among a new class of trade, resulting in trial orders, which we have since been following up with good prospects. We intend to exhibit at St. Louis, believing that it will pay us to do so.

We had exhibits at Paris and Buffalo, and while it is very difficult, if not impossible, to trace the direct results of such exhibits, yet on the whole we were satisfied with the results of both of these exhibits, and we looked upon the same as perhaps being a better advertising proposition than the trade papers.

At Paris our exhibit was in charge of our foreign representatives and we believe that results proved satisfactory to them. We were unable to trace many sales resulting from our Buffalo exhibit, although we believe that the general advertising received was of considerable value. We certainly had many callers and interested many people. Under proper management we are inclined to believe that an exhibit at St. Louis would repay us for its cost.

In our opinion we received sufficient returns, both direct and indirect, from our exhibits at Paris and Buffalo to warrant the expense. An exhibition of a high character places the manufacturer before many people with whom it would otherwise be impossible to get into close contact. For these reasons and prompted by a feeling of patriotic duty, we intend to make an exhibit at St. Louis.

In our line the direct results are very small indeed but we feel that an exhibit properly attended is a good investment. If it is possible for us to secure the space which we desire at St. Louis and some one can be spared from this office to properly represent the company, we shall certainly be there with a handsome exhibit.

Our exhibit at Paris was handled through a local agent and brought us very little, if any, direct returns. Our exhibit at Buffalo, however, was under our personal supervision and we believe gave us quite a little prestige on certain machines. We undoubtedly received orders, both directly and indirectly, as a result of our exhibit, but like all other orders given on account of an advertisement we could trace only such as directly referred to our exhibit. The only thing we might add to your two questions, by way of suggestion, is that in the event of awarding medals, a different method be employed than was in vogue at Buffalo, where, apparently, any exhibitor could procure a medal. Where but one Gold Medal is awarded for each class of articles, an exhibitor would feel a natural pride in receiving such a medal.

We are strong believers in the advantages of exhibiting at such expositions as will be given in St. Louis, and we have exhibited at fourteen of the different expositions since 1874. We always prefer a live exhibit—that is, one where the machinery is running, and, if possible, producing its regular products. We think, with the exception of the New Orleans Exposition, every one of the expositions has brought us good returns and helped us to build up trade.

It is practically impossible to trace, more than in a general way, the results of making these exhibits. There is no question in our mind but that indirect returns result and warrant the expense incurred. Persons who examine exhibits of machine tools do not come prepared to place orders at the time, but an impression is made upon the party which may result in an order later on. It is one of the ways of keeping your product before the people, giving them an opportunity of examining the machine itself.

We consider that our exhibit at Buffalo brought us sufficient direct and indirect returns to warrant the expense incurred. We had power and an operating exhibit, and the expense was a heavy one. We, however, had plenty of competent, hustling, wide-awake representatives at the exhibit, and this we believe in great part made the returns. They were able and ready to take care of people who stopped and appeared interested. We kept very full records of every one whom we talked to, and we made it a point to talk to every one who stopped. These were afterward followed up.

The Chicago World's Fair was international enough in scope to pay exhibitors and we think the Paris Exposition was also satisfactory; but the one at Buffalo was more of a domestic affair and many who were there decided not to exhibit in future. We believe it is better to have an exhibit where you can show your goods to foreign buyers than to try to sell them from a catalog or samples and think the St. Louis Exposition will be much better in this respect than was the Pan-American.

We did not exhibit at Buffalo, because we could not get enough space to make a good representation of our line. We exhibited at Paris and felt well repaid, as we disposed of our whole outfit and had a good deal of trade resulting from our exhibit there. We were also large exhibitors at Chicago, and sold nearly our entire exhibit. We kept a record book with names of visitors to our space and made a number of valuable customers in foreign countries, and also sold a large bill of tools in this country. We can trace directly a great deal of benefit in the way of trade through acquaintances made at the expositions. We intend to exhibit at St. Louis and feel that it will pay manufacturers to do so if they make goods adapted to the general wants in their line throughout the world. If products are adapted to a certain locality, only, of course exhibitions cannot be of so great benefit; but we feel that there is no greater opportunity to present goods to possible buyers than at such representative expositions as the one at St. Louis promises to be. The earnestness, intelligence and straightforwardness of the heads of departments connected with the St. Louis Exposition will have much to do with encouraging manufacturers to make special efforts to exhibit there. I might add that it is shortsightedness in many exhibitors to go to a large expense to fit up fine exhibits and then place them in charge of incompetent men. They don't select as good talent to represent them as they do to prepare their exhibits, and when a possible customer comes along, seeking information regarding the special adaptability of a tool or device, he fails to find a man competent to explain it and give such information as he has come to the exposition to get.

Those who will Exhibit, but do not feel so Confident of Results.

Our exhibits at Chicago, Paris, and Glasgow have only brought in small direct results—certainly not enough to warrant the expense. Indirectly we have probably received returns, although it is only our guess.

We regard an exposition in the light of an advertisement, and it goes without saying that all advertisements in trade papers do not bring direct returns to warrant the expense incurred; but for all that, we consider it necessary to advertise, as most of the benefit of our advertising comes indirectly.

We are in doubt as to whether our Paris exhibit brought returns to commensurate expenditures; hard times set in throughout Europe subsequent to the exposition, and this somewhat counteracted the desire to purchase new tools. Did not exhibit at Buffalo. We will exhibit on a large scale in St. Louis, believing the Fair will prove successful in every way.

We exhibited at Paris and were it not for the fact that our machines were grouped with others represented by our agents, thus reducing our expense, we should have considered it quite a failure. If we had not exhibited we think we would have seen no great difference in our sales. It is our intention to exhibit at St. Louis, but our only reason for doing so is that we presume our competitors will be there also.

It is very difficult for us to tell whether or not our exhibits at Paris and Buffalo brought us any returns, or, at least, sufficient to warrant the expense that was incurred. Nevertheless, we have always believed in exhibiting at large expositions, as we secure a large amount of advertising, the results of which are undoubtedly beneficial.

As to whether our exhibits at Paris or Buffalo paid, we say emphatically, No! We look at it in this way: That while it may not pay to exhibit, in a financial sense, and while it may mean a loss in dollars and cents, our wares have an extended sale over an extended area of territory and we feel that we cannot afford not to exhibit.

As to direct results, in the machine tool line, you can hardly expect the exhibit to bring sufficient direct returns to warrant the expense. But on the other hand if you take into consideration the fact that your machines will become better known throughout the country, which will no doubt bring future inquiries and consequently orders, we think the small expense should not be considered.

We believe that all of our exhibits in the various domestic and foreign expositions have paid on the broad ground that advertising pays. We think it would be very difficult for anybody to tell just what he got out of an exposition. We have had trouble about getting our space assigned. In general, expositions are not nearly as good as they would be if space could be given out in ample season so that makers of machinery could have plenty of time to prepare their exhibits.

We must say that we are not very much in favor of expositions, but are rather forced to show our goods, as our competitors always make a good display. We went into the Paris Exposition more on account of our foreign agents, who had, during the previous years, done a very nice business for us. The depression came along soon after this exposition and since then our foreign business has been rather light. It is our intention to make quite a display at St. Louis, for we agree with you that a "dead" exhibit is of no value. We are therefore making preparations to have a large display.

Our exhibit at Buffalo did not bring us sufficient returns to warrant the expense incurred, but it is our intention to exhibit at St. Louis. Under the head of "Remarks," beg to say that a page advertisement in MACHINERY would give better returns than all the expense incurred would bring in exhibiting at one of these expositions, and at a great deal less cost. The reason of our going into these various expositions has been in almost every instance at the very urgent request of our sales agents, but where they have been asked to share the expense, we think they are about as tired of it as we are. We have been in a great many expositions for years past and this has uniformly been our experience.

At the Philadelphia Exhibition our returns, direct and indirect, were very satisfactory, but we were disappointed both in Chicago and Paris. As to St. Louis, we expect to be there; not that we expect it to pay, but because we cannot afford not to be represented. It is a strange fact that nearly all large exhibitions occur at a time when business is dull. At Philadelphia in '76, at Chicago in '93 and Paris in 1900 business was very bad in Europe and there is every probability of the same state of affairs at the time of the St. Louis Exhibition. We think the St. Louis Exhibition is coming too quick after Paris and Buffalo.

It is our intention to exhibit at St. Louis if proper space can be obtained, although our exhibit at Paris did not bring direct or indirect returns enough to warrant the expense incurred. We attribute our failure at Paris, however, to the fact that our officials at Washington have failed to sign a treaty with France that would bring us into closer commercial relations with that country. We have to pay an import duty, as the case now stands, of 3 to 7 cents a pound on machinery that we manufacture, and are thus frozen out of the French market. Another reason for loss at Paris was the exorbitant prices charged by concessioners who had bought the right to furnish the supplies and do the work required by exhibitors.

It is our intention to have space at St. Louis as we had at Paris. We do not consider that a great deal of benefit is derived from these expositions, but they serve as an advertisement, and a few customers may be secured by having machines shown off to good advantage. We recollect one rather peculiar incident in connection with the exposition in 1893 in Chicago, where the writer gave a person a catalog and some eight or nine years later he turned up with the same catalog ready to make purchases to the extent of $2,500 or $3,000, and we secured his entire order; but of course cases like this are rare. We were not benefited greatly by the Paris Exposition, and on this account neglected to have space at the Buffalo Exposition. We understand that manufacturers in general are to go into the St. Louis Exposition with good-sized spaces and we desire to do the same.

We exhibited at Paris, and the total cost, including transportation, etc., was $5,000. We believe that the results would have been better by an expenditure of 10 per cent. of the above amount in advertising in a legitimate trade journal. We were very much disappointed in the business received from our exhibit in Paris. It is our intention to exhibit in St. Louis, provided we can get suitable space and the conditions imposed by the managers are not of such a character as will, in our judgment, interfere with our exhibit. The rumor has reached us that they propose to force all exhibitors to display their respective machines in different groups. If this is true, it will affect us disadvantageously, for we manufacture two distinct lines of machine tools, and if we should thus be obliged to have two men in St. Louis, where one ought to be sufficient, we will probably withdraw our application.

We have had a number of people mention our exhibit in Buffalo and state that they were pleased with what they saw but in most cases they were users of our machines. Exhibiting our product at any exhibition is similar to advertising in your paper or in any other mechanical journal. We feel that there is a limit to this advertising, when the returns are considered. It is a certain amount of money expended in nothing more nor less than advertising, and as you well know, it is rather difficult for us to be sure of the exact results. If we should fail to exhibit, and our competitors should exhibit, we are sure a great many people would be making inquiries as to why we were not there; and the chances are that they would be under the impression that we did not have anything of importance to bring forward, and for this reason did not care to take part. But do you not think that all of the manufacturers in this country should look at this in a broader sense and be willing to send their machinery to this exhibition, if for nothing more than to show the true American spirit? Supposing that manufacturers of all kinds of products should get together and finally decide that they were not sure the returns would be equal to the expenses and fail to send their goods to this exhibition, imagine what a condition this would be, and for this reason I think we should exhibit our machinery at St. Louis, even if our competitors actually failed to do so.

Those who will not Exhibit.

Of the 83 replies received, all from firms who exhibited either at the Paris or Pan-American expositions, or at both of these, as the case may be, 28 do not propose to exhibit at the Louisiana Purchase Exposition, and 12 are still uncertain. In a few instances, as indicated by the extracts from letters below, there are special or individual reasons why they will not take space at the coming exposition, as for example, because the character of the product may not be such as to make a live exhibit possible, except as the tools be shown in connection with other machines; or the diversity of product may be so large that an unusually large and expensive exhibit would be required to make a comprehensive display. The ruling, also, on the part of the exposition managers, that no dealers will be allowed to exhibit, but that all products must be shown by the manufacturers themselves, precludes manufacturers from exhibiting jointly, through some dealer, and thus saving a considerable portion of the expense.

For the most part, however, those who are not to be represented at St. Louis will stay away because they feel that their exhibits at Paris and Buffalo did not net satisfactory results and several express themselves very positively in this respect. One concern writes: "We have failed up to the present time to have received the first indication that either of our exhibits at Paris or Buffalo has done us one cent's worth of good." Another one says: "We are not satisfied that any exhibit we have made has brought sufficient business to pay for the expense and time." Another, "We made a showing at Paris which we have reason to believe was a pretty good one, but we have never been able to see how we have been repaid for the expense we were put to." And another, "Our experience in these matters is such that we are not over-enthusiastic." Several letters of like character were received from those who will not exhibit, which we will not take the space to publish; but below are a few extracts from communications expressing in a more varied manner the opinions of the writers and which are fairly representative of those who will rank among the stay-at-homes in 1904:

We exhibited at Buffalo and it was by all means a very unprofitable venture. It is not our intention to exhibit at St. Louis, owing to the fact that they have laid down very rigid lines which will not enable several of the smaller manufacturers to make a combined exhibit.

It is not our intention at present to exhibit at the World's Fair. It would be expensive, as we would have to maintain the exhibit independently. If we could place our exhibit in the hands of one of our representative dealers in St. Louis, who would exhibit machinery as a dealer, we would no doubt have done so.

We have always felt that in the case of the larger expositions it was a desirable thing to go to them, but this year we have not as yet decided to go to St. Louis and doubt very much if we shall do so. Such an exhibition involves a great deal, not only in the money expense but in the withdrawing from our force some of the best men for a protracted period.

Our experience with such affairs has been rather unfortunate; unprofitable from a business standpoint and unpleasant from a personal view. We believe that one-quarter of the outlay necessary to the installation and maintenance of a proper exhibit, invested in almost any other advertising proposition, and especially used judiciously among the standard trade papers, would produce infinitely better results.

Our exhibits at both the Paris and Buffalo expositions were not productive of business results that would warrant our again taking space in an exposition of like character, although, from the standpoint of "prestige" our results were flattering. For the amount of labor, time and expense involved in preparing and maintaining an exhibit of this kind, we believe the results are inadequate, or, at least, they have been so in our case.

From previous exhibits at expositions we have not received enough results to give us a fair return for the amounts expended. We believe that if we had spent the same amount of money by some other method of advertising it might have brought more returns. Lest this be considered a rather one-sided view, we will say that we believe there is no better way to advertise certain lines of manufacture than by public expositions.

I personally believe that the only persons who make money out of these big expositions are the men who draw salaries from the exposition, and that nine-tenths of the exhibitors net a loss for their trouble. This is from observation rather than from experience, although I have had some unfavorable experience of my own. I have repeatedly written the management of the St. Louis Fair that I considered the managers are the only ones who would be benefited by the exhibit.

Your favor of the 2d is received. We decided after the World's Fair in '93 that it had not paid us, and that we would not go into another American exhibition. There seems to be more effective ways of reaching the home trade for an equal expenditure of money. But we are satisfied with the results of our exhibit at Paris. Europe was a newer territory for us, which it is not so easy to cover by traveling representatives and newspaper advertising.

Our exhibit at the Paris Exposition was absolutely without profit to us. The expense was very great for a concern of the character of ours, not only in the first cost of investment, but in freights, the cost of maintenance, and various incidental items for which only the French know how to charge. A live exhibit at St. Louis would be expensive, and we believe that there is a lull coming in the machine tool trade that will extend over a long period; therefore we think there are other ways of advertising that are more desirable and profitable.

We considered at the conclusion of the Paris Exhibition that we had obtained very little satisfaction as a result of our exhibit. Our trade in France has, however, gradually increased from that time, but it is difficult to determine exactly how much of this trade is due to the Paris Exhibition. Following this we exhibited at Glasgow with very good results. We did not, however, exhibit at Buffalo, and do not propose to exhibit at St. Louis. We consider that the money expended for such exhibits in this country can be applied to better advantage in other ways.

We went to considerable expense in making and maintaining an exhibit at the Paris Exposition, but have been unable to trace any returns that would in any way warrant the expense incurred. We look at these expositions as a rather expensive means of advertising, and so far as we are able to judge it is one of the means of advertising that does not pay us, for our tools are of such a character that they must be shown in connection with other machines to be operative. Many of our tools are shown by the manufacturers of such machines, applied to the machines, where they can best be shown.

Those who are Uncertain.

As stated above, 12 of the concerns heard from in reply to our circular letter had not at the time of writing decided whether they would exhibit, the reasons for the most part being that their previous exhibits had not paid and their hesitancy in the matter springing, evidently, from a feeling that it might be a mistake not to exhibit, in spite of the expense, as long as competitors were to have displays. A few of the letters from such firms are quoted from below. Inasmuch, however, as there are more applications for space in the machinery building than there is space to be had, it is probable that these 12, or most of them, at least, can be counted with the 28 who will not exhibit.

The Pan-American exhibit brought noticeable direct and indirect returns. An exposition is an advertisement, but we doubt, however, whether the expense was as profitable as though it had been incurred through other channels.

We are hesitating about arranging for any exhibit at the St. Louis Exposition, as we have seen no direct results from other exhibits of like kind. We believe if the same amount of money necessary to make a good display should be used in having travelers make personal calls on the trade, that far better results would be obtained.

Our experience has not been very satisfactory at previous expositions, and it is a question whether we will exhibit at St. Louis. Our direct sales at Paris probably paid the expense of the exhibit; and of course we got more or less advertising from same; but in a general way we do not think that exhibits of this kind bring direct returns enough to warrant the expenditure of both time and money.

Our impression is that we have not from a financial point of view received any great benefit either directly or indirectly from exhibits. The great majority of people who visit these fairs are not looking for business; they simply glance at what they see in passing by, and at the World's Fair it seemed to the writer that the most interest taken in general manufacture, or goods of a general character, was manifested by foreigners, largely German and Japanese.

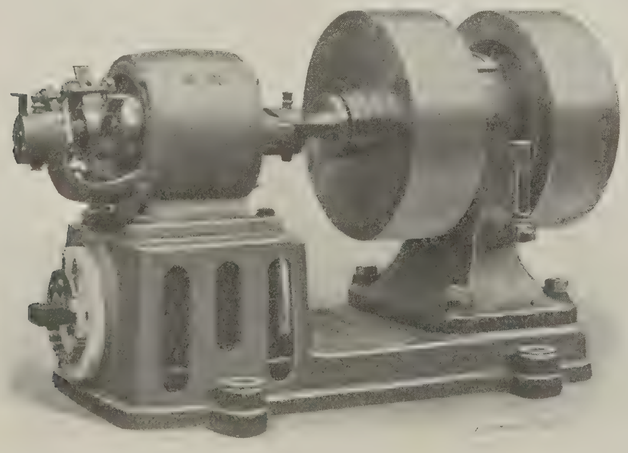
We do not feel very enthusiastic about going to St. Louis and it is uncertain whether we do so. We have exhibited in all of the principal expositions since 1873, and are unable to say whether they ever did us any good or not. The expense increases at every exposition that is held, and in our opinion the showing of goods is growing less valuable at such places, for the reason that people are getting tired of them. The first one or two expositions attracted a great deal of attention, but the interest in them is dwindling away, and it is our opinion that the principal part of the exhibitors take their wares to an exposition because they feel almost forced to do so.

* * *

A NEW GERMAN ELECTRICAL OIL-TESTING APPARATUS.

FRANK C. PERKINS.

It is very necessary where apparatus is in operation continuously and at medium or high speeds that the highest grade of lubricating oil be used. In large shops, power plants and factories where a considerable quantity of oil is required it is very desirable before purchasing to thoroughly test the oils both in order to find out the most desirable oil for the particular apparatus in use as well as to determine whether subsequent shipments are up to the standard determined upon.



Oil-testing Device, Electrically-driven.

A new electrically operated oil testing apparatus has recently been brought out by the Elektricitats-Actien-Gesellschaft, formerly W. Lahmeyer & Co., of Frankfort-on-the-Main, Germany, which is of more than passing interest. It is possible with this oil tester to accurately determine the frictional coefficient of different grades of oils at varying temperatures. It consists of a short length of shaft running in a bearing of the ring-lubricated type, and carries a heavy flywheel at each end which produces the ordinary pressure on the bearing.

A pin coupling is provided on this shaft in order that the motive power can be uncoupled at any moment while running. The apparatus is designed to be driven by an electric motor, by mechanical means or by hand. For laboratory purposes the machine is arranged with flywheels for different bearing pressures and an exact device for measuring the speed. The apparatus when electrically driven as noted in the accompanying illustration is equipped with a motor having an output of about 1-6 of a horse power, which operates at a speed of 1,800 revolutions per minute. The motor is set upon a common base plate with the oil testing machine and drives the latter by means of a pin coupling.

The machine, when mechanically operated and driven by belt, is of similar construction, having a suitable coupling for disengaging the motive power at the proper time. When the oil testing machine is hand driven, two small reduction gear spindles are arranged so as to obtain a speed of from 1,500 to 1,700 revolutions per minute at the flywheel spindle, a similar uncoupling arrangement being also provided as above.

When testing a sample of oil about one-half a pint of the lubricant is placed in the bearing and the motor is started, the flywheel shaft being run at full speed for a short time, when the motor is disconnected by means of the coupling, allowing the tester to continue running until it comes to rest. It is only necessary to note the time required for the apparatus to come to rest in order to compare the lubricating qualities of the various samples, the better the quality of the oil, of course, the longer the shaft will run before coming to rest.

When another sample of oil is to be tested, benzine is passed through the bearing in order to thoroughly clean it, and a blast of air is allowed to pass through as well, to dry it out, thus obviating the necessity of taking the apparatus apart. This method of cleaning has been found to work with perfect satisfaction after many trials of both ways.

This electrical testing apparatus is fitted with electrical resistance coils for warming the bearing to any desired temperature. A wide range of regulation can be obtained, and the frictional coefficient of various classes of oils can be tested under normal conditions of working of different types of machines.

With the mechanically driven oil testing machine, tubes are provided in the oil reservoir, through which hot water may be passed and these tubes can also be used for cooling by passing cold water through them at any desired temperature.

A method of determining whether or not the oil is likely to solidify, is to place the lubricant to be tested between two polished iron plates and laying them together, when it will be found that if the oil is at all likely to solidify it will be difficult to move the plates against one another after a short time has elapsed.

In order to test the oil to determine whether it is free from acid, it is only necessary to dip a polished copper plate into the sample for a short period of time, and note whether there is any difference between that part of the plate which was in contact with the oil and that which was not immersed.

* * *

In an article on safety mining lamps, published in the *Journal of the Franklin Institute*, Mr. Rufus J. Foster gives a history of the various schemes of lighting used in gaseous mines. Candles and various forms of lamps were early used for lighting mines, but, of course, these could not be used when the workings became foul. Under such conditions the skins of putrid fish were sometimes hung up close to the face of the coal. The slight phosphorescence of the skins enabled the miner to barely see the outlines of his work. Not so repulsive, and more interesting, were the "steel mills" used for lighting mines. These crude devices consisted of a steel wheel mounted on a shaft carrying a small pinion. Meshing with this pinion was a larger gear wheel operated by a crank, the whole being mounted in a light frame so that the machine could be easily carried about. A boy vigorously turned the crank with one hand while with the other a piece of flint was pressed against the side of the steel wheel. The result was a shower of sparks having a very slight illuminating effect, being dangerous to boot. Several disastrous mine explosions are recorded which resulted from the use of the mills. The invention of the Davy safety lamp in 1815 is one of the great benefits conferred on humanity by the inventor. It has saved countless thousands of miners' lives and made the operation of gaseous mines possible that without the Davy lamp could not be worked at all.

THE POOLE WORM-DRIVEN BORING MILL.

The half-tone, Fig. 1, illustrates an 8-foot boring mill which is one of a new line of machines that has recently been brought out by The J. Morton Poole Co., Wilmington, Del. These machines have been designed for the heavy duty that is required by the use of high-speed tool steels, and although the machine shown is belt-driven, provision has been made for the application of any make of motor without encroaching upon valuable floor space or bolting unsightly brackets to the bed or uprights.

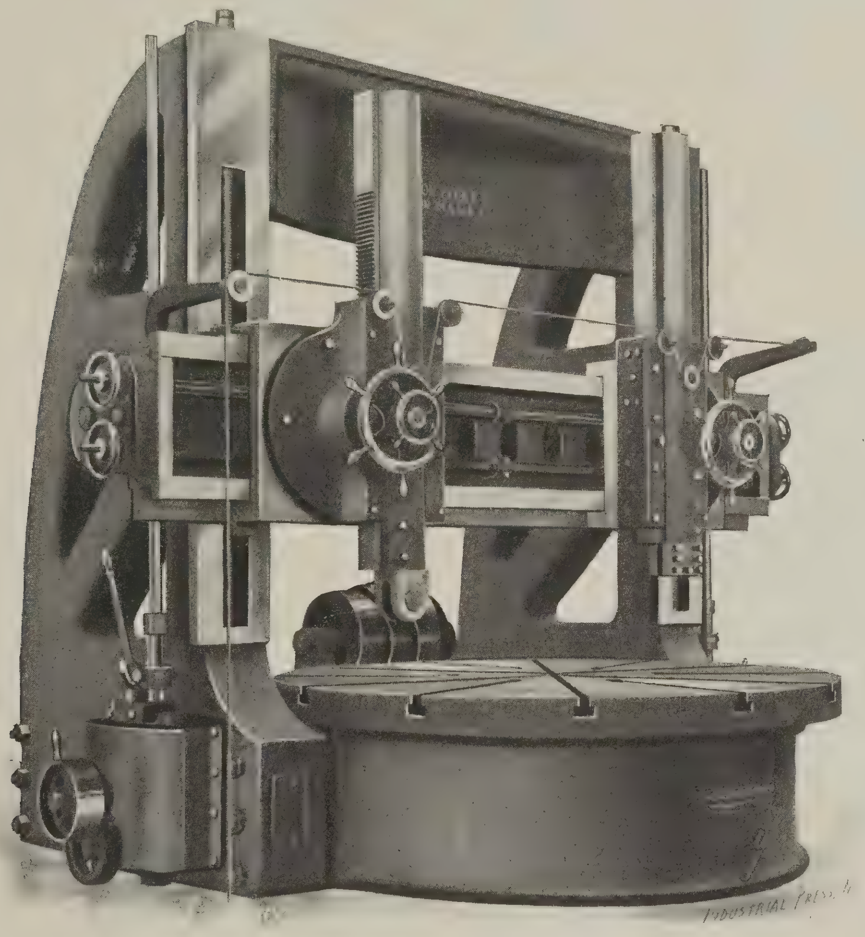


Fig. 1. J. Morton Poole Boring Mill.

The table rests upon wide flat bearings at its extreme outer edge, and is driven by a powerful "Hindley" worm wheel which is mounted on the spindle between the upper and lower bearings. This method of placing the worm wheel on the spindle, enables the operator to elevate the table from its outer bearings and take the thrust on the spindle step bearing, when running at high speeds, without destroying the alignment of the worm and wheel. The driving worm runs in an oil chamber in the bed and the table bearing is automatically lubricated by rollers located in oil pockets and held up against the bearing surface by springs.

The arrangement of the worm gear and driving mechanism is clearly shown in Fig. 2. The worm wheel, which, on this size of mill is 64 inches in diameter, has 96 teeth of 2-inch pitch. The worm, having 8 threads, thus provides a 12 to 1 gear reduction. The gears, *G* and *H*, are keyed to the back gear shaft and drive the loose friction gears, *A* and *E*. The chain gear, *T*, runs loose on the back gear shaft and carries the pinion *L*, which drives the back gears, *U*, *S*, and *R*, the latter running loose on the shaft. The chain gear can drive the back gear shaft direct, by operating the friction clutch between *G* and *T*, or a back gear ratio of 8 to 1 can be obtained by engaging the clutch, *O*, which is keyed to the shaft with the hub of gear *R*. The cone pulley has three steps for 6-inch belt, and a 3-inch Morse silent chain transmits the power from the cone shaft to the back gear shaft. This arrangement of gearing gives back gear ratios of 12, 36, 95, and 285 to 1. When a two-speed friction countershaft and three-step cone pulley are used, 24 table speeds are available, and either series of eight speeds can be obtained without shifting the belt or stopping the machine. The various speeds are obtained by a lever and hand wheel conveniently located at the right of the machine.

In Fig. 3 is shown the feed box with the cap removed. On each end of the main worm shaft is a feed worm, *B*, driving the worm wheel, *C*, which is keyed to the hub of the pinion *D* running loose on the shaft. Gear *F* is also loose on the shaft and is driven from *D* through the gears *I* and *J*, which are loose on the other shaft and give a feed back gear of 8 to 1. Either *D* or *F* can be engaged with the shaft by means of a sliding key operated by the lever *B'* upon shaft. Gears *K*, *M*, *N*, and *P* are keyed to the shaft and drive the four loose gears, *Q*, *V*, *W*, and *X*; any one of which, or the rapid traversing spiral gear, *Y*, can be engaged with the shaft by the lever *C'* and a sliding key running in a slot in the shaft. Spiral gear *Y* is driven at a constant speed, through the gear *Z* and the shaft *A'* by the pulley and gears shown at the left of the machine in Fig. 1. By these various combinations of gears we may obtain 8 feeds from 1-64 to ¾ inch, and a quick traverse of the crossheads in or out, and the tool bars up or down, at a rate of 8 or 13 feet per minute, and it is impossible to throw in any of the feeds while traversing. The feeds and traversing speeds are reversed in the gear boxes on the ends of the cross rail, by means of small hand wheels. Both feeds and speeds of each head are entirely independent and can be applied at any angle at which the swivel heads may be set.

A lever in front of the right-hand upright controls a friction clutch for elevating and lowering the cross

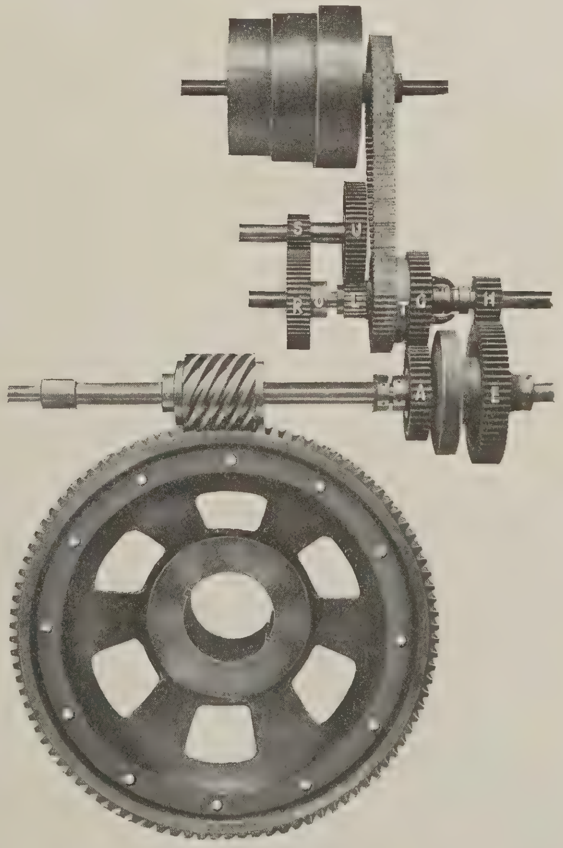

Fig. 2. Worm Drive for Table, with Morse Chain and Gear Connections.

rail at a rate of 4 or 7 feet per minute, and this arrangement dispenses with the usual pulley, bevel gears, brackets and shaft that are generally placed on the top of a boring mill. The usual chain connection for the tool slide counterbalance has also been replaced by a wire rope.

When it is desired to make the machine motor-driven, a small constant speed motor is attached to the left upright for the power traveling of the heads, tool bars and cross rail, and a variable speed motor is bolted to the bed in place of the cone pulley, shaft and brackets. A silent chain pinion, of the proper size to give the correct back gear speed, is keyed to the motor shaft and the rest of the driving mechanism remains exactly as illustrated for the belt drive.

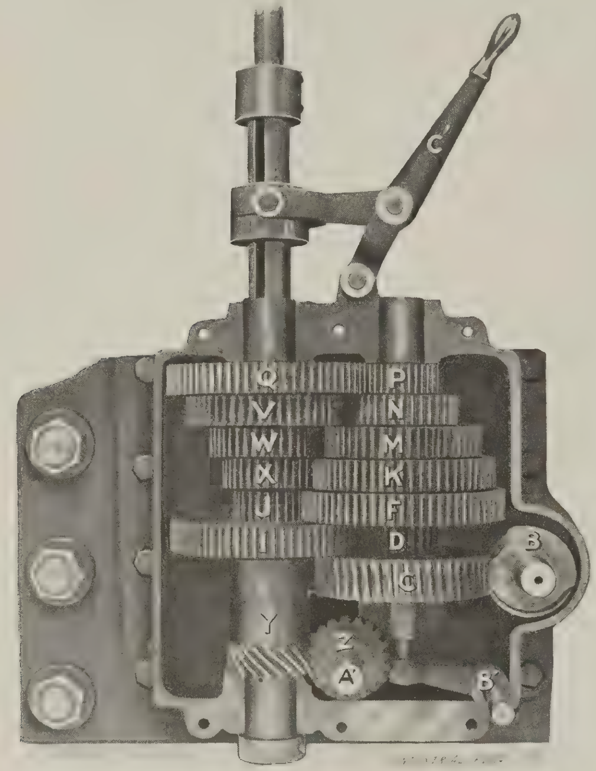

Fig. 3. Feed Box for Boring Mill.

* * *

Mr. W. P. Atwell, the U. S. consul at Roubaix (in Northern France) says that American machinery and labor-saving tools are making great headway in that great industrial district. American agricultural machinery, tools, etc., are being used extensively and with great success. There is a large demand in the district for all kinds of American machinery, tools, hardware, typewriters, desks, farming implements, stoves, motor cars, bicycles, novelties, etc. The sales of such goods should be intrusted to general agents who understand the language and trade methods of the French. Printed advertising matter is useless unless printed in French. Goods should be securely packed, and all weights and measures should be quoted in the metric system. German imitations of American machinery are sold there as the genuine, but at very low prices.

* * *

In a little periodical called *The Corbin*, issued in the interests of a lock-making concern, a small East Indian padlock was recently illustrated and described. To unlock it requires four distinct operations. First, a thumbscrew has to be turned by which a bail is drawn down revealing a hole into which a screw-bitted key is inserted and turned until a spring throws back a front plate and reveals the keyhole. Two keys are required to unlock, one being inserted after the other and each drawing a separate bolt. The locking is the reverse of this tedious operation which leads the writer of the description to remark: "The lock is an ingenious one and may answer in a land where time is reckoned by centuries and an hour is a mere nothing, but in this country of the split-second watch and mile-a-minute train, the ordinary citizen has no time to spend in turning three keys and a thumbscrew to open a single lock. He would be likely to use an axe instead."

BOILER BRACING.—2.

CALCULATIONS FOR THROUGH STAYS.

CHARLES L. HUBBARD.

High pressure boilers and those of large size are usually provided with through braces. Sometimes two or three through braces are placed in line across the head, a short distance above the tubes, and the upper part of the segment is supported by crow foot braces. When through braces are used in the upper part of heads they interfere seriously with the inspection of the boiler. Aside from this, the method of through bracing is preferable to any other, as it does away with all pins or bolts. The braces are straight steel rods, without welds, and an even tension can be secured upon all of the braces, which is very difficult, if not impossible, in the case of diagonal braces. For boilers 66 and 72 inches in diameter, five through braces may be used, and, if properly spaced, allow sufficient room for inspection. Boilers 60, 54 and 48 inches in diameter may have a combination of through and crow foot bracing. Below 48 inches they are mostly used for heating purposes or for running small engines at comparatively low pressures, and crow foot bracing will be found sufficiently strong. Through bracing consists of rods passing through the entire length of the boiler, with heavy nuts and washers at the ends on the outside, and check nuts on the inside. Stiffening pieces of channel or angle iron are riveted to the heads to support them.

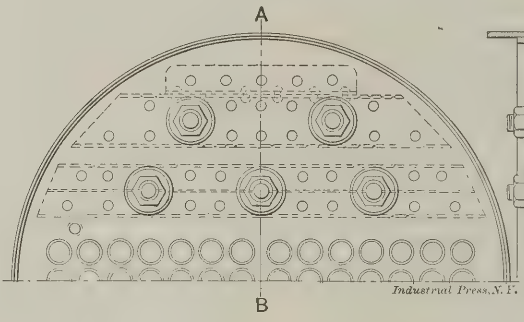

Fig. 1.

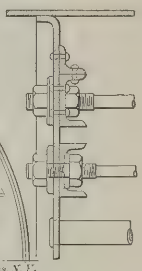

Fig. 2.

Fig. 1 shows the general arrangement of the channels and braces, and Fig. 2 a section on line *A B*. The upper bar in this case consists of a channel iron with an angle riveted to its upper flange to give it greater strength. The lower bar is made up of two angles riveted to the head, as shown.

Where angles are used instead of a channel, it is necessary to countersink slightly around the holes for the braces, to give a solid bearing for the washer and check nut. The outside washer is sometimes made of copper slightly cup-shaped on the under side in order to give a tight bearing around the edge. It is more common, however, to use heavy cast-iron washers and embed them in red lead to make them tight. When channel bars will give the required strength, they are preferable to angles for stiffening pieces, but for high pressures the standard weights will, in many instances, be found too light, and resort must then be made to angle irons, of which there is a great variety of sizes and weights to choose from. In this form of bracing the channel bars act as beams, carrying the loads due to the pull on the rivets, and the beams in turn are supported by the rods. The general method of designing through bracing, which is given here, can be found in "Steam Boilers," by Professors Peabody and Miller. We shall take it up here more in detail in order to refreshen the

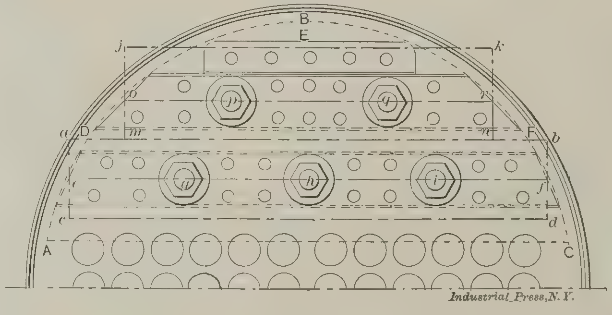

Fig. 3.

reader's mind on certain points which come more strictly under the head of mechanics. Referring to Fig. 3, let us take up the different steps in detail. The area to be supported is found in the way already described in a previous article and is shown by *A*, *B* and *C*. The rivets for fastening the head to the channel bars are laid out as nearly as possible in equi-distant rows; the maximum distance between them being checked by the formula already given for this purpose. In practice they are usually placed from 4 to 5 inches apart. The load carried by each rivet is then computed the same as for crow foot bracing, and the size is made such that the stress shall not be more than 6,000 pounds per square inch. No rivet should be placed nearer than 3 inches to the shell or tubes on account of the straining effect due to expansion. Channel bars of suitable width are then drawn in, and the stays, usually five in number, are laid out, leaving sufficient space (not less than 19 or 20 inches) between the two upper ones for access to the boiler.

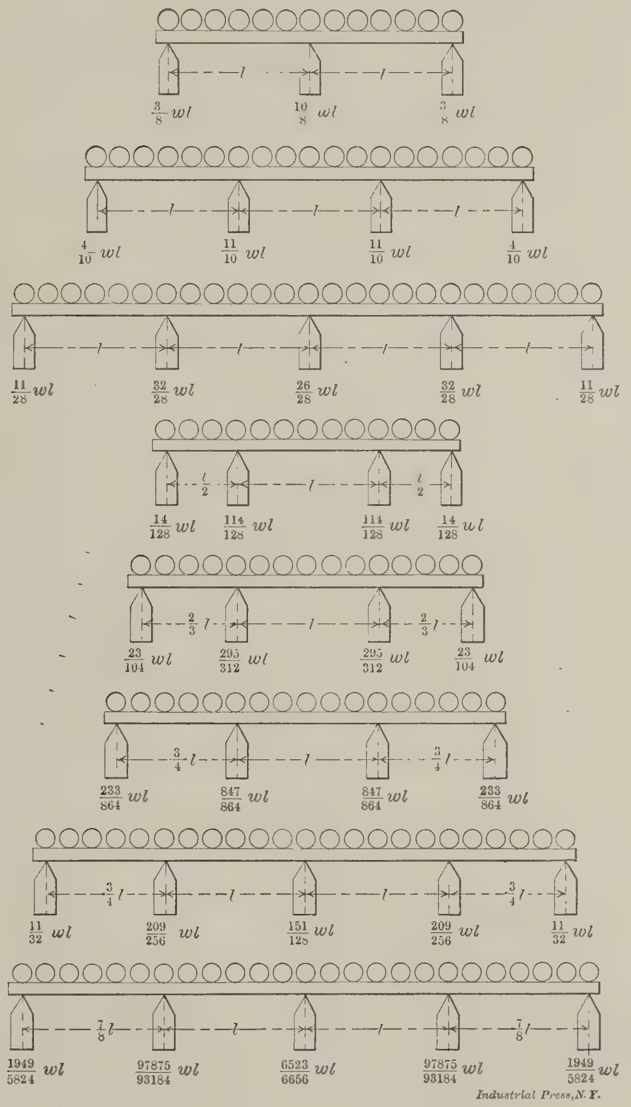

Fig. 4.

It is common to use 7-inch channels, or their equivalent, in angles, for 72 and 66-inch boilers; 6-inch channels for 60 and 54-inch boilers, and 5-inch for 48-inch boilers. It is only necessary to assume a width at this stage of the problem in order to arrange the rivets and stays; the weight of the bars can be computed later. The next step is to determine the required size of the stays or braces. The area to be supported by the lower stays may be taken as that of a strip or rectangle bounded on the bottom by the line *c d*, half way between the lower line of rivets in the lower channel and the line *A C*, and bounded at the top by the line *a b*, half way between the lower rivets in the upper channel and the upper rivets in the lower channel.

The ends of the rectangle are formed by the vertical lines *a c* and *b d* drawn through the extremities of the center line of the channel at *e* and *f*. This strip is commonly provided with three stays in boilers from 54 to 72 inches in diameter, and with two in 48-inch boilers, although different engineers may vary this arrangement somewhat.

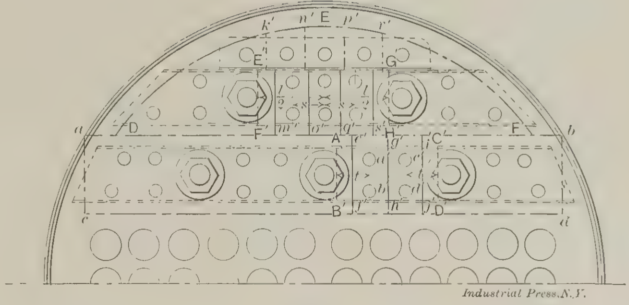

Fig. 5.

The strip may now be treated as a continuous girder. Where a uniformly loaded beam passes over more than two supports, the rules applying to simple beams no longer hold, as new forces and conditions are introduced. By a somewhat complicated process, values have been computed for the loads acting on the various supports for different arrangements of spacing. These results are shown in the diagrams, Fig. 4.

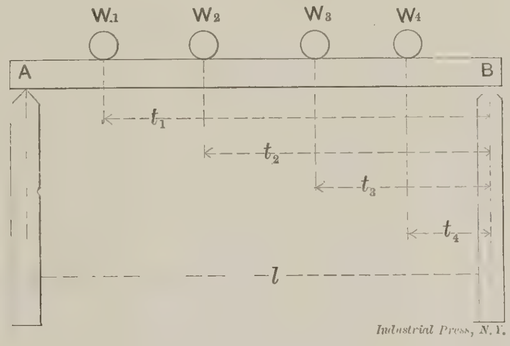

Fig. 6.

In all cases *w* is the load per unit of length; that is, if *l* is taken in inches; then *w* is the load per inch in length of the beam, and equals, of course, the total load divided by the length of the beam.

Referring to Fig. 4 we find for the case of a continuous girder with five equally spaced supports, that the greatest loads are carried by those next to the ends and are equal to $\frac{32}{28} w\,l$ pounds each. *w* being the load per unit length, is evidently equal to the width of the strip in inches multiplied by the boiler pressure per square inch, and *l* is the distance, *eg*, *gh*, etc., between the supports in inches. Having found the greatest load carried by any of the lower stays we then proceed to do the same for the upper ones before calculating the required size.

TABLE I.

Diameter of Rod.	Area of Section in inches.	Weight of Rod per foot.	Diameter of Upset Screw Ends.	Threads per inch.	Thickness of Nuts.
$\frac{3}{4}$	.4418	1.47	1	8	$\frac{3}{4}$
$\frac{13}{16}$	.5185	1.72	$1\frac{1}{8}$	7	$\frac{7}{8}$
$\frac{7}{8}$	.6013	2.00	$1\frac{1}{4}$	7	$\frac{7}{8}$
$\frac{15}{16}$	.6903	2.30	$1\frac{1}{4}$	7	1
1	.7854	2.61	$1\frac{3}{8}$	6	1
$\frac{1}{8}$	.9940	3.31	$1\frac{1}{2}$	6	$1\frac{1}{8}$
$\frac{1}{4}$	1.227	4.09	$1\frac{5}{8}$	$5\frac{1}{2}$	$1\frac{1}{4}$
$\frac{3}{8}$	1.484	4.95	$1\frac{3}{4}$	5	$1\frac{3}{8}$
$\frac{1}{2}$	1.767	5.89	2	$4\frac{1}{2}$	$1\frac{1}{2}$
$\frac{5}{8}$	2.073	6.91	$2\frac{1}{8}$	$4\frac{1}{2}$	$1\frac{5}{8}$
$\frac{3}{4}$	2.405	8.01	$2\frac{1}{4}$	$4\frac{1}{2}$	$1\frac{3}{4}$
$\frac{7}{8}$	2.761	9.20	$2\frac{3}{8}$	$4\frac{1}{2}$	$1\frac{7}{8}$
2	3.141	10.47	$2\frac{1}{2}$	4	2
$\frac{1}{8}$	3.546	11.82	$2\frac{5}{8}$	4	$2\frac{1}{8}$
$\frac{1}{4}$	3.976	13.25	$2\frac{7}{8}$	4	$2\frac{1}{4}$
$\frac{3}{8}$	4.430	14.77	3	$3\frac{1}{2}$	$2\frac{3}{8}$
$\frac{1}{2}$	4.908	16.36	$3\frac{1}{8}$	$3\frac{1}{2}$	$2\frac{1}{2}$
$\frac{5}{8}$	5.411	18 04	$3\frac{1}{4}$	$3\frac{1}{2}$	$2\frac{5}{8}$
$\frac{3}{4}$	5.939	19.80	$3\frac{3}{8}$	$3\frac{1}{2}$	$2\frac{3}{4}$
$\frac{7}{8}$	6.491	21.64	$3\frac{5}{8}$	$3\frac{1}{4}$	$2\frac{7}{8}$

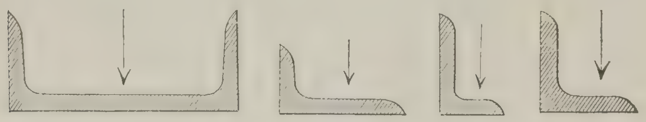
The area to be supported by the upper stays is that of the segment, *D B F*; This area may be computed by the rule already given. Next construct a rectangle by drawing vertical lines *j m* and *k n* through the extremities of the center line of the upper channel, at the points *o* and *r*, making the height *j m* such that the area shall equal that of the segment just found. Treat this as a continuous girder with four supports. If the stays are spaced so that the distance *o p* equals two-thirds of *p q*, then we shall find from Fig. 4 that the greatest loads are carried by the supports at *p* and *q*, and are each equal to

$$\frac{295}{312} w l,$$

in which *w* equals the width *j m* of the rectangle multiplied by the boiler pressure, and *l* is the distance *p q*.

TABLE II: GIVING PROPERTIES OF CHANNELS AND ANGLES.

[In the following are the moments of resistance and other properties for different sizes and weights of channels loaded as shown in the accompanying sketches.]



CHANNELS.

Size.	Width of Flange.	Thickness of Web.	Weight per foot.	Moment of Resistance.

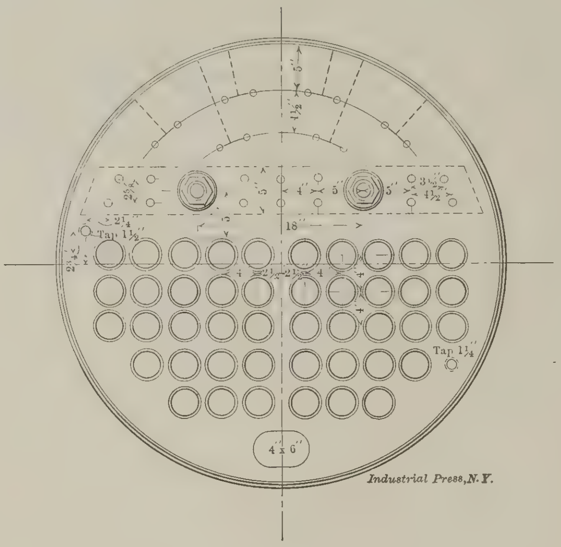

Fig. 7. Forty-eight inch Boiler.

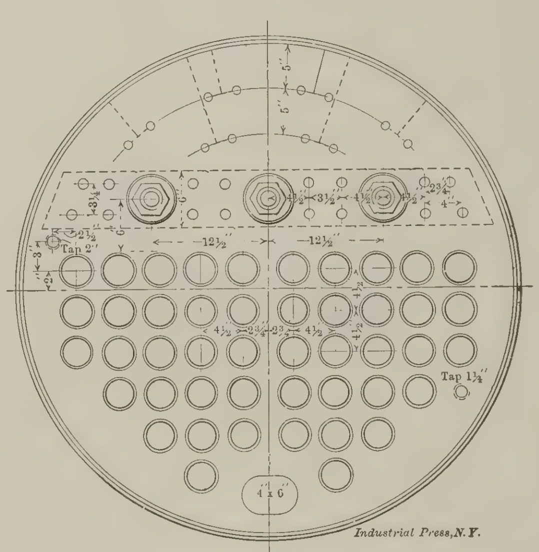

Fig. 8. Fifty-four inch Boiler.

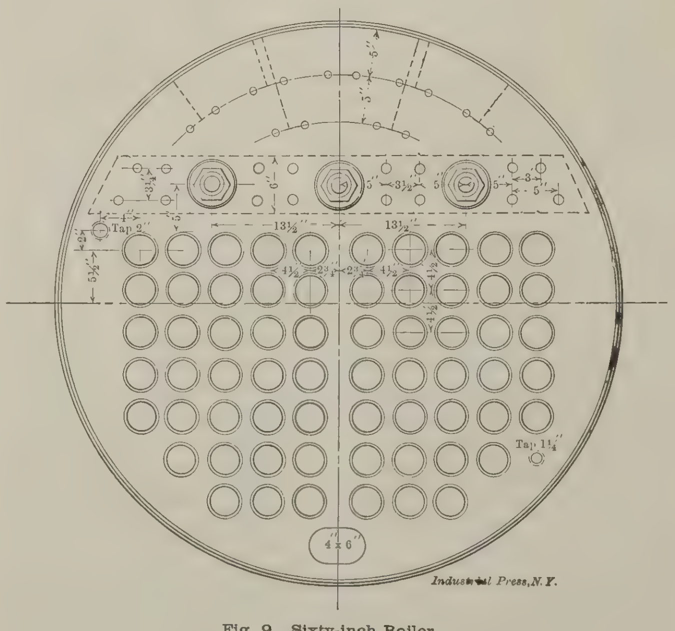

Fig. 9. Sixty-inch Boiler.

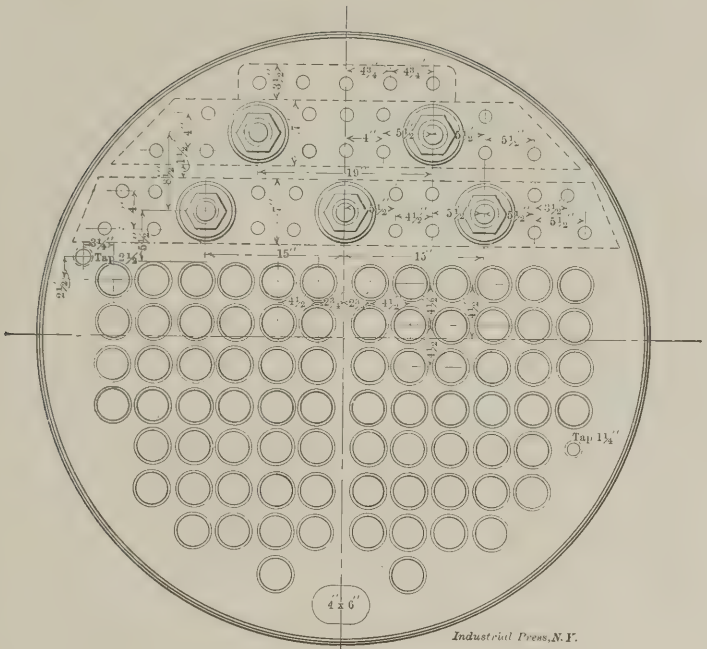

Fig. 10. Sixty-six inch Boiler.

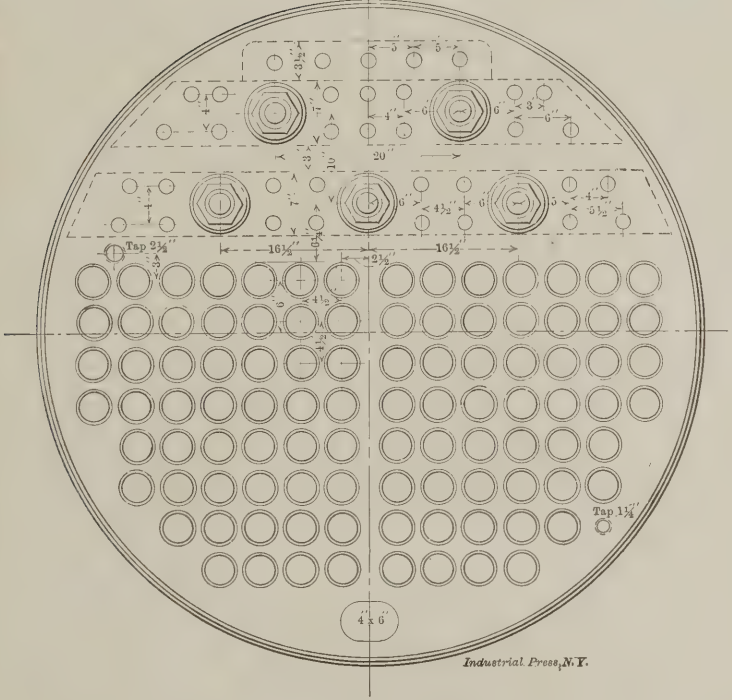

Fig. 11. Seventy-two inch Boiler.

In computing the required size of the stays we may allow a stress of 10,000 pounds per square inch for mild steel. By taking the greatest load found for any one stay and dividing it by 10,000, we have the required area of section in square inches, and the corresponding diameter can be found at once from a table of areas. The ends of the stays should be upset so that the diameter at the root of the thread shall be as great or greater than the body of the stay. If an allowance is to be made for corrosion it can be added directly to the diameter thus found. The working load is sometimes fixed by government rules or by insurance companies, and may vary somewhat from the above, but the method of computation will be the same in any case.

Table 1 will be found useful in proportioning the stays, nuts, etc.

In computing the required strength of the lower channel the maximum bending moment must first be found. This is done by taking a section of the bar, cut by the lines *A′ B′* and *C′ D′* (Fig. 5), drawn ¼ the diameter of the large washers from their centers, and treat it as a simple beam supported at both ends and carrying two loads symmetrically placed. The loads are each equal to the area supported by a pair of rivets, multiplied by the boiler pressure per square inch. The area supported by a pair of rivets, as *a′ b′*, is taken as that bounded by lines drawn half way between the rivets and the adjacent points of support, for example, *e′ g′* is half way between the upper line of rivets in the lower channel, and the lower line in the upper channel, and *g′ h′* is half way between the rivets *a′ b′* and *c′ d′*, etc. In the case of a beam loaded as above, the maximum bending moment $M = \frac{Wt}{2}$, in which $\frac{W}{2}$ is the load on a pair of rivets, and t is the distance of the rivets from the line of support, *A′ B′*.

Having determined the value of M for any given case, the "moment of resistance" can be found from the relation $\frac{M}{f}$ = moment of resistance, in which f is the safe working stress in the outer fibers of the beam. In the case of rolled steel beams used in this manner it is common to assume a safe working stress of 16,000 pounds per square inch.

In the case of the upper bar the channel and angle iron are riveted together and treated as a single beam supported at both ends and having three loads symmetrically placed. Under these conditions the maximum bending moment,

$$M = \left(\frac{l}{2} \times \frac{W}{2}\right) - (s \times w) \text{ in}$$

which W = the total load, which is equal to the area *m′, k′, r′, s′*, multiplied by the steam pressure per square inch, w = the load on area *q′, p′, r′, s′*, l = the distance between the points of support or the distance between lines *E′ F′* and *G′ H′*, s = the distance between the rows of rivets as shown.

The supporting lines *E′ F′* and *G′ H′* are drawn ¼ the diameter of the large washers from their centers and the loads as before are taken as equal to the area supported by a vertical row of rivets, multiplied by the boiler pressure. The supported areas are divided by lines drawn half way between the points or lines of support, as already described. The moment of resistance is computed from the bending moment and suitable sizes of channel and angle bars are selected and riveted together to give the required strength.

If the required moment of resistance is greater than any found in the table for channels the bars must be made up of angles taken from Table II.

In case the rivets in either the upper or lower channel are not symmetrically placed, the position and amount of the maximum bending moment may be found as follows, by comparing it with a beam with any number of loads *not* symmetrically placed.

Knowing the weights of the loads, W_1, W_2, W_3, etc., in Fig. 6, the first step is to determine how the total load is divided between the points of support, *A* and *B*. This may be done by considering the beam hinged at one end, as at *B*, and carrying the loads W_1, W_2, W_3, etc., with a resisting force or support at *A*. As the bar remains stationary, it is evident that the forces tending to rotate it in one direction about *B* must be just equal to those acting in the opposite direction. In other words, the moment $Al = W_1t_1 + W_2t_2 + W_3t_3 + W_4t_4$, from which equation the value of the force represented by *A* can easily be found. Knowing the resisting force at *A*, that at *B* can be found by subtracting *A* from the total load. To find the point where the maximum bending moment occurs, begin at *B* and take the sum of the loads, $W_4 + W_3$, etc., until a quantity is obtained which is equal to, or greater than, the resistance just found at *B*. The point at which this last load acts is the position of the maximum bending moment. For example, suppose $W_4 + W_3$ is less than *B*, and $W_4 + W_3 + W_2$ is greater, then we know the greatest bending moment occurs at W_2, or strictly speaking, somewhere between W_3 and W_2. Taking the sum of the moments about W_2, we have for the value of the maximum bending moment a quantity $= Bt - [W_3\ (t_1 - t_3) + W_4\ (t_2 - t_4)]$.

Figs. 7, 8, 9, 10 and 11 give detail drawings of boilers of various sizes designed by the foregoing methods to carry a working pressure of 100 pounds per square inch, and will be found useful for comparison in the design of new work. It has been assumed in all cases that the heads are not less than ½ inch in thickness.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

The steamship *Deutschland* broke all ocean records when she reached Quarantine in New York Harbor, September 8, having made the westward trip in 5 days, 11 hours and 54 minutes. This beats her best previous run by 69 minutes and the best record of the *Kronprinz Wilhelm* of the North German Lloyd line, by 3 minutes.

On July 14, 1903, the Great Western Railway made a record run from Paddington to Plymouth, England—a distance of 245.75 miles in 234 minutes—without a stop. The train consisted of five cars, weighing 125 tons; the weight of the locomotive is 54 tons and that of the tender is about 35 tons. The average speed for the entire distance is 63 miles per hour.

A ten-car Manhattan Beach train was recently run on the elevated lines, Brooklyn, New York, to take the New York Twenty-third Regiment on an excursion. This was the longest train that has been run on an elevated road. It was made up of ten motor cars. Each car had four 60-horsepower motors—forty motors in all. These forty motors were all connected on the circuit, giving the train a propelling power equal to 2,400 horse power.

The hulls and machinery for the five battleships for which Congress made an appropriation for the fiscal year, commencing July 1, 1903, will cost, when completed, about $20,000,000, and the armor, armament and equipment will require an additional outlay of $1,500,000. The annual depreciation of these vessels, taking into consideration their wear and tear as well as their fighting value, is estimated to be at least 4 per cent., or a total of nearly a million and a half dollars; and this is exclusive of the running expenses of these expensive attributes of the "majestic arm of the law."

In the paper "Axle Lighting" read before a recent meeting of the American Institute of Electrical Engineers by Mr. Elmer E. Sperry the statement was made that in August, 1882, the Pennsylvania R. R. electrically equipped car No. 397 with Faure accumulators imported for the purpose from France. Not only is this the earliest application of electricity to car lighting in this country, but in the world. The first installation of solid electrically illuminated trains, is that of the Pennsylvania Limited, between New York and Chicago, in the middle eighties. These are still in continuous service and all are direct-connected sets in the baggage compartment, supplying the lamps and the storage batteries beneath each car.

The United States Consul at Frankfort, Germany, says that the German papers report the discovery by Mr. Edward Mollard, a Frenchman, of a new metal called "selium." The discoverer, it is said, claims that selium costs but one-twelfth as much as aluminum and is lighter and stronger. It does not rust, and is therefore suitable for use in shipbuilding, for the manufacture of pipes, and for railroad construction. On account of its cheapness—and as it is capable of a fine polish, resembling nickel—it would be desirable for manufacturing cooking utensils. Its density is 2.6, and its hardness not quite that of iron, but greater than lead or zinc. Its power of resistance is said to be greater than that of iron, but less than that of steel. The melting point is high, being about 2900 degrees Fahr. In melting, it contracts somewhat, but molding in forms is not impossible.

The *Scientific American* illustrates and describes what is said to be the largest transformer in the world. It was built by the Stanley Electric Manufacturing Co. for the Pittsburg Reduction Co. to be used in their Niagara Falls plant for the manufacture of aluminum. The transformer is of 2,000 kilowatt capacity. The primary circuit receives current from the Niagara Falls of 908 amperes at 2,200 volts. This current is "stepped down" in the secondary winding to 40,000 amperes at 50 volts, the manufacture of aluminum requiring a powerful current of low voltage. The transformer measures 7 feet, 2 inches square at the base and is 8 feet, 8 inches high. The coils are oil cooled, being incased in a tank which is filled with heavy mineral oil. The heat absorbed by the oil is in turn absorbed by a coil of pipe in the top through which is circulated cold water.

Petroleum was first used for road purposes in California in 1898, solely for the purpose of laying the dust, which, during the long dry seasons, become a serious nuisance if not a menace to life and property. It was soon discovered, however, that not only does the petroleum serve the purpose of making dustless roads, but it immediately begins to bind together the loose particles constituting the road surface, whether clay, sandy loam, loose sand, gravel or fine material on top of macadamized roads. A tough stratum is formed, resembling asphalt pavement. Roads built on drifting sand or clayey dust, no matter how deep, where trotting with a buggy was impossible and for a pair of strong horses to pull a ton was a very laborious process, became indurated, resilient, and firm, so that driving teams could trot with ease and the same pair of horses pull 2½ tons more comfortably than they formerly did one ton. Petroleum having a large percentage of asphalt in suspension as have the heavy oils of California and Texas, is best for road-making purposes—and cheapest.

The proposed race of airships at the St. Louis Exposition has done much to stimulate the invention and production of motors of extremely light weight, and, according to the *Scientific American*, a gasoline motor has been constructed by the Walters Power Company, Jersey City, which is the lightest on record for an engine of this type. The contract stipulated that the motor alone should weigh not more than 26 pounds and should yield at least 2 horse power. The completed motor comes well within these requirements, having a weight of about 24¼ pounds and an output of 2¼ horse power. Even with the addition of the carbureter, the weight is but 25½ pounds. In the construction of the motor aluminum is used wherever possible, and the other parts are made as small and compact as practicable. The general design, however, closely follows standard lines. The motor is of the four-cycle type and the cylinders have a 2⅛-inch bore by a 2 7-16-inch stroke. One feature which is particularly noticeable is the absence of radiating ribs on the main body of the cylinders. It was found that the heat of the cylinders could be dissipated with sufficient rapidity from the smooth surface of the cylinder. However, in order to insure sufficient strength the ribbed formation is retained on the cylinder heads and the valve casings, for at these points the pressure is the greatest.

Much interest is evinced in engineering circles by the approval of the Naval Board of Construction of Rear Admiral Melville's report recommending that one of the new scout ships to be constructed for the government should be equipped with steam turbines. The construction abroad of the two English Channel turbine steamers the past year, and their successful performance, and this action on the part of the Navy Department in this country, will both have a powerful influence tending to the introduction of turbines on ocean-going steamships of much larger size. In his report, submitted previous to his retirement from the active duties as Engineer-in-Chief of the U. S. Navy, Rear-Admiral Melville said:

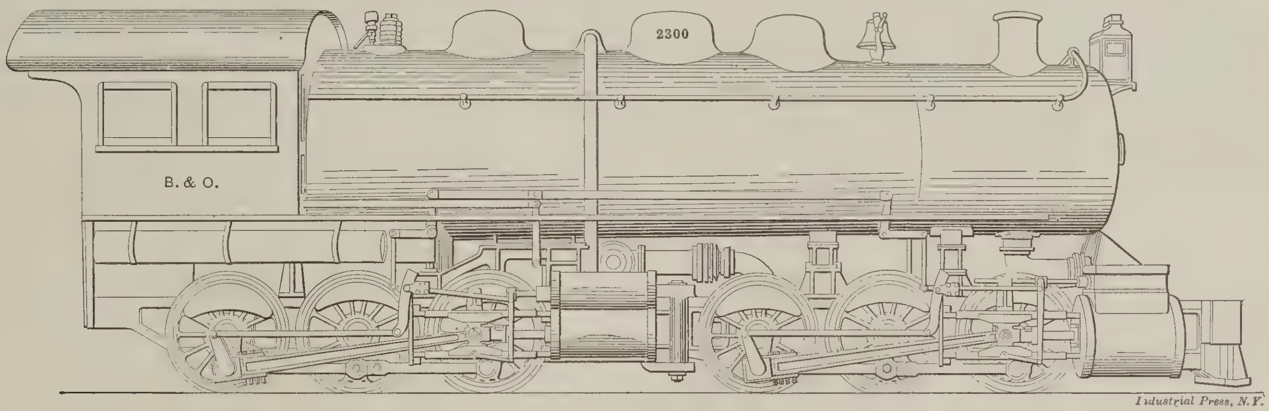
"I respectfully recommend that one of the new vessels of the navy of not more than 5,000 tons displacement, and preferably of the scout or very fast cruiser class, be fitted with steam turbines instead of reciprocating engines. My reasons for this recommendation are that the steam turbine has now passed beyond the experimental stage, and various vessels in which it has been fitted, particularly fast passenger steamers, have proved eminently successful." He adds that the ability to use highly superheated steam, the few moving parts and the reduced engine room are in themselves sufficient reasons for extensive experiments with the steam turbine; and he favors the installation of such turbines in a small vessel, not because they may not prove efficient on a larger one, but because he believes that it is not a good policy to change the motive machinery in the larger ships until it has been shown by exhaustive trials on the smaller scout ships that it will be wise to make the change.

MALLET ARTICULATED TYPE LOCOMOTIVE FOR THE B. & O.

Railroad Gazette, September 4, 1903, p. 636.

An order has been placed with the American Locomotive Company by the Baltimore & Ohio R. R. for a very heavy freight locomotive of the Mallet articulated type that has been quite largely built for European railways. It is the intention to have this locomotive perform the work of two ordinary locomotives and to thus dispense with the aid of a pusher on heavy grades.

The Mallet compound is of the four-cylinder type. Usually all of its wheels are drivers, which are arranged in two groups. The rear group is carried by the main frame and is driven by the high-pressure cylinders. The forward group is carried by a supplemental frame and is driven by the low-pressure cylinders. The frame and wheels of the low-pressure engine form a truck on which the forward part of the locomotive is supported. The arrangement gives a locomotive a long total wheel-base but short rigid wheel-base. The total weight is available for adhesion. It is especially adapted to slow, heavy work on grades where sharp curves must be passed. The Walschaert valve gear is used.



Heavy Freight Locomotive for B. & O. R. R.

The building of this locomotive by the B. & O. is an experiment. Should it demonstrate its usefulness in the service for which it is designed, others will doubtless be built. The boiler will carry the unusual pressure of 235 pounds. The following dimensions, furnished by the B. & O., compare the Mallet type with the 1-7 class, which are the heaviest locomotives used on the road in regular freight service.

General Dimensions.	Articulated.	1-7
Gage	4 ft. 8½ in.	4 ft. 8½ in.
Fuel	Bituminous coal.	Bituminous coal.
Weight in working order	285,000 lbs.	193,500 lbs.
Weight on drivers	285,000 lbs.	173,000 lbs.
Weight engine and tender in working order	415,000 lbs.	325,000 lbs.
Wheel base, driving	30 ft. 6 in.	16 ft. 6½ in.
Wheel base, rigid	10 ft. 0 in.	16 ft. 6½ in.
Wheel base, total	30 ft. 6 in.	24 ft. 9 in.
Wheel base, total, engine and tender	61 ft. 5 in.	57 ft. 7½ in.
Width of frame	5 in.	4 in.
Center to center		44 in.
Cylinders.		
Diameter of low-pressure cylinder	32 in.	
Diameter of high-pressure cylinder	20 in.	22 in.
Stroke of piston	32 in.	28 in.
Valves.		
Kind of valves	Balanced.	Balanced.
Type of gear	Walschaert.	Link.
Wheels.		
Number of driving wheels	12	8
Diameter of driving wheels outside of tires	56 in.	56 in.
Material of driving wheel centers	Cast steel.	Cast steel.
Thickness of tire	3 in.	3 in.
Driving box material	Cast steel.	Cast steel.
Diameter and length of driving journals	9 in. x 13 in.	9 in. x 13 in.
Boiler.		
Style	Wagon top.	Belpaire wide fire-box.
Working pressure	235 lbs.	205 lbs.
Inside diameter of first ring	76 in.	69½ in.
Horizontal seams	Sextuple riveted. Butt seam.	Double welt. Butt seam.
Circumferential seams	Double riveted.	Double riveted.
Fire-box length	105 in.	104⅞ in.
Fire-box width	77 in.	66 in.
Fire-box water space, front	5 in.	5 in. bot. 7 in. top.
Fire-box water space, sides	5 in.	5 in. bot. 6½ in. top.
Fire-box water space, back	5 in.	4 in. bot. 7 in. top.
Fire-box crown staying	Radial.	
Fire-box staybolts	Flexible and screw	Flexible.
Tubes, number	376	369
Tubes, diameter	2¼ in.	2 in.
Tubes, length over tube sheets	18 ft. 9 in.	13 ft. 9½ in.
Tubes, heating surface	4,135	2,662.92
Fire-box, heating surface	190	184.32
Total heating surface	4,325	2,847.24
Grate surface	56.1	48.06
Height of stack above rail	15 ft.	15 ft.
Ratios.		
Heating surface to grate surface	77.1	59.24
Heating surface to cylinder volume	.0068	.00216
Tractive power	63,800	39,688
Heating surface to tractive power	15.43	13.98
Tractive power to weight on drivers	4.46	4.31
Tender.		
Tender frame	Channel.	Steel.
Water capacity	7,000 gals.	7,000 gals.
Coal capacity	13 tons.	13 tons.

FRICTION BETWEEN WOOD AND IRON.

Engineering (London) August 21, 1903, p. 254. (Translation.)

The civil authorities in the Dortmund colliery district finding there was no accepted standard friction coefficients of wood on iron for the guidance of those having to design brakes for the winding drums used in mines, requested Professor L. Klein, of Hanover, to investigate the subject. In his experiments the test pulleys, which were mostly 15.75 inches diameter, were driven by a Pelton water wheel working under a constant head of 85 feet. The brake blocks were attached to a lever from the end of which weights were suspended. The machine having been gaged with the aid of straps, cords, and steel bands and spring balances, and very good curves having been obtained, experiments were made in three different ways. In the first set the load and speed were varied, but the pressure kept constant by altering the surface in contact, in accordance with the load. In the second set the pressure was increased, while the speed was kept constant. In the third set the speed and pressure were varied, the braking area being kept constant. This third method was finally applied because the experiments established that, within certain limits, the speed and pressure did not affect the friction coefficient. The limits were circumferential speeds from 3¼ feet to 65 feet, and pressure from 7 pounds to 142 pounds per square inch. Constant figures were generally arrived at after about half a minute.

As a rule the wood fiber was parallel to the pulley face, as in ordinary practice (*a*); sometimes the fiber was placed crossways to the pulley face (*b*); and end grain blocks were also tried (*c*); the letters indicate these conditions in the tables in which we summarize the results. Table I. concerns pulleys of cast iron or wrought iron finished smooth; *A* means that the pulley was carefully wiped, *B* that it was cleaned with benzine; *C* that the wood was soaked in oil. Table II. concerns wrought-iron pulleys not specially finished. In this case, as is well known, the rough points on the surface cause the brake-block to oscillate; the braking effect is hence diminished and more uncertain, as the pulley has time to slip away under the block when it is not pressed on. Definite values, therefore, cannot be given. Beech and oak suffer more on rough pulleys than poplar, elm and willow, but are more efficient in braking power, probably because the charred particles fill up the rough spots. Poplar proved to be the best brake-block material; it gives high friction and is little affected by oil. Willow is inferior, being sensitive to oil and giving diminished friction under heavy loads. Carefully finished and cleaned wrought iron is a better friction pulley material than rough wrought iron or cast iron.

ENGINES AND PUMPS WITHOUT GLANDS.

Mechanical Engineer, England, August 29, 1903.

An interesting paper, read by Mr. Andrew Watson before the Mining Institute of Scotland on mine engines and pumps having no glands or soft packing for the piston rods, was published in the *Mechanical Engineer* of August 29, 1903. The principle employed is that of parallel grooves in the rod, or in the internal surface of a "horn," which takes the place of the ordinary gland. These grooves fill with condensation, making what is ordinarily known as "water-packing." The principle is one that has been used in this country to considerable extent in the construction of pressure regulators and similar apparatus that must work with a minimum of friction, but so far as we know it has never been used for the packing of steam engine piston rods, except in the case of tandem compound engines, between the high and low-pressure cylinders.

It appears from the paper referred to that mining engines have been in successful use in some of the Scottish collieries for 40 years, which have no glands, but instead have "horns," as shown at *A* in the figure. These horns are bored to fit the piston rods and are internally grooved, the grooves being parallel and about ¼ inch wide and deep. The grooves are cut at a distance of 1 inch apart the whole length of the horn and at the inner end a ring of white metal, bored out to fit the piston and "saw cut" is fitted. This ring has a thickness of about ⅜ inch and a breadth of 1⅛ inch. The first engine fitted in this way had the horn cast upon the cylinder cover, and bored out, as before described. As a precaution a stuffing box was placed upon the end of the horn of the first engine so made, but no packing was used. This engine was in use for a period of 15 years, after which it was sold, and all trace of it has been lost.

The three coupled winding engines at Cadzow Colliery, with cylinders 24 inches diam. and 5 feet stroke, working at a pressure of 80 pounds per square inch, have been altered by simply fitting the horn upon the stuffing boxes, as before described. The horns might be made longer than they are at present, but they work most satisfactorily, and allow no steam to pass out. An iron casing, *B*, with an inside diameter ⅝ inch greater than that of piston rod, is fixed to the outer flange of the horn, enclosing the piston rod, and into the space between the casing and the rod a small quantity of exhaust steam is allowed to pass. This maintains the piston rod at a temperature of about 212 deg. F. If large slow pumping engines were so fitted it is certain that a considerable saving in steam would ensue, as the loss caused by using cold piston rods must be great.

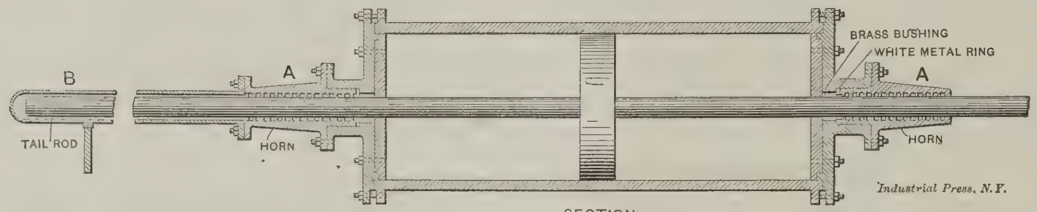
END VIEW



SECTION

Piston Rod with Packing without Glands.

At Cadzow Colliery, working under full load, it has been found that since the horns have been fitted to the winding engines, full steam is admitted for 8½ revolutions per minute, whereas, when ordinary packing was in use, steam was admitted for 9½ revolutions. It should, however, be noted that before the horns were fitted the piston rods were not in good condition. Experiments made with one of the pistons of these winding engines showed that when disconnected from the cross-head and in a position ready for work, the piston and rod, weighing fully 1,000 pounds, could be easily pulled by one man along the cylinder. A Salter spring balance was fixed to the outer end of the piston rod and registered 100 pounds—the power necessary to start and move the piston and piston rod. If a marking of white lead be put on the rod it remains on it for hours. These horns have been in use at Cadzow Colliery for six years, and the repair and upkeep of the same are practically nil.

The advantages of having engines fitted with these castings or horns are as follows: 1. There is a minimum of friction and consequent saving in the consumption of steam. 2. The piston rods last very much longer, owing to the diminished friction and wear. 3. The rods carry the piston, so that the piston may be said to float, and does not rest on the bottom of the cylinder. 4. There is a saving in packing and labor, and it is no longer necessary to stop the engine at possibly inconvenient times in order to pack the stuffing boxes.

PICKLING CASTINGS.

Railroad Herald, August, 1903, p. 13.

There are two general methods of treating castings, which are to be machined, to remove hard scale, viz.: the sand-blast and the acid bath. Iron castings are usually pickled with sulphuric acid or hydrofluoric acid, the former being most commonly used. The sulphuric acid pickling solution is usually made up of one part of sulphuric acid to ten parts of water. The sulphuric acid should always be poured into the water while the latter is being stirred. The reason for this is that a chemical reaction takes place which causes the bath to become quite warm, but there is no dangerous ebullition if properly mixed. But if the water is poured upon the sulphuric acid, the latter, being much heavier than water, remains at the bottom. When an attempt is made to stir the solution, the water enters the acid in small streams, and is instantly raised to the boiling point, generating steam, which may cause an explosion. Such an accident would be likely to throw the concentrated acid over the workman and result in serious burns.

Sulphuric acid will not attack the sand or black oxide of iron which form the scale upon castings, but the sand and scale are porous and the acid soaks through and attacks the iron under the scale. It finally dissolves a sufficient amount of iron under the scale to loosen the latter. When the workman sees that the scale is all loose the castings should be removed and washed, preferably with hot water. If the castings are small it is a good practice, after washing, to immerse them in a soda solution for a short time in order to thoroughly neutralize any acid.

One great objection to the use of sulphuric acid as a pickling solution is that if there are any soft or spongy spots in the iron, the acid will penetrate these, and it would be practically impossible to wash it out or neutralize it in the soda bath. Any acid thus entrapped in the castings will continue to eat until it is changed to sulphate of iron or green vitriol. This will tend to make the spongy or soft spots in the iron still worse and may weaken the castings to a large extent. If the acid has been used a number of times a large portion of it is converted into green vitriol, and hence the solution will not attack the iron. In this case it is necessary to add more acid to the bath or else to throw away the old bath and make up a new one.

While the workmen may receive quite serious burns from sulphuric acid it is not nearly as dangerous as hydrofluoric acid. The thin hydrofluoric acid will penetrate the skin and attack the flesh and bones underneath and may result in very serious injuries. It will also attack the finger nails very readily, but if used with care it makes a pickling solution which has a number of advantages over sulphuric acid.

Hydrofluoric acid is commonly sold in three grades. The first contains 30 per cent. of acid, the second 48 per cent., and the third 52 per cent., the balance of the solution being water. The 30 per cent. solution is that usually employed for pickling castings. One gallon of the 30 per cent. solution should be used to twenty to twenty-five gallons of water. If it is desired to pickle more rapidly less water may be used, and if it is desired to get more use of the acid—that is, make it do more work—slightly more water may be used. Hydrofluoric acid does not act upon the iron to an appreciable extent, but attacks the sand and dissolves it. It also dissolves the black oxide of iron.

When castings are pickled in sulphuric acid the surface is left with a dull or black appearance. When pickled in hydrofluoric acid the surface has a much whiter and often almost silvery appearance. The surface of castings pickled with hydrofluoric acid is also very much smoother than those pickled with sulphuric acid. For this reason hydrofluoric acid pickling is used in almost all cases in which the parts are to be polished or nickel-plated, and sulphuric acid pickling only in cases where it is desired to remove the scale so as to facilitate the machining of the castings.

When pickling with hydrofluoric acid the small casting may be put into the bath and the larger ones may have the acid poured over them just as if working with sulphuric acid. The hydrofluoric acid bath is always used cold, but should be kept above the freezing point. The bath can be used repeatedly by adding about one-third the original quantity of acid before introducing a new lot of castings. If it is desired to keep the surface of the castings bright after they are pickled in hydrofluoric acid they should be washed with hot water immediately after coming out of the acid and should be left in the water until they are heated through. If this is done when the castings are taken out of the water they will dry quickly from the heat which they have absorbed from the water. If the castings are washed in cold water they will remain wet for some time and hence will rust. A little lime is frequently added to the washing water which is used after hydrofluoric acid pickling.

When handling concentrated hydrofluoric acid the workman should always use rubber gloves. If any acid is dropped or splashed on the skin it should be washed off at once with water and dilute ammonia and this will usually prevent any injury. The dilute hydrofluoric acid of the pickle bath will not attack the skin instantly, but the workman should never put his hands into this solution, as it will attack the hands to some extent and will result in serious sores if he persists in handling the castings when wet with the pickling solution. The dilute sulphuric acid pickling solution will not injure the hands if it is spilled upon them; in fact, its only effect is to make the skin coarse and rough.

For pickling brass castings a solution is frequently made up by mixing three parts of sulphuric acid and two parts of nitric acid and adding to each quart of the mixture about a handful of common table salt. This mixture is frequently used undiluted with water and is to be handled with great care, as it will attack the hands badly. One advantage of this solution is that it leaves a good color on the castings, and hence it is frequently used for this purpose.

The pickling solution used for brass castings must be kept in an earthenware crock or in a vitrified bath tub, and the bath must be large enough to dip the large castings into it. Owing to the fact that hydrofluoric acid will attack sand it cannot be kept in a crock or jug, as it would immediately eat a hole through it and escape. Hydrofluoric acid must be kept in a lead carboy, but the dilute acid can be kept in wooden tubs or barrels. Either dilute or concentrated hydrofluoric acid will dissolve glass very readily, and hence cannot be kept in a glass bottle. Concentrated sulphuric acid is frequently kept in iron tanks, but dilute sulphuric acid attacks iron readily, and hence it is necessary to keep dilute sulphuric acid in earthenware jugs and jars, glass bottles or wooden tubs or vats.

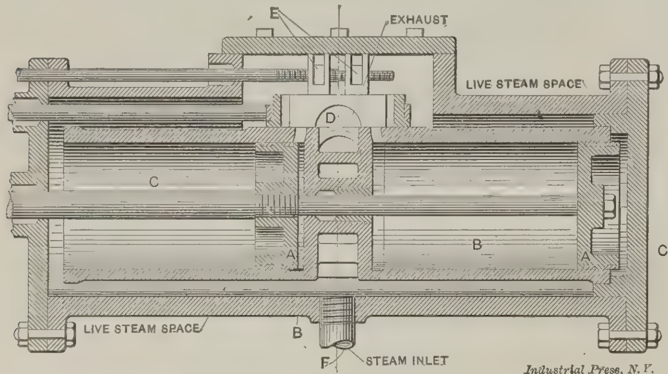
NOVEL JACKETED ENGINE.

Power, September, 1903, p. 486.

The steam engine, a longitudinal section of the cylinder of which is shown on next page, was designed by Mr. J. C. Lemon for Mr. Louis Hicks, Cincinnati, O., to reduce cylinder condensation. There are two working cylinders, with a piston in each fixed to a common piston rod, and the two working cylinders are enclosed in an outside cylinder so as to form a steam space entirely around the inside cylinders, thus completely jacketing the cylinder heads, walls and pistons. In addition to this jacketing, the live steam following the pistons in the open ends of the cylinders washes the cylinder walls, and the effect of the whole arrangement is, to a great extent, to supply heat to the admission surfaces.

The valve is a slide valve with cut-off blocks on top, so as to obtain a wide range of cut-off. A trap was attached to the outside cylinder, into which the water condensed in the outside cylinder and open ends of the inside cylinder was drained. It will be observed that each working cylinder is single acting, the combined effect of the two giving the cycle of the common engine. Dimensions follow.

Diameter of cylinder, inches	6.125
Diameter of piston rod, inches	1.0
Stroke of piston, inches	10.0
Displacement of each piston, cubic inches	286.8
Horse-power for one revolution and one pound mean effective pressure	.000724
Clearance in head end, per cent	4.8
Clearance in crank end, per cent	4.2



Industrial Press, N. Y.

Steam Jacketed Engine Cylinder of Novel Design.

The tests show the following interesting results:

First—The lowest steam consumption of record, so far as the designer knows, for so small an engine.

Second—That the steam consumption is lowest when the expansion is the greatest, while in the ordinary engine the best result is obtained at about four or five expansions.

Third—That steam of high pressure (130 pounds gage) is expanded in this engine to atmosphere at exhaust with the minimum loss, thus accomplishing the same result in a simple engine that is obtained by multiple-cylinder engines.

DATA OBTAINED BY TESTS.

1. Number of test	1	2	3	4
2. Cut-off, per cent. of stroke	5.5	9.9	23.4	34.
3. Steam pressure pounds by gage	131.	131.4	132.	133.
4. Average revolutions per minute	89.4	90.8	92.6	90.4
5. Duration of test, minutes	60.	60.	60.	60.
6. Condensed steam from cylinders	59.36	98.25	224.	297.8
7. Total heat in one pound of dry steam at average pressure of test	1190.5	1190.6	1190.7	1190.9
8. Heat in one pound of water at temperature of exhaust	180.	180.	180.	180.
9. B. T. U. absorbed by engine for each pound of steam delivered from cylinder	1010.5	1010.6	1010.7	1010.9
10. Condensed steam from trap	12.25	18.43	18.30	12.20
11. Total heat in one pound of steam used in trap	1190.5	1190.6	1190.7	1190.9
12. Heat in one pound of water at temperature of trap	327.5	327.6	328.0	328.5
13. B. T. U. absorbed by engine for each pound of steam condensed in trap	863.	863.	862.7	862.4
14. Weight of condensed steam from trap reduced to the same basis as that delivered from cylinder Item 13 ÷ Item 9 × Item 10	10.46	15.74	15.62	10.30
15. Total equivalent weight of steam delivered from cylinders	69.82	113.90	239.62	308.1
16. Average M. E. P.	22.48	35.80	60.65	77.73
17. Horse power of engine	2.91	4.71	8.13	10.17
18. B. T. U. per horse power per minute	403.	407.	408.	510.
19. Pounds of steam per I. H. P. per hour	23.99	24.20	29.57	30.30

DOUBLE-ACTING PUMP.

Le Genie Civil.

An interesting double-acting pump was recently exhibited at the Cardiff Exposition of the Royal Agricultural Society by Messrs. W. H. Wilcox & Co., of London. It is here shown in section in Figs. 1 and 2, from which it will be seen that the construction is very simple. It has two pistons which are made to move in opposite directions. Each piston is attached to a crank and carries a spherical valve. When the pistons are moving away from each other a partial vacuum is produced between them and the liquid rises into the body of the pump. On the return stroke the space between the pistons is contracted and a portion of the liquid is forced through the upper valve into the delivery pipe. There is no foot valve, that in the lower piston taking its place. These spherical valves are of rubber and the pistons are packed with leather. In the operation it is a matter of no moment whether the shaft makes a complete revolution or not and it can be moved by power or by hand.

Pump without Cylinder Heads.

G. L. F.

CARBORUNDUM AS A FURNACE LINING.

Electrical Review, August 28, 1903, p. 351.

Further details as to the employment and value of carborundum as a furnace lining, and as a means of preserving less refractory materials against fire or high temperatures, to which brief reference was made in the issue of December 12, 1902 (see MACHINERY for February, 1903), have been given in a recent article printed in the German *Zeitschrift fur Beleuchtungswesen.* When any object such as a crucible, retort, or furnace is to be treated, the carborundum powder is mixed with one-third its weight of water-glass, and the whole diluted with water until it forms a cream suitable for application with a stiff brush. If, however, the carborundum is likely to come into contact with basic substances, either basic bricks or basic slags, the water-glass is replaced by fireclay, using 85 parts of carborundum to 15 of the clay. It is then laid on the surface which is to be protected just as if it were an oil paint, and in such quantity that it forms a layer about 1-50-inch thick. To produce a film of the thickness quoted requires about 3½ ounces of carborundum per square yard. Brickwork must be thoroughly air-dried before the coating is put on; mortar especially must be as dry as possible, or, on heating, evolution of steam may blow the coating off. Massive structures of brickwork are best heated gently for some time and then permitted to become cool before the "paint" is applied. When the painted surface has been allowed to dry for 24 hours, it is ready for use; but it should be warmed slowly the first time. Gradually the water-glass disappears, and the carborundum remains as a kind of glaze, which is perfectly smooth, does not form a slag with the ash of any fuel, withstands rapid heating and cooling, and does not chip off. The process is available for any furnace or apparatus used in connection with gas or solid fuel firing. At the Düsseldorf Exhibition, a tube-welding furnace was shown, which had been given a 1-50-inch coating of carborundum and water-glass. This furnace was worked for 10 hours a day for 6 months, and at the end of that period was in as good condition as at first, no repairs having been called for. A mixture of equal parts of carborundum and fireclay can also be employed to stop any cracks in coal gas retorts, being capable of application while the retorts are still hot. In one experiment two leaky retorts were mended in 3 minutes, and they afterwards lasted for 3 months. If the retorts are to be repaired cold, the usual mixture of carborundum with water-glass should be used, but in other cases that with fireclay is preferable. Porcelain crucibles are, with advantage, coated inside and out with the same protective layer; this makes them last longer than usual, and enables them to bear rapid and frequent changes of temperature. Crucibles for the manufacture of steel are better painted on the outside only.

Special Machine for Cutting Files.

FILE-CUTTING MACHINE.

Der praktische Maschinen-Konstrukteur, July 16, 1903, p. 120.

The machine consists of a light frame anchored to its foundation by four bolts; a table which can be moved along its support as shown in Figs. 1 and 2 and which may be set at any delivered cutting angle by the adjusting screw *i*. The hammer *a* is carefully fitted and is always held in its closed position. The blow is dealt by means of the back spring *p* the strength of which is regulated according to the size of file being cut; a light spring being used for small and a heavy for large files. The actual strength of the blow delivered can be regulated according to the size of the spring by the handwheel f_1. The pressure chain, which may be tightened by the handwheel, passes up and over the roller g_1, against which the spring cap *g* has a bearing, and thence down to the frame of the machine where it is fastened. The automatic regulation of the blow, which is always proportioned to the file being made, is effected by the crank arm d_2. By means of an arrangement, not shown in the drawings here reproduced, a foot treadle can be used to easily and quickly regulate the blow to any degree of intensity. This is of special importance in the cutting of three-cornered files where the blow must be comparatively light at the point, and heavier at the middle and tang. In order to obtain a fine tooth at the point, there is an arrangement whereby the pressure is automatically relaxed as the chisel approaches the point of the file. The operating mechanism is shown in Figs. 1 and 2, in which the checknut b_3 is loosened and the chisel c_1 is brought down against the thinnest part of the file to be cut. Then this checknut is run down towards the tappet b_1, and so held that there will be a play of from .2 to .6 inch according to the type and size of file to be cut.

Power is applied through a tight and loose pulley shown at the side of Fig. 1, and operates upon the lift of the hammer through the cam shown at the side of the same illustration. The feed of the table with the file is effected by means of an eccentric b_2 with a ratchet connection to the mechanism shown at the right of Fig. 2. G. L. F.

ERICSSON, THE MAN.

Egbert P. Watson, in the Iron Age, August 13, p. 12.

The dedication of a new statue to the memory of John Ericsson at Battery Park, New York City, the first of August, led Mr. Egbert P. Watson to contribute some brief reminiscences of the great engineer in a short article in the *Iron Age*. Mr. Watson knew Ericsson for twenty-five years and as a machinist at the old Novelty Iron Works, New York, worked on the *Monitor*, and in fact, drove the first bolt in her turret. Later he held an editorial position on a technical paper and took occasion to comment favorably on the *Monitor*, before it had gone into commission. The vessel had many enemies in high positions so that Ericsson was grateful to anyone who stood up for her. Mr. Watson had not met Ericsson up to that time and consequently was greatly surprised to receive a note, asking him to call. Now this was a very unusual thing; the country was in the throes of civil war, and every one was at the highest tension, Ericsson especially, for his reputation and fortunes were staked upon what might happen within a very few hours. That he should be capable of unbending for an interview with a total stranger, when he refused to see officials of high standing in the army and navy was remarkable, to say the least. The appointment was kept and a very brief one it was, merely rushing in and rushing out of the room upon Captain Ericsson's part, with a cordial grasp of the hand and a few words to express his obligations for the article, and Watson found himself upon the doorstep, being literally thrust out by Ericsson with a "Good morning, sir, I am busy."

Mr. Watson further relates:

Thereafter I had occasion to call, by his invitation, many times, and saw him under all conditions of life, once when an attempt to blackmail him had been made by a fatuous reporter of a daily paper. To say that he was angry is a very mild expression; he was simply furious. The reporter had an article with him written by some one on the staff which he said Captain Ericsson might like to see before it was published; it raked the *Monitor* system fore and aft as a mere job to get the people's money. Ericsson read the article and then asked the reporter what it would cost to suppress it—to trap him. The reply was:

"One thousand dollars."

"Go and publish it, you infernal scoundrel; I do not care what you publish. I live for the truth, but you are an infernal liar; I will not have such a man in my house another moment; get out!"

I saw him just after this incident and he was still fuming from it.

This narrative, to be truthful, should record that this was frequently his mood, and he had much to make him so.

Ericsson was by nature a most forceful man, combative and assertive to a marked degree; he was not diplomatic or reticent about anything; if he had an opinion he gave it in old fashioned Anglo-Saxon terms that left no doubt of what it was. Once when I supposed I had invented a desirable form of screw propeller he looked it over carefully, and then said: "It is not worth a damn." On another occasion, however, when I showed him a working model of a lever engine, a type he particularly approved of, he said it was excellent, very good indeed, and he would like to see it in action. He asked how fast the model had run (it was 4 feet long and 8 inches beam), and when I replied at the rate of three miles an hour for a short distance, he said: "My, my! You have done a great thing; I never could make a model go faster than one and a half miles an hour."

These incidents are not related because I happened to be an actor in them, but for the reason that they show Ericsson to have been fair-minded and not incapable of seeing value in the ideas of others, although this view is taken by many at this day, upon very slight evidence.

It is not generally known that for his *Monitor* plans Ericsson never received one penny from the government in any form, and all bills introduced in Congress to compensate him were killed by his enemies. It was the same with the United States steam vessel *Princeton*, which was the first screw steam vessel of war owned by the navy, and the pioneer in naval screw steamers, although the English naval steam vessel *Ranger* was built shortly after. Through the influence of naval officers of the period Ericsson was never rewarded for her plans and engines, which were a distinct innovation at that time. These things had their influence in a marked degree, and while he was a man who would not submit to an injustice if he could help it, in these instances he was powerless. Another incident which happened long after the civil war came about through the neglect of the managers of the Centennial Exposition, in 1876, to invite Captain Ericsson to contribute a history of his inventions. He was greatly chagrined, but this could be remedied, and he set about it. It took the form of a large volume containing his principal engines and devices of every kind from the beginning of his career. It was profusely illustrated with costly engravings and printed on plate paper made expressly for it. The edges were gilded with pure gold, or 18 carat, at least, and bound in the best turkey morocco. This book cost $60 a volume or $60,000 for an edition of 1,000 copies for complimentary distribution; none of them was ever sold by Ericsson. It was doubtless the most costly work ever gotten out in this country.

Although Ericsson was not a wealthy man he was very lavish in his expenditures and his right hand never knew what his left had given away. At one time he was having a large, intricate casting for a surface condenser made at the Morgan Iron Works, New York. The casting had been poured and the foreman of the foundry wanted to leave it in the sand to cool; but Ericsson was anxious to see it and ordered it dug out. It looked all right and after a little badinage with the foreman about his timidity Ericsson went away. The next day, however, told a different tale—the shrinkage had torn the casting in two and the foreman awaited his visit with anxiety. When he came and saw what happened he merely said: "Can you make another with what you know now?" "Yes, sir," said the foreman. "Go ahead then," said Ericsson. That condenser casting cost $1,500 and the loss fell upon Ericsson.

In appearance Ericsson was of middle height, but he had immense shoulders and chest, and must have possessed great strength; his countenance was stern and forbidding, but when pleased he could lighten up, and in that mood was a handsome man. During the last thirty years of his life he lived in what was once a popular residence section of New York, but had finally become a cheap boarding-house section, inhabited by many Italians and with a "flavor of mild decay" over all. He disliked change so much, however, that he could not be induced to move to other quarters.

The models of all his inventions were displayed in glass cases around the room, and they were beautifully made. Every detail was constructed upon a certain scale and woe be to the model-maker if he departed in the least from the drawing. Ericsson was a fine draftsman and declared that all dimensions were on his drawings and that the machine would go together if the drawings were followed. At 84 years of age he sent his secretary with some drawings to show me that his hand had not yet lost its cunning. They were surprisingly clear for a man of his years. Late in life he shunned all association with every one. He had become very deaf and was sensitive to his infirmity, but he did not forget anyone who had ever had his regard and confidence.

TRAIN RESISTANCE AT HIGH SPEEDS.

The signification of T_1 was accidentally omitted from the note "Train Resistance at High Speeds," which appeared in the *Engineering Review* section of the September number. Therefore the formula is repeated in the following, with the signification of all the symbols employed:

$$S = \frac{4 + 0.13\,V + 0.004\,A\,V^2\,[1 + 0.1\,(n - 1)]}{T_1}$$

where

S = the train resistance in horse power per ton;

V = the speed in miles per hour;

A = the cross sectional area of the car in square feet;

T_1 = weight of train in tons;

n = the number of cars in the train inclusive of the locomotive.

* * *

According to experiments made in Germany the danger of firemen receiving a fatal shock when playing a hose onto a charged electrical conductor, is not nearly so great as has been popularly believed. First, it has been shown that the resistance of the human body from the hand to the earth when standing on wet ground, is not less than 15,000 ohms, and that a current of 0.03 ampere is not fatal under ordinary circumstances, although dangerous. A stream of water was directed by a nozzle onto a bare wire having a cross-section of 0.145 square inch and carrying a three-phase current of 6,000 volts. With the end of the nozzle only 12 inches from the bare wire, the tests demonstrated that it was not possible to receive a fatal shock when pure water passed through the hose. But with the water containing 0.5 per cent. of soda, the distance must be increased to nearly 40 inches before there is no danger of fatal shock. On a 550-volt direct circuit with the nozzle directed onto the wire at a distance of less than 1¼ inches from it, the actual current transmitted through pure water was only 0.016 ampere, or slightly more than one-half the limiting value.

A READING ROOM FOR EMPLOYES.

L. G. STEBBINS.

One of the greatest, if not the very greatest, influences upon a man's thought and consequently his conduct is in the matter of his intellectual food, that is to say, what he reads. Everybody who can read, does read, and the tremendous influence of what they read upon their minds and characters cannot be estimated. The public press claims to, and certainly does influence public opinion to a great extent. How is this possible? For the reason that the public reads and the public's opinions and conclusions are formed from what they read concerning a given subject. Almost everybody reads the daily papers, and all, with a mind of average activity, form opinions and arrive at conclusions based upon what they have read about a certain subject. In these days when the workingmen are coming more and more to think for themselves, it is of the utmost importance that their line of thought be in the right channels and their meditations along lines which make for the peace and well-being of the community to which they belong. The best way to secure a pretty evenly-balanced mind is to read only what is moderate, fair-minded and correctly stated, without prejudice or jealousy or anything that tends to warp a man's mental vision. It may be true that some men are born with a taste for the vicious, and such men will of course, be the hardest to deal with, but the great majority of men have minds of good caliber, capable of good mental balance, provided they are developed by proper influences and proper food.

Every employer has it in his power to do something in this work of education, and the results in the long run certainly justify the slight expense he may undergo in his effort to help along a good cause. He can provide some good literature for the men in his employ to read, and he can furnish them a good, light room to read it in, and he can encourage them to spend some of their spare time in the reading room connected with the shop. The plan is entirely feasible, and will work out for the good of both men and employer. Let the employer select a good, clean, light room—in the office building if possible—and furnish it with chairs, long tables, book shelves, paper files, etc. Everything should be selected with a view to comfort and durability, and should not be the cheapest that can be bought. Let the men feel as though the place was theirs to be enjoyed, and they will be a rather unusual set of men if they do not proceed to enjoy it. In the selection of the reading matter the employer should use his best judgment and should have a good assortment at all times so that interest in the enterprise will not wane on the part of the men. Let two or three copies of each of the best local papers be provided, and also two or three of the leading papers of the section of the country where the plant is located, taking care to exclude the sensational and flashy "yellow sheets" which are working untold mischief among the workingmen of our country to-day. Good magazines (the best are not too good) should be accessible, both trade publications and other magazines covering the general field of literature. In addition to this there may be some good books, novels, history, and technical works bearing upon the various phases of the work the men are engaged in. Above all things steer clear of political questions and do not select the reading matter with a view of proselyting the men to your convictions as regards the question of which is the best party. Exclude the rabid paper whether it be of your own party or another.

The expense of providing reading matter for a reading room that would be a credit to the shop ought not to be over $2 per week at the outside, and I really do not know how $2 per week could be spent to better advantage. There will be a good many magazines received gratis from publishers which can go into the reading room, and gifts of books will be forthcoming when the public spirited men of the town learn of what is going on in such and such a shop. The room should be open to all employes, of course, and most of them will drop in, perhaps out of curiosity at first, but later they will have formed the habit of depending upon the reading room for information of various kinds, and by reading and comparing the views of daily papers that are acknowledged to be solid and respectable, with the "yellow sheets" which some of them have been accustomed to read, will be led to drop the sensational paper, and take up the other one. This thing has happened, and would happen often if the comparison between the two classes of papers were brought to their attention daily for a while. The reading room should be open during the noon hour so that the men who carry their dinners may profit thereby, and for two or three hours during the evening. There are generally some men in the shop with natures inclined to be studious, and a man of this character can usually be found who will act as librarian and have charge of the reading room under the head of the firm. Such a man will take interest in the scheme, and will do much towards making the enterprise a success.

It is true that almost every town of any size has a free public library and some will say that there is no necessity for a reading room or library, if you choose to call it such, connected with a shop. The fact is that while there are libraries the workingmen are conspicuous by their absence from the reading rooms of the public institutions. They and their families may draw books from the library, but they are not found in the reading room, poring over the latest and best in science, history or fiction. The best thing about the shop reading room is that it fosters the spirit of fraternal feeling that exists between shopmates, and the men can come to the room without feeling ill at ease because they do not look as well as some one else. They can drop in at the room after supper and mingle with friends, reading good newspapers, and some of them perhaps studying to be better workmen. Occasionally a short, practical talk on some of the burning questions of the day may be given—another means of educating men and training their minds to run in the right channel. Men form opinions from hearing other people talk, and next to reading this is undoubtedly the most important factor in a man's education. In every town there will be found public spirited men, of good character, wisdom and moderate in their expressions, who will be glad to address a gathering of men, realizing as they do that the peace, prosperity and well-being of the community depend on the conduct of the workingmen of the place. A well read, educated man is the best man in the world to have for a neighbor, be he a millionaire or a workingman, and every man who employs ought to be glad to have an opportunity to assist in educating his men so that they will be a credit to him and the town where they belong.

From a purely selfish standpoint—that of returns on the money invested—the enterprise will certainly prove its value after a fair trial. Educated men make good workmen, and good workmen turn out good work, and good work gets good customers, etc., and so on. But a man, be he employer or not, should not worship the money god too fervently, else his efforts may come to naught after all. There is certainly something higher in this world to live for than mere money getting, and happy is the man who learns this early in life and shapes his course accordingly.

The scheme I have outlined is not Utopian to a very great extent, and the whole plan is practical and entirely feasible. Many manufacturers have already instituted reading rooms of this kind and we think they are more than satisfied with the results. It is a movement in the right direction, and a step forward in the march of progress. It will be a great help in the solving of the great question of the day—the labor question—as a man who has absorbed all the good things that have been written in regard to the brotherhood of man, and the relation of labor to capital, views of moderate and fair-minded men both employers and employes, is pretty sure to try and deal fairly when a question comes up for settlement between himself and his employer.

* * *

Out of 16 tests of boiler joints, with nickel steel rivets, made by the Bethlehem Steel Co., the plate failed in two and the rivets in six, when in single shear; and when in double shear, the plate failed in six tests and the rivets in two. In single shear the ultimate shearing strength of the rivets was 45,000 pounds, and when in double shear 88,000 pounds. It was deduced that a ¾-inch nickel steel rivet could safely replace a 1 1-16-inch or even a 1⅛-inch steel rivet.

AN INTERESTING ROPE TRANSMISSION PROBLEM.

The situations and requirements of rope drives are such that it is very seldom that any two installations will be alike, and the engineer in designing a new drive is obliged to refer in almost every case to the fundamental principles governing such drives, rather than to the precedent of former experience.

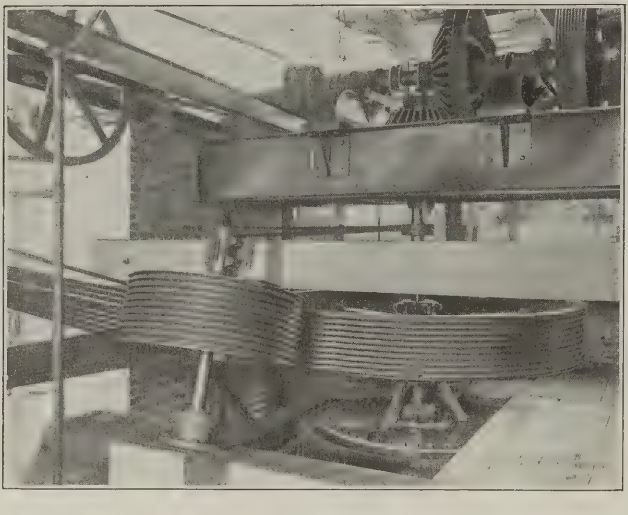

Fig. 1. Showing Wheel Casing and Idler.

An unusual problem was presented in the installation of a rope drive for Messrs. James & E. H. Wilson, operating a large woolen mill at Pittsfield, Mass. The mill was formerly operated by steam power. An excellent water power, however, is located about three-quarters of a mile from the woolen mill, in a building formerly vacant, and which would probably have been abandoned were it not for the water power. Messrs. Wilson purchased the abandoned mill with the idea of using the water power for generating electricity, the electricity to be transmitted for driving their woolen mill, thus taking advantage of the economy of the water power over their steam plant.

The ordinary method of transmitting power from a turbine shaft by means of gears was found impracticable and the only economical method that seemed to be available was by means of manila rope transmission. The shape and dimensions of the wheel house, however, were such that 16 feet was the greatest available distance between the vertical water wheel shaft and the dynamo. The power to be transmitted was 200 horse power, and it is quite evident that these centers were exceedingly short for a rope transmission, especially as on account of the vertical turbine shaft and the horizontal dynamo shaft the drive must be a quarter twist.

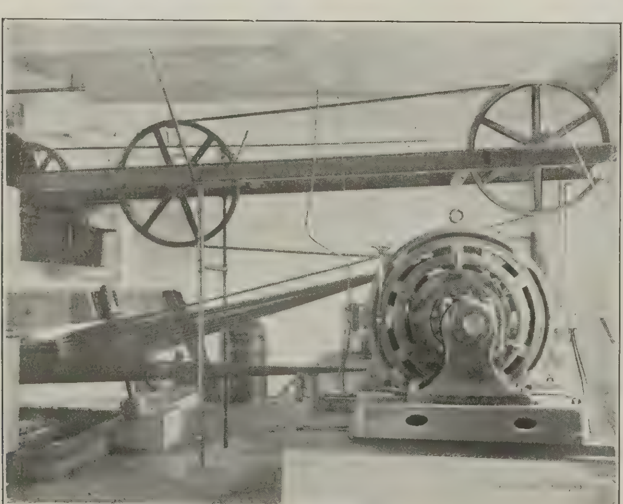

Fig. 2 Generator, with Tension Carriage Overhead.

The plant was designed and installed by H. W. Caldwell & Son Company, of Chicago, Ill., through the engineers in charge of their eastern sales and engineering office at 95 Liberty Street, New York City. So far as the designers are aware, this is the shortest quarter twist drive in use where a considerable amount of horse power is transmitted and a number of ropes are employed.

The illustrations shown will make the arrangement of the drive plain. Fig. 1 shows the water wheel case and the vertical shaft supported at its upper end by a heavy steel construction. The heavy support necessary for the gear drive is some indication of the comparative ease of operation of the modern rope transmission as compared with the old gear drive. In Fig. 1 is also shown the deflecting idler carrying the slack ropes, which, as will be noticed, is placed very close to the driving sheave. A portion of the tension carriage is also shown overhead.

In Fig. 2 can be seen a portion of the driving sheave at the left of the cut. The photograph of Fig. 1 was taken from a position in front of the window shown in Fig. 2. The position of the generator with reference to the driving sheave is clearly shown in Fig. 2; the receiving sheave being on the other side of the generator. The lower ropes are the pulling ropes and the slack is taken to the tension carriage from the driving sheave over the upper groove of the deflecting idler. The one-groove re-winding idler is placed above the generator; from thence the rope passes over the tension carriage sheave and returns to the driven sheave on the generator.

Particular attention is called to the quarter twist arrangement of the ropes, another view of which is shown in Fig. 3.

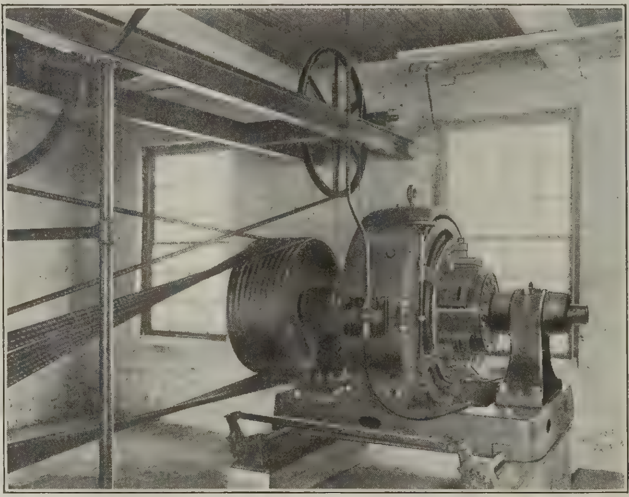

Fig. 3. Generator, showing Receiving Sheave.

In installing the drive the driving and driven sheaves were placed according to the usual rules for setting quarter twist belts or ropes. The 10-groove deflecting idler was placed as nearly theoretically correct as could be, and the tension carriage and the re-winding idler were placed in position. The rope was then wound, and by raising the generator slightly the catenary of the ropes between the driving and driven sheaves was taken into account, so that the ropes would lead correctly between the two sheaves.

The speed of the ropes is about 5,000 feet per minute, and notwithstanding the short centers, high speed, and the many reverse turns, the drive has given excellent satisfaction since its installation. A recent report from Messrs. Wilson is to the effect that the drive is working very satisfactorily—this report coming about a year after the installation of the transmission.

The driving sheave on the water wheel shaft is 96 inches diameter, running 209 revolutions per minute. The driven sheave on the generator is 34 inches diameter, running 585 revolutions per minute. Both sheaves are grooved for ten 1⅛-inch ropes. The distance between the deflecting idler sheaves and the driven sheave is approximately ten feet.

The engineers of H. W. Caldwell & Son Company having this installation in charge feel that the successful solution of the problem is an instructive precedent for the use of rope drives in situations heretofore considered too difficult for this class of power transmission.

LETTERS UPON PRACTICAL SUBJECTS.

MACHINING A DIFFICULT PUNCH AND DIE.

Editor Machinery:

Some years ago the writer was called upon to make a punch and die for producing special washers of the shape shown in Fig. 1. These were to be about 1-32 inch thick, 1⅜ inch in diameter, with a ⅜-inch hole, and to have on the periphery 48 saw like teeth. It will be readily seen that the punch and die for such a piece would not be an easy one to file up. The die was made of a block of tool steel 4 inches long by 3 inches wide and about 1 inch in thickness, and in order to cut the teeth, after it had been bored out, the chuck shown in Fig. 2 was employed.

This consisted of a casting *A*, driven onto the steel shank *B* which fitted the index center of a Hendey shaper. The block was held in the chuck by means of four setscrews, *CC*, while its back rested against the face *E*. This chuck was placed in the index center spindle and the center plate elevated so as to give the proper clearance to the teeth which were cut by the tool shown in Fig. 3. The point of this tool was ground to the shape of the teeth to be cut and the chuck was indexed around, 1-48 of a revolution at each cut, until all of the teeth were properly formed. Through the opening *F*, in the back of the chuck, the operator was enabled to observe the work as it progressed.

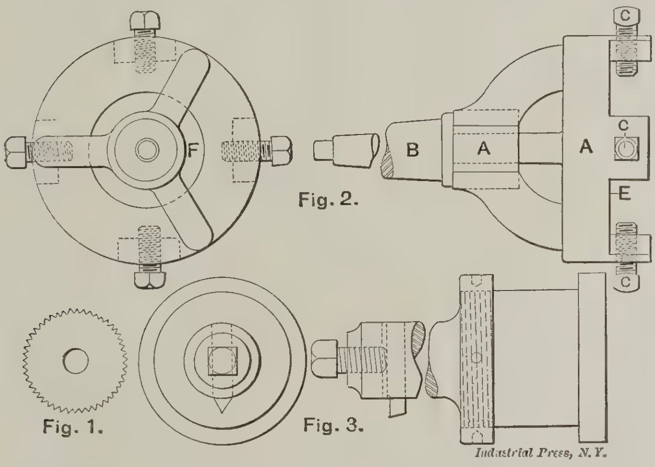

Fig. 1. Fig. 2. Fig. 3.

Chuck and Tool for Making a Difficult Die.

The punch was made upon a universal milling machine using a cutter of the proper angle for the teeth, and indexing the work in the regular index head. After machining as above described, but little filing was required to fit the punch and die so that they produced most satisfactory results. Nix.

A BORING ATTACHMENT FOR THE LATHE.

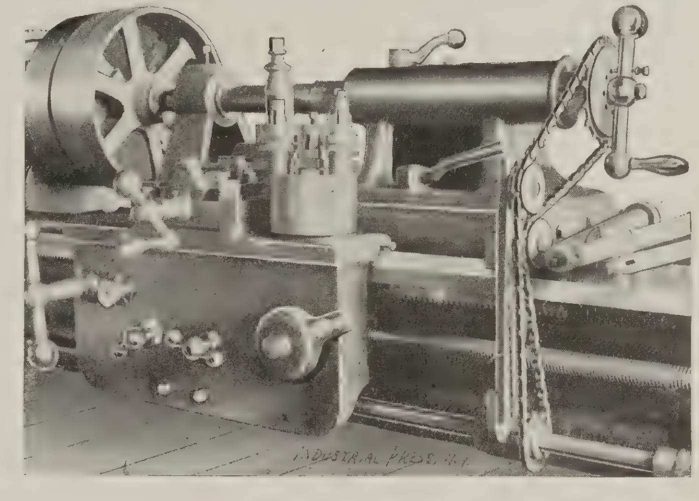
Editor Machinery:

The photograph herewith shows a 16-inch lathe as we have fitted it up for boring purposes. The boring bars fit the tailstock spindle, which has a groove planed across its face in which tongues on the bars engage to prevent their turning, thus relieving the taper shank of this duty. The cutter end of the bar is rigidly supported close to the work by the bracket shown in the cut. Flat cutters are used and are held by a set screw in the end of the bar.

The production and maintenance of these cutters being somewhat expensive led to making some special tools which would facilitate their production. After being cut off in a power hack saw they are placed in a shaper and, several at a time, are planed where they straddle the boring bar. They are then finished in a lathe having stub bars, all fitted to one piece, screwed on the nose of the spindle. They are turned and relieved, and after being hardened, are again put in the stub bar and ground with a grinding attachment which is fitted to the lathe. In this manner they are produced rapidly and accurately and when a set is once made it is rarely necessary to make other than finishing cutters as these are ground down for roughing cutters as soon as they wear below size.

The stub arbors and their holders are shown on the right wing of the carriage, one for each size of bar. Some of the cutters are also to be seen on the cross-slide and three of the boring bars are lying on the lathe bed.

The most important part of the outfit is the arrangement of the power feed for the tailstock. An ordinary bicycle chain is used and as the sprocket on the feed rod as well as the idlers are supported from the tailstock, any movement of the latter does not interfere with the action of the feed. The upper sprocket is a running fit on the tailstock feed screw. It has eight holes in its outer face and in one of these holes the spring pin in the bell crank is slipped to engage the feed.



Lathe Fitted with Boring Attachment.

With a single exception the whole arrangement works very satisfactorily; the lathe is a stiff one and the cutters can be fed through at a high rate of feed. Two or three cutters are used, according to the accuracy required, while holes that need to be better than can be produced with a cutter of this kind are reamed by hand after boring. The one fault mentioned is that the feed should engage and disengage at the feed shaft instead of at the tailstock screw, the advantage being that the chain would then stop with the feed. Corneil Ridderhof.

Grand Rapids, Mich.

TOOLS FOR TURNING AND BORING PISTON RINGS.

Editor Machinery:

While the boring and turning of "snap" rings for small engines does not require any great amount of skill on the part of the operator, since a slight variation is allowed on both inside and outside diameters of the rings, yet if they are to be produced in large quantities, the introduction of special tools which will increase the speed of production will be found a good investment. With this object in view the tools here shown were designed, and judging from the increased output they have served the purpose very well.

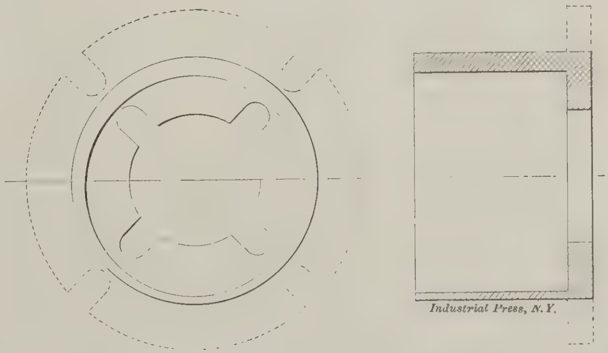


Fig. 1. Casting for Piston Rings.

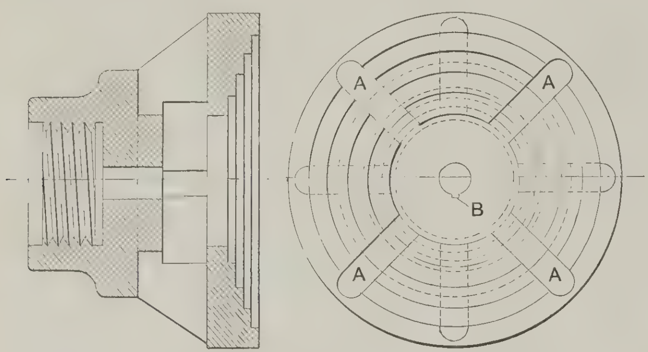
The tools consist of a bell chuck, cutter head and boring bar. The casting from which the rings were made is shown in Fig. 1 and has a small flange 1 inch wide on the inside for clamping them to the chuck. On the smaller sizes this flange is on the outside, as shown by the dotted lines. There are four slots cast in the flange which correspond with the slots in the bell chuck, thus doing away with the necessity for drilling bolt holes or for removing the nuts from the bolts in order to remove or replace the work. The bell chuck, shown in Fig. 2, is fitted to the spindle of the lathe and has a series of counterbored seats in the face to receive the different sizes of ring castings. The slots for clamping the bolts, above referred to, are cast at *AA* and are of sufficient length to accommodate all of the sizes of rings.

The boring bar, shown in Fig. 4, is made of a piece of 1½-inch tool steel turned down at the ends to a diameter of 1⅜ inches. These turned portions are eccentric with the remainder of the bar so that when the bar is held by the ends it will have a throw of ⅛ inch. The shorter end has a feather key to correspond with the keyway in the chuck, at *B*, so that the bar revolves with the chuck and the work. The turret head is bushed to 1⅜ inches to receive the long end of the bar.



Industrial Press, N.Y.

Fig. 2. Bell Chuck for Turning Piston Rings.

The cutter heads, of which there are two, a rougher and a finisher, slide on the bar and have a compound movement due to the eccentric motion of the bar as it travels with the work and to the sliding movement of the turret as it feeds it along to the work. The eccentric motion of the bar causes the cutting tool to advance and recede from the work and thus bore a hole that is ⅛ inch eccentric with the outside of the ring which, at the same time that the boring is in progress, is being turned on the outside with an ordinary turning tool. A slot at *C* in the cutter head, Fig. 3, engages with a lug in the face of the turret and thus prevents the cutter head from turning with the work, at the same time allowing it to move freely with the motion of the bar.

When the casting has been roughed out the bar is withdrawn from the chuck a sufficient distance to allow the roughing head to be removed, and the finishing head is substituted.

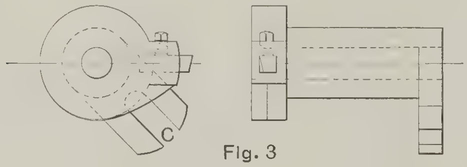


Fig. 3

Fig. 4

Industrial Press, N.Y.

Figs. 3 and 4. Cutter Head and Bar for Boring Piston Rings.

The ring is then simultaneously finish turned and bored in the same manner in which it was roughed out. A gang tool is used to cut the rings off to the proper width, two rings being cut off at a time. This operation completes the rings and the time occupied is about one-half that formerly required when they were finished by first boring the casting and then shifting the amount required for the eccentricity and turning on the outside. The tools here described were made to fit a 24-inch turret lathe but any stout lathe with turret attachment can be used just as well. H. H. Esbenshade.

Waynesboro, Pa.

A DOUBLE-ACTING PUNCH FOR A SINGLE-ACTING PRESS.

Editor Machinery:

The writer recently had occasion to make 4,000 small brass caps of the shape shown at the right in the accompanying drawing. Having no double-acting press on which these could be punched and drawn simultaneously the method first suggesting itself was to make them in two operations, blanking them out first and then drawing in a second operation. But, as this would entail a double amount of work, after a little consideration the punch here illustrated was designed for punching and drawing the work on a single-acting press, in the same manner in which it would have been done on a double-acting press had one been available.

The die is made in one piece, similar to the ordinary die used on the single-action presses, the only difference being a deeper recess for the blanking punch in order to give a sufficient throw to the internal punch for it to force the cap through the bottom part of the die. As the brass was but No. 24 gage it did not require very great pressure to draw the cap up to the required 5-32 inch in length. When the piece was blanked, the punch was flush with the die and the lever *G* had just come into contact with the stop *A* which, as the punch continued to descend, caused the internal punch to move forward ahead of the blanking punch and force the punching through the die, thereby forming the cap in a single operation. As the blanking punch was withdrawn the strippers *B B* relieved the cap from the internal punch and the spring *D* returned it to its original position within the blanking punch. Geo. C. Reith.

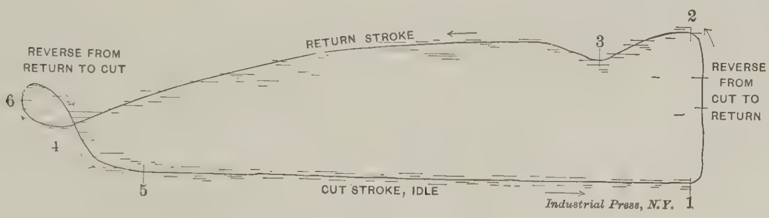
PLANER INDICATOR DIAGRAMS.

Editor Machinery:

The advent of individually motor-driven machine tools has, by direct electrical measurements and readings from dial instruments, resulted in a ready determination of the power required to drive them. This has been very satisfactory for those tools in which the power consumption varied but slowly, but less so with others, such as planers, with which the rapid changes at the ends of the stroke made accurate readings of the fast moving needle rather difficult. On studying the influence of belt speed and shifting rate on the action of the planer it became plain that a power diagram, analogous to that used in steam engines, which would give a graphic picture of the occurrences throughout the stroke, and more particularly of those at reversal, would be very desirable. An electrical instrument maker undertook the building of suitable apparatus which consisted of a special type of amperemeter, with a recording drum, etc., arranged very much as the usual engine indicator. The drum, carrying the paper, was rotated from the planer table through a reducing gear. As the makers thought that the friction of the pencil would too seriously dampen the action of the ampere meter needle, this was brought into contact with the paper at short intervals only. A stirrup, wide enough to cover the entire field of the needle, was from time to time depressed by clockwork and in turn insured the momentary contact of the pencil carried by the needle. This explains the peculiar appearance of the diagram, which is made up of a series of horizontal dashes; the one shown representing a number of consecutive table strokes. The continuous curve was drawn in by hand. The general outline is characteristic of all obtained on various planers.

The power taken on the cut stroke, idle, is constant. At 1 a very rapid power increase is started to reverse the table to the return; the almost vertical rise shows that it is very sudden. Then a gradual fall of power takes place during the whole of the return stroke, except near the start, where there is, from 2 to 3, a peculiar dip and recovery. The absence of a steep peak at 2 shows that the width and speed of the belt have been well chosen and that the reversing cam has been correctly designed, all working together harmoniously. It is natural to expect that, once the return is well started, the power would remain fairly constant to the beginning of the next reverse; but the diagram shows a continuous drop; this is characteristic of all tests made on other sizes of planers also, and an appearance which the writer is at a loss to satisfactorily explain. At 4 the change into the cut stroke begins to make itself felt by an increase of power beyond the actual reverse; the power then gradually and smoothly drops to that taken throughout the cut stroke. It is the continuance of the power rise beyond the actual reversal that causes the rather unexpected loop at this end of the diagram. This also is a general characteristic. Though at first sight this loop appeared anomalous a little reasoning shows it to be expected. To overcome the inertia of the fast running pulleys in reversing them calls for an increase of power; as the beginning of the reverse takes place during the return stroke the power must rise near the latter's end, attain a maximum at about the time when the reversal has been effected and then fall. As the power during the cut is less than during the return the curves must cross and form a loop. At the change from cut to return the same phenomena occur, but manifest themselves as a dip instead of a loop, because the power required at the beginning of the return does not fall as low as that taken by the cut stroke, so that the curves, though approaching, do not cross to form a loop; the action at both ends is similar, varying only in degree. The motors used were all of the three-phase, alternating current type, with 50 periods per second.



A Typical Planer Indicator Diagram.

Philadelphia, Pa. HENRY HESS.

ANOTHER METHOD OF TURNING A BALL.

Editor MACHINERY:

The writer has read with much interest the article in the June number of MACHINERY upon the subject of ball turning. In the shops of Messrs. Richard Pohle & Co., Riga, Russia, many balls are turned, for valve purposes, in what is believed to be a faster and more accurate method than that described by Mr. Otis. The balls are first turned on centers to a diameter about 1-64 inch greater than the finished size and as nearly round as possible. The centers are then cut off and the balls finished in the arrangement shown in the photograph, Fig. 1.

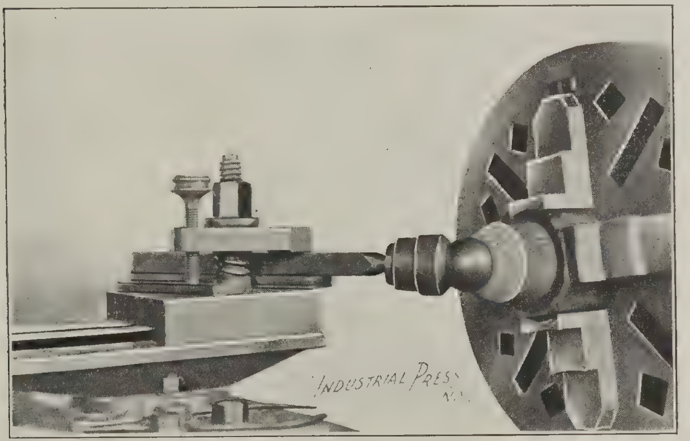


Fig. 1. Another Method of Turning a Ball.

A piece of hard wood is put in the chuck and bored out to fit nearly one-half of the ball. The finishing tool consists of a single piece of steel bored out to a diameter of from 55 to 66 per cent. of the diameter of the ball. The cutting edge at *AA*, Fig. 2, must be very sharp and perfectly circular, and when grinding is necessary, it should be done on a machine to insure accurate results.

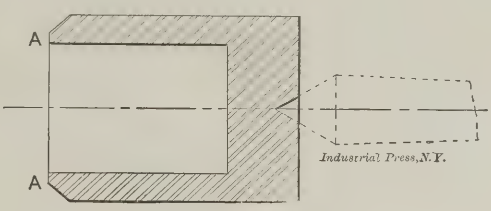

Fig. 2. Tool used for Ball Turning.

The ball is placed in the wooden chuck and the tool pressed against it at an angle of about 45 degrees. While revolving, both the ball and the tool will rotate against one another and in a short time the ball will be cut perfectly round and smooth. Naturally, both ball and tool will heat very considerably, so that it is necessary to cool the ball in water. It is, therefore, a good plan to turn two balls at once so that one may be cooling in the water while the other is in the chuck. This method has been employed for a number of years and has always produced very good results. The photograph was taken when turning a ball 2 inches in diameter. A. WIND.

Riga, Russia.

FACING AND COUNTERBORING LARGE SPIDER CASTINGS IN THE DRILL PRESS.

Editor MACHINERY:

In a shop where paint mixing machines are built the writer came across a method of facing and counterboring large castings in the drill press which may prove suggestive to readers for the machining of other work in a like manner. An idea of the shape and size of the castings may be gained from Fig. 1, in which is shown the nature of the work to be done. As will be seen the casting has two hubs which are required to be bored to a finished diameter of 5 inches, then faced at *AA*, *BB*, *CC*, and *DD*, respectively, and lastly counterbored at *FF* to a depth of 1 inch and a diameter of 7 inches. It is at once obvious that the large drill press which is equipped with a floor base is the proper machine for the work, and that it would be very difficult to do the work in any other machine.

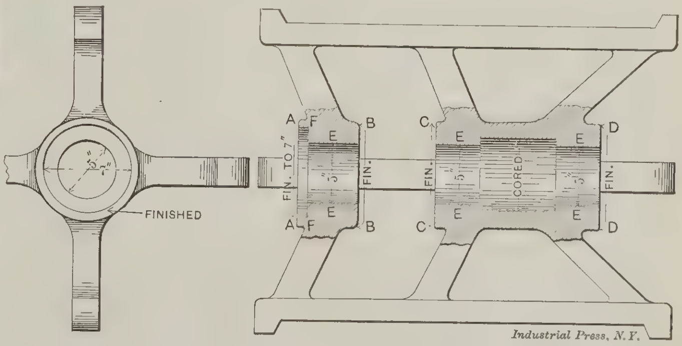

FIG.1. CASTING AS BORED, FACED, AND COUNTERBORED.

The boring to a finish of the cored holes in the hubs presented no unusual difficulties; a large boring bar of approved construction being used and the projecting end allowed to run in a bushing, bolted to the floor base of the drill, to which the work was strapped. To accomplish the facing of the four hub faces and the counterboring of the seat in an expeditious and accurate manner, however, required other means than those used for the boring. It was for this work that the special facing and counterboring tool illustrated in Fig. 2 was used.

As will be seen the special tool consists of the regulation bar, turned taper at one end to fit the drill press spindle, and rounded at the other to enter easily the supporting bushing on the base of the press. This bar has five holes let through it to accommodate the boring head. The holes are indicated in the engravings by letters *C*, *D*, *E* and *F* respectively. Three holes are for the cutter bar and the other two are tapped holes for the feed screw *G*. In the cutter head, *H* is the bar, *O* the "goose neck" cutting tool, a seat for which is provided in the cutter clamps *M* at either side of the center as the taking of under and upper cuts necessitates. *I* is the connecting strap between the cutter bar and the feed screw; *J* the bar-fastening nut; *G* the feed screw and *K* the hand knob. *N* is a cap screw used for fastening the cutter and cutter straps to the cutter bar.

In using this tool the bar was projected down through the hubs of the casting until the end ran in the supporting bushing at the base. The cutter head was then in the position shown in Fig. 2. First the surface *A* was faced, the feed screw being turned a little by hand at each revolution—the large opening making this an easy matter. Next the seat *FF* was bored and finished in the same manner, feeding the spindle of the drill down for depth and the feed screw of the cutter head for diameter. After this the under face of the upper hub was faced by removing the cutter head entirely; feeding the spindle downward until the upper three holes in the bar were clear of the under face of the upper hub; then relocating the cutter head with the feed screw in the same hole as it occupied in the first instance; but with the cutter bar in the upper hole *C*. Thus the cutter bar was merely reversed and the facing of the under side of the hub accomplished by feeding the spindle up instead of down. The two faces of the lower hub were faced in the same manner, the cutter head being removed and reversed as required.

THE STRENGTH OF GEAR TEETH.

Editor Machinery:

From time to time much valuable information has been published in the columns of Machinery relative to the strength of gear teeth; and the formulas by Mr. Wilfred Lewis, reproduced in the July data sheet, accompanying the Engineering Edition, are very valuable to those who have to make calculations concerning the strength of the standard gears—or rather the safe load, as the formulas do not give the ultimate strengths.

In one case, however, which recently came to the writer's attention the Lewis formulas did not seem to call for a gear strong enough for the given purpose. In this case the writer was called upon to design a large cast-iron gear to run at a speed of 100 feet per minute and to carry an extremely heavy load. Lewis' formulas having been used with good results at higher speed, it was natural to suppose that they would apply equally well to this case. As this gear was too large for the shop to handle the design was submitted to several of the parties who make a specialty of large gear work and their opinion was asked as to its fitness to stand the load for which it was designed. Without exception they replied that the gear was not strong enough for the required duty and when the gear tooth was calculated as a cantilever beam, assuming the load to come at the top of the tooth, it was decided that the proper factor of safety had not been allowed.

The writer then began to study the subject more fully with the object of finding a formula which would give the ultimate strength as well as the safe load, so as to be able to vary the factor of safety to suit the given case, and also to calculate the strength of tooth when made shorter than the standard depth. There are so many rules for the strength of gear teeth that there is probably much truth in the statement made in Grant's gear book that, "If a gear tooth should break, the designer can always find a rule to prove that it must have met with an accident, as it was properly designed." It seems to me that the best way to treat this subject is to first calculate the ultimate strength of the tooth and then divide by the proper factor of safety to get the safe load at the pitch circle.

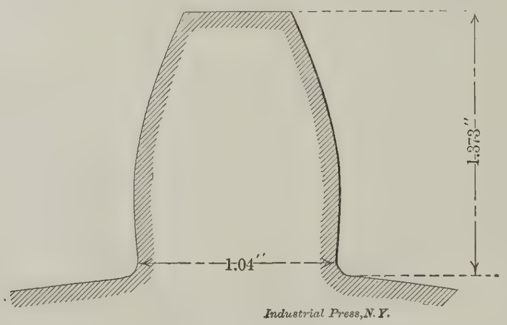
Among Cooper's collection of 24 rules from different writers, published in the *Journal of the Franklin Institute*, July, 1879, will be found the following method, which was used by James Watt to find the ultimate strength of cast-iron gear teeth. He found that a bar of 1-inch square cast-iron would break if a load of 600 pounds be applied at a distance of 12 inches from the point of support; then if the load was applied at 1 inch from the point of support, the bar would break with a load of $12 \times 600 = 7{,}200$ pounds. Hence the following formula for the ultimate strength of cast-iron gears:

$$U.\,S. = \frac{7{,}200 \times (\text{thickness of tooth at root})^2 \times \text{length of face}}{\text{full depth of tooth.}}$$

For example: What would be the ultimate strength of a cast-iron gear tooth of 2-inch circular pitch, 5-inch face; the gear having 30 teeth? The figure shows the thickness of the tooth at the root to be 1.04 inch and the depth of tooth 1.373 inch. Then:

$$U.\,S. = \frac{7{,}200 \times (1.04)^2 \times 5}{1.373} = 28{,}300 \text{ pounds.}$$

This rule, however, would require cast-iron to have an ultimate strength of flexure of 43,200 pounds, whereas for ordinary cast-iron most authorities give 36,000 pounds per square inch. Assuming the latter value and calculating for a beam of 1 inch square section and 1 inch deep, we have:



Industrial Press, N.Y.

Tooth of Gear used in Example.

$W\,l = S\,R.$

$W =$ Breaking strength in pounds.

$l = 1.$

$S = 36{,}000.$

$$R = \frac{(\text{side of square})^3}{6} = \tfrac{1}{6} = \text{moment of resistance.}$$

Then

$$W = \frac{36{,}000}{6} = 6{,}000 \text{ pounds}$$

and for safety, unless the ultimate strength of flexure is known, it would be better to use 6,000 pounds in the formula in lieu of 7,200 pounds.

Substituting this value in the above example the ultimate strength of the tooth would equal

$$\frac{6{,}000 \times (1.04)^2 \times 5}{1.373} = 23{,}600$$

Whenever the ultimate strength of flexure is known for any material, take one-sixth of the value for use in the formula.

Having found the ultimate strength of the tooth, the next step in order is to find the safe load. This would depend upon the speed at the pitch circle; for as the speed increases, the liability of the tooth breaking from shock becomes greater. The following factors of safety and corresponding speeds have been computed by the writer as giving good average results:

Speed of teeth in ft. per min.	100 or less	200	300	400	500	600	900	1200	1800	2400
Factor of safety.	3½	4½	5½	6	6¼	6½	8½	11	13	15

For example: What is the safe load of the above gear running at 20 revolutions per minute, taking 36,000 pounds as the ultimate strength of flexure?

$$\text{Speed in feet per min.} = 20 \times \frac{2 \times 30}{12} = 100$$

Corresponding factor of safety = 3½.
Then

$$\text{Safe load} = \frac{23,600}{3.5}\ 6,743 \text{ pounds.}$$

The safe load for this gear as figured by Lewis' formulas would be:
$8,000 \times 2 \times 5 \times .102 = 8,160$ pounds, indicating a considerable less factor of safety than when figured by the other formula. Some authorities claim that cast-iron should never be strained beyond one-third of its ultimate breaking strength, as that is the elastic limit for the material.

For the same gear in steel having an ultimate strength of flexure of 120,000, the ultimate strength would equal

$$\frac{\frac{120,000}{6} \times (1.04)^2 \times 5}{1.373} = 78,660 \text{ pounds,}$$

and the safe load would be

$$\frac{78,660}{3.5} = 22,474 \text{ pounds.}$$

Lewis gives for a safe load for steel 20,000, so that by his formulas the safe load would be $20,000 \times 2 \times 5 \times .102 = 20,400$ pounds, giving in this case a smaller value than that obtained by the other formula, therefore indicating that a greater factor of safety has been used. J. T. Giddings.

East Providence, R. I.

[In the above discussion of the strength of gear teeth no consideration has been taken of the shape of the tooth, the weakest point being assumed in all cases to be at the root of the tooth. In Mr. Lewis' investigation he systematically determined this point from a series of drawings of involute cycloidal and radial flank teeth and his formulas, based upon this investigation, are generally accepted as the most reliable data at present published concerning the strength of gear teeth. They are, however, open to criticism in the matter here referred to, in that the strengths of iron and steel are assumed and the results given in safe strengths. If in the place of the values *S* given by Mr. Lewis we substitute the ultimate strength of the material considered there is no doubt that the formulas will give more reliable values for the strength of the three forms of teeth considered than any other method of calculation. For special forms of teeth, stub teeth, etc., it is sufficiently accurate to figure them as a simple beam with the weakest point at the root of the tooth; for whatever error may then occur will be upon the safe side for strength, and for the investigation of gear teeth in this manner the formulas here presented by Mr. Giddings will be found perfectly reliable and in very convenient form for use.—Editor.]

A MILLING FIXTURE.

Editor Machinery:

The piece shown in Fig. 1 is a latch chuck, made of cold rolled steel, that is used on a special machine for holding the ends of rods. The body and the center holes on both ends were turned in the lathe and the other holes were drilled in a special jig. The fixture shown in Fig. 2 was designed for holding the chuck while milling the longitudinal slot to receive the latch which was required to be exactly central with the axis of the piece. While not of unusual design, it possesses some advantages that make it especially useful when it is necessary to perform milling operations of this nature. It is so made as to be free from any outside incumbrances and the parts where wear is likely to become appreciable are carefully hardened. The clamping mechanism is of a gradual wedging action thereby holding the work securely and at the same time permitting the quick removal of one piece and the insertion of another by simply turning the milled knob to the right or left as may be desired. As will be seen, the clamping mechanism is entirely enclosed, thus avoiding dust and dirt and lessening the liability to accident from any external cause. While the illustration shows only one way in which this device may be employed, a wider field of application will without doubt suggest itself to the reader, as it is suitable for holding all kinds of milling jobs, especially where the work is polished and would be marred by clamping in a vise in the ordinary manner.

The fixture is made of liberal proportions, to insure rigidity, and is tongued and slotted for clamping bolts. Through the center of the body of the fixture is drilled a hole carrying the tightening clamp *B*, the larger diameter of which fits snugly in the hole while the neck is turned down and threaded to fit the clamping knob *C*. To prevent the piece from turning, when the knob is turned, a groove is cut the entire length of the larger diameter and into this fits the point of the setscrew *D*. The upper face of *B* is milled flat on a taper of 1 inch per foot and this part of the piece is made very hard. When clamping the work, the shoulder of the knob brings up against the body of the jig at *E*; on reversing, the two screws *FF*, with their points seated in a rounded groove in the knob, prevent it from being withdrawn.

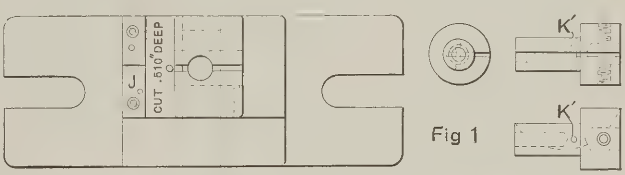


Fig 1

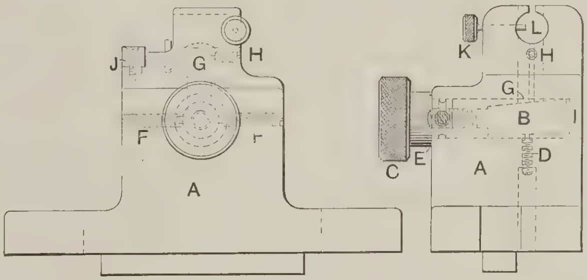

Fig.2

Industrial Press, N.Y.

Fixture for Milling Slot in Latch Chuck.

The semi-circular faced plug *G* stands vertically in the position shown, one end resting on the inclined face of *B* and the other bored out to conform to the diameter of the work. A spline is cut on one side to receive the point of the screw *H* which, while permitting a free movement up and down, checks any tendency for the piece to rotate. This plug fits the hole so freely that when it is released it falls away from the work by gravity. When the parts of the fixture are assembled the chamber in which the slide *B* is located is filled with vaseline and the plug *I* driven in, thereby completely enclosing the mechanism and preventing the ingress of grit or the escape of oil.

The milling of the slot in the work is performed with an ordinary metal saw of the required width; setting it central is simplified and facilitated by the set gage *J*, which is of tool steel, hardened and fastened in place with screws and dowel pins. The depth to be cut is measured by the graduated dial on the milling machine. In this case it is .510 inch, and this is stamped upon the fixture for convenience of future reference. To operate the fixture the pin *K* is withdrawn a sufficient amount to clear the hole *L* and the nose of the chuck to be milled is inserted against the stop pin. The chuck is rotated by hand, at the same time pressing upon the head of the pin *K*, until the pin slips into the fulcrum pin hole for the latch, K^1, Fig. 1, that has been previously drilled in the work. A turn of the knob *C* then clamps it tightly for the milling operation. C. H. Rowe.

Salem, Mass.

A NEW FORM OF FRICTION CLUTCH.*

The friction clutch is a very old invention, and is probably as familiar to every one in its simplest form as any other machine detail. It is, however, only in recent years that inventors have, in any great numbers, seriously attempted to overcome the defects of the ordinary cone clutch, and their attempts have been attended with such success as to lead to the introduction of a very large number of clutches of moderate power into machinery. This is proved by the fact that in recent years a good many engineering workshops have been devoted, either wholly or in part, to the manufacture of clutches of certain well-known forms. A number of such makers have supplied clutches for many thousands of horse power for purposes in which they were little used a few years ago. A familiar illustration is the extensive introduction of friction clutches to countershafts in place of the ordinary fast and loose pulley. It might therefore be thought at first that, in an apparently simple matter, there was very little more to be said and nothing more to be discovered. The importance of the friction clutch, however, justifies a very careful consideration of the problem, as to whether, in view of the modern developments of motive power, particularly in internal-combustion engines and of high-speed machinery of great power, there are not yet improvements possible in this subject.

Industrial Press, N.Y.

The usual object of a friction clutch is to impart motion from a piece of machinery to another piece of machinery at rest, and thus the friction clutch differs in its object, in a very essential manner, from any ordinary form of coupling, or from the well-known jaw clutch. In the latter there is not—or should not be—any relative motion between the parts connected. Hence the strains involved are of a statical nature, and, however great, do not involve a mutual action of the nature of a shock, whereas where two pieces of machinery, not having the same speed, have to be connected with each other, there would be a shock due to inertia, unless the connection was made by means of a friction clutch, or some equivalent, such as a slipping belt, allowing the two pieces of machinery to gradually come to the same speed. This gradual effect is therefore the primary object of the friction clutch, and how important this object is, will be realized when it is remembered that it is impracticable to start any machine instantaneously, for the magnitude of the stresses and strain caused when a machine is set in motion by another, increases with the suddenness of the operation, and all appreciable shock can be obviated by allowing the action to take place gradually.

During the whole time that the two pieces of machinery are coming to one speed—which in the case of the friction clutch is caused by one starting another into motion, while in the case of a brake it is caused by one bringing the other to rest—during this time work is being lost at the surfaces where the slipping is taking place, and consequently heat is generated. The more gradual the action, therefore, the greater the amount of heat, which reaches its greatest amount in the case of the friction dynamometer, where slipping takes place the whole time, and all the work of the moving machine is converted by the friction into heat. Further, it may be said—speaking practically—that wherever there is friction between two surfaces, there is a certain amount of wear taking place, which may be diminished by the use of suitable lubricants. The better, however, the surface is lubricated, the less the effect of friction, and consequently the less the gripping power of the clutch.

Stated briefly, the four conditions which seem to be involved in the problem of the friction clutch are:

1. It must have sufficient gripping power.
2. Undue wearing of the surfaces must be avoided.
3. Provision must be made for conveying away the heat where there is much slipping contact in the clutch.
4. Motion should be imparted to the driven shaft without shock.

We are thus met at the outset with the contradictory conditions which have made the problem of the friction clutch such a difficult one. The author does not remember seeing in any previous writings on the subject, or in the statement of inventors themselves, the important fact mentioned in condition 3, but it certainly does account for the large number of instances in which friction clutches have failed to give satisfactory results for anything but the smallest powers.

---

* Paper read by Prof. H. S. Hele-Shaw before Institution of Mechanical Engineers, Leeds, England.

Looking at the various clutches in use they may be classified and represented diagrammatically as follows:

1. The cone clutch, Fig. 1, where considerable pressure between the surfaces is obtained by the wedge action of the cone.
2. Various forms of rim clutch, Fig. 2, in which the action is obtained by means of levers.
3. Clutches with rings or segments expanding within a drum or annulus, Fig. 3.
4. The brush clutch, Fig. 4, in which brushes of wire are thrust into a finely serrated or grooved plate.
5. The coil clutch, Fig. 5, in which a coil of metal or wire rope with blocks is employed to give great gripping power.
6. The "Weston" clutch, Fig. 6, in which the friction effect is produced by a number of circular disks connected alternately with the driving and driven machine.

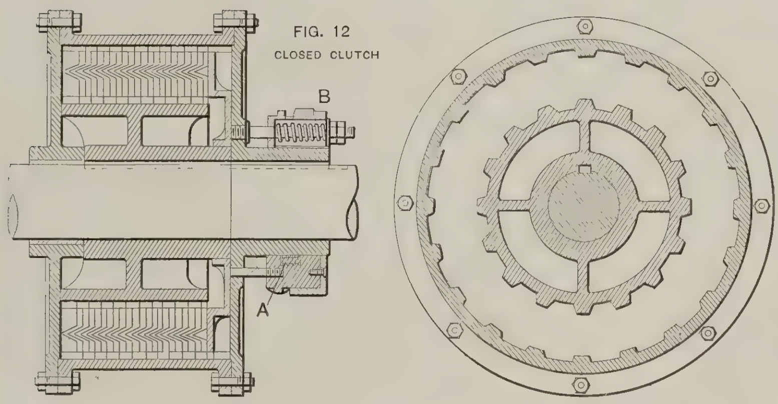

FIG. 12
CLOSED CLUTCH

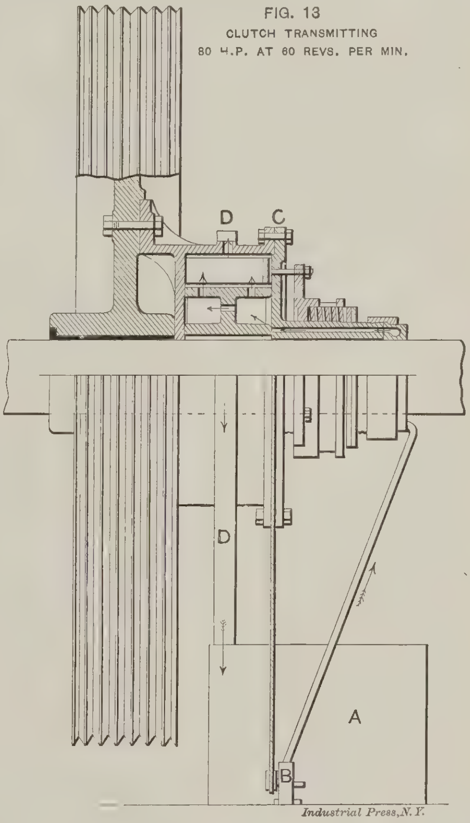

FIG. 13
CLUTCH TRANSMITTING 80 H.P. AT 60 REVS. PER MIN.

Industrial Press, N.Y.

There are numerous modifications in detail of all these clutches, but the inventions in connection with them—which are very numerous—relate principally to the mode of obtaining the requisite pressure between the friction surfaces. Thus taking the case of the expanding ring or segment, which is one of the most successful forms, wedges, right and left-handed screws, and toggle-joints have all been used in different ways for expanding the rings or segments; but no clutches appear to have been designed for the purpose of allowing slipping to take place to any considerable extent, so as to prevent, at the same time, undue wearing and heating of the friction surfaces. These clutches, if not transmitting considerable power and not required to slip, serve their purpose very well. Some, such as the coil clutch, the "Weston" clutch, and the expanding ring clutch, may be made to transmit great powers, but it may be safely said that not one of the foregoing clutches has yet been designed so as to be capable of slipping for more than a very short time, without being seriously injured, even if the surfaces in contact were not actually destroyed.

There are plenty of illustrations in mechanical science where it has hitherto been impossible to reconcile conflicting conditions, such, for instance, as the variable change speed gear, especially when required to be of high power and high efficiency, and it is an important question whether the present case forms another example or not. The author believes there is a way out of the difficulty, and this he proposes to bring forward in the present paper. It is quite possible that there are other ways, and if engineers consider the matter of sufficient importance, it may put them on the track of overcoming the difficulty by a way other than that which will now be described.

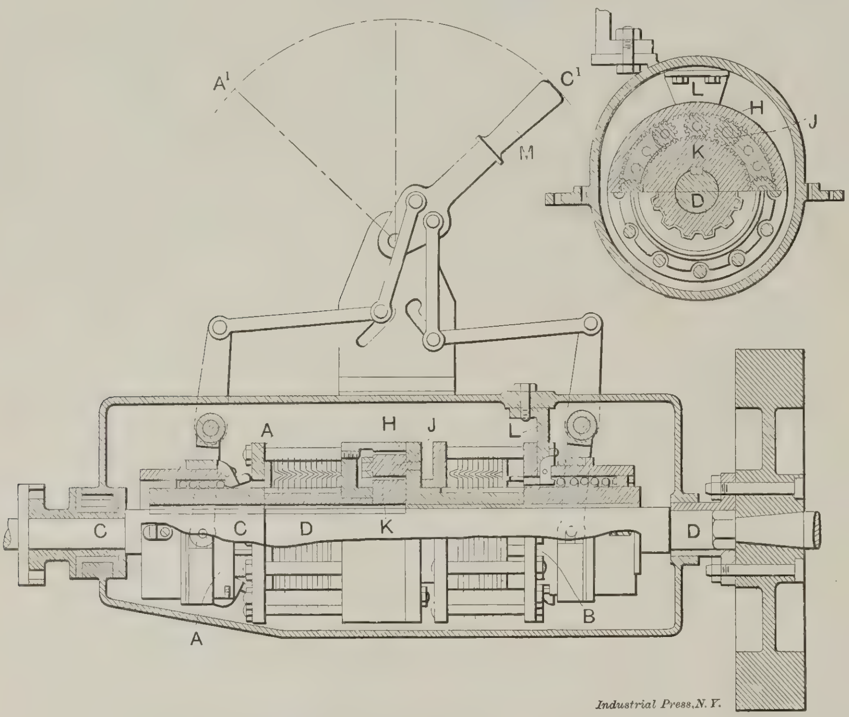
Suppose a sheet of metal is pressed into a frustum, the section of the corrugation being the frustum of a cone, and that the disk is placed upon another one similarly corrugated. It will be observed that not only do portions of the frusta not make contact with each other, but there is also a space left between the flat portions of the disks.

By placing these disks together as in Fig. 10 and turning one alternately to the other, an amount of friction is produced which depends on the acuteness of the angle of the frusta. If a number of these plates are now placed in a box of the type of the "Weston" coupling, so that the plates alternately engage with two sleeves, one connected with the driver and the other with the follower, as in Fig. 7, it will be found—first, there is very considerable gripping power; second, there is a tendency to part rapidly with heat, owing to the separation of the disks of metal.

By the ordinary theory of friction, the former effect—in a box of given length, if the gripping power is compared by actual measurement with the "Weston" clutch—will be found to be much greater, and yet this cannot be accounted for by the ordinary laws of friction, since the increased effect of the wedge action (which varies with the cosecant of the angle of the cone) is directly in proportion to the diminution in the number of plates which it is possible to put in a box, which diminution varies according to the same law. There is, however, a still more striking difference between the gripping action of the flat and corrugated plates when a lubricant is introduced.

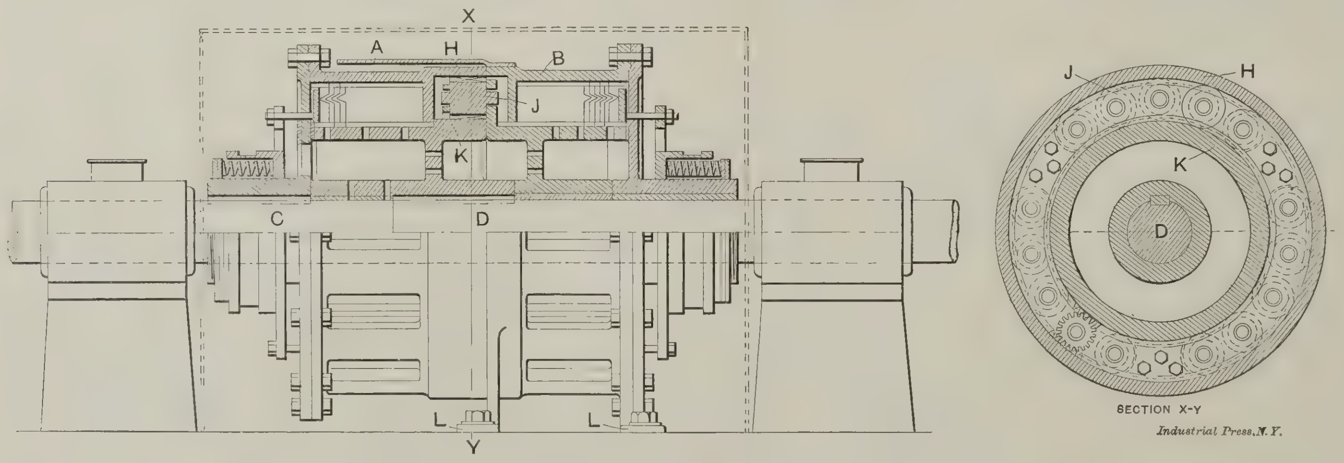
Efficient lubrication of the surfaces in contact is insured by drilling the faces of the plates as shown in the sectional view, Fig. 8, and in the perspective view, Fig. 9. It will be noticed from this illustration that the number of plates in a given space depends upon the angle of the corrugation, thus: Four plates with 30 degrees occupy the same space as six plates with 50 degrees. These four plates, however, give a better grip than the six plates with 50 degrees, and have the great advantage of allowing a freer circulation of liquid, as may be easily seen from the figure. The plates are also much more rigid with the more acute angle.

Two views of a standard type of clutch for shafts up to 2 inches in diameter are shown in Fig. 11. The shaft is divided at A, the outside case B being keyed to the left-hand piece of shafting, and driving the set of plates having external driving teeth. The core C keyed to the right-hand shaft drives the plates with internal driving teeth. Pressure is applied to the plates as follows: The sliding sleeve D, containing a coil spring, is fitted with pins, which project through the outside case of the clutch; these pins press against a flat disk, which in turn presses against the plates, causing the clutch to drive. When the operating lever is worked so as to release the plates, the ring E encircling the sleeve withdraws the trigger pins from the holes into which they fit; the spring pressing on the opposite end of the trigger pin causes the trigger to fly up, and the clutch is thereby kept out of operation. By moving the lever so as to force the ring E against the trigger, the pin end falls into the hole opposite to it, and the coil spring is then allowed to transmit its pressure to the plates.



Industrial Press, N. Y.

Fig. 14. Reversing Gear with New Form of Friction Clutch.



Industrial Press, N. Y.

Fig. 15. Reversing Gear with Friction Clutches, as applied to Steam Turbine.

Fig. 12 shows a section of a larger type of clutch as fitted to a 3-inch shaft. The action of this clutch is similar to that described in Fig. 11. The triggers, however, are worked by separate coil springs, A; the pressure is also applied to the plates by means of separate springs, B, instead of a single one, as in the type illustrated in Fig. 11. A considerable amount of lubricant can be contained in this clutch owing to the construction of the casing. The right-hand view indicates in section the form of driving teeth adopted.

A view of a clutch transmitting 80 horse power at 60 revolutions per minute is given in Fig. 13. One of the conditions of working of this clutch is that it should run for at least two hours daily transmitting only 30 horse power, the main shafting running at its full speed of 60 revolutions. It must pick up its load gradually and without shock. The cooling and lubricating fluid is contained in the tank A placed on the ground. The fluid is raised to the clutch case by means of the small rotary pump B, driven by a band from the clutch case at C, the path of the fluid being indicated by arrows. It leaves the casing through a series of holes in the periphery, being discharged through these by centrifugal action. It is then collected in the annular trough D, which, fitting loosely over the revolving casing, directs the fluid back into the supply tank A. This clutch has been at work at Pilkington's plate glass works, St. Helens, for a period of five months, running day and night, and fulfilling every requirement satisfactorily.

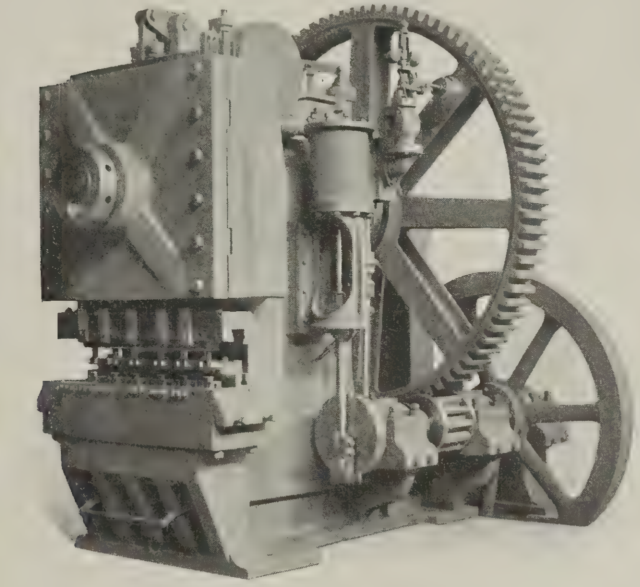
The clutch is the chief factor in a wheel train reversing gear, and the author has recently designed such a reversing gear in which the new clutch is employed. This reversing gear, shown in Fig. 14, consists of two clutches, A and B. The outer case of the clutch A is keyed to the reversing shaft C, which may be a propeller shaft, the core of A being keyed to the engine shaft D. Inside the rim of the outer case of A, teeth are cut in the direction of the shaft, forming an annular wheel H. To the internal core of clutch B a series of pinions are fixed, as shown at J; these pinions gear with the annular wheel H. They also gear with the wheel K, keyed to the engine shaft, the three together forming an epicyclic train. The outer case of B is held stationary, being fixed to the frame of the machine by a bracket L.

The gear operates as follows: When the lever M is in position C^1, clutch A is made free and clutch B comes into action. The core of B carrying the pinions J is now fixed to the outside case of clutch B (which is permanently at rest), and, as the core of B is free on the engine shaft, the toothed wheel keyed to this shaft at K transmits motion to the pinions, which, being also in gear with the outside case of A, causes the shaft C, to which A is fixed, to rotate in a reverse direction and at a slower speed than that of the engine. When the operating lever M is in mid-position, both clutches are inoperative and the reversing shaft is at rest. When the lever M is in position A^1, clutch B is free; at the same time the plates in clutch A are caused to grip, and as the outside case of A is keyed to the reversing shaft and the core of A to the engine shaft, the two rotate together in the same direction. The toothed gearing at H, J, and K now rotate as a fixed mass, the teeth themselves not being in operation.

The presser rings of clutches A and B on this gear are fitted with the spring and trigger arrangement described previously in connection with Fig. 11.

The locking system of operating links and levers renders it impossible for both clutches to grip simultaneously, no matter how suddenly the operating lever *M* may be moved from one extreme position to the other. The inclosing case of the whole gear acts as an oil bath, and thereby insures an efficient system of lubrication.

Fig. 16 shows the design of a reversing gear of this type for a steam turbine of 1,000 horse power, the number of revolutions per minute being 700 to 800. The action of this type of reversing gear may be made as quick or slow as desired, but with a fairly heavy flywheel attached to the gear it has been found possible to change from full speed in one direction to full speed in the opposite direction in five seconds.



Steel Splice Bar Press

A satisfactory clutch is one of the most difficult things to secure for automobile purposes. The ordinary type of cone clutch, which is generally employed, the cone of which is covered with leather, can rarely be maintained in a normal condition, for the following reasons: A great command over the car, especially in driving through traffic, is secured by allowing the clutch to slip. When slipping has been going on for some time the surfaces are generally so altered in their condition that either the clutch will not grip at all or it grips violently and harshly. The result in driving is not only most unpleasant, but it is very inimical to the car itself.

One of these clutches has been fitted to a fairly heavy car, on which the engines had been changed from 6 to 12 horse power. This clutch, although the plates were only 6 inches in diameter, drove the car so satisfactorily that the 6 horse power gear has, under very trying conditions of the British Association tests on road resistance, been found quite strong enough for the purpose. Since then the cone clutch of a 24 horse power Darracq car has been changed for one of the type here described, with remarkable improvement in its action. It has been found capable of driving the car so altered, although a fairly heavy one, for long distances, even in hilly country and without ever going off top speed, which is a direct gear to the driving wheels. The actual speed at the normal revolutions of the engine on this car is 70 kilometers (i. e., about 45 miles) per hour. This example shows the possibilities of the clutch, with which the car can be driven for any required distance at the speed of 3 or 4 miles per hour, or even less, and after running for an hour or two under these conditions the clutch does not get hot. Of course, the main object of the change gear, which is to increase the power if necessary, is not attained, since the slipping of the clutch can only involve loss of power; but this is a case in which, with an engine of sufficient power, variation in the range of speed is really a more important object than the saving in power.

* * *

A LARGE SPLICE BAR PRESS.

The use of steel in machine construction has of late been finding much favor with machine builders and an example of what may be accomplished in this direction is well illustrated by the splice bar press that has lately been built by the Long & Allstater Co., Hamilton, Ohio, and is illustrated in the photograph herewith. While the working construction of this press is not particularly out of the ordinary it is nevertheless quite remarkable for the materials that have been used and for the weight of the parts. The press complete has a total weight of 86,000 pounds and, with the exception of the engine, is made wholly of steel, the main casting alone weighing 43,000 pounds. The crankshaft is a nickel steel forging and all of its journal bearings are lined with bronze bushings. These bushings are required on account of the steel construction which makes it necessary that all working bearings must be lined with bronze to prevent the running of steel on steel. Consequently not only the shaft but the slide body, cam and cam pintle, which gives the movement to the slide, are all bronze bushed and the slide has bronze gibs for taking up the wear on the front, back and each side. The jaws on the clutch and wheel are faced with tempered steel plates, which may be removed and renewed when they become worn.

The slide is counterbalanced and the machine is driven by a direct-connected engine. It has a capacity for punching at one stroke six holes through 1 inch thickness of nickel-steel splice bars. The punch and die holder may be adjusted up to a distance of 40 inches from center to center of the outside holes. The main objection to the use of steel for machine construction has been the difficulty of procuring satisfactory castings of large size, but the construction of such a machine as this certainly indicates that there is now no limit, within ordinary ranges, to the use of cast steel for machine building.

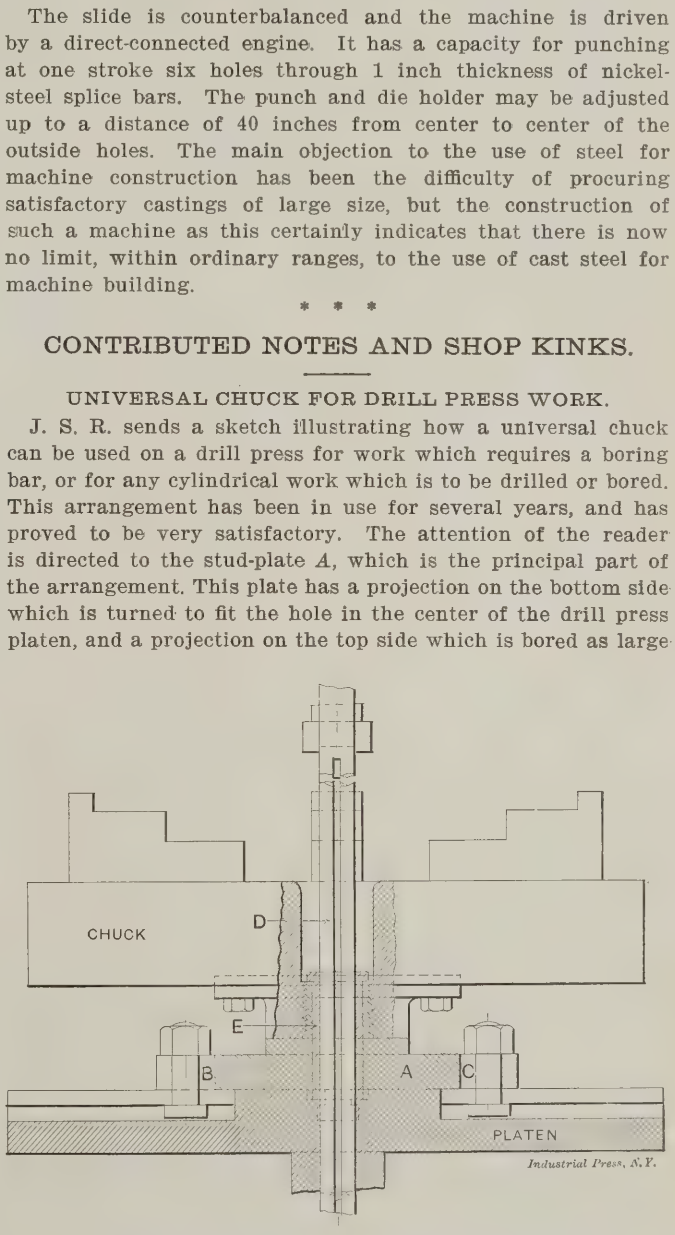
CONTRIBUTED NOTES AND SHOP KINKS.

UNIVERSAL CHUCK FOR DRILL PRESS WORK.

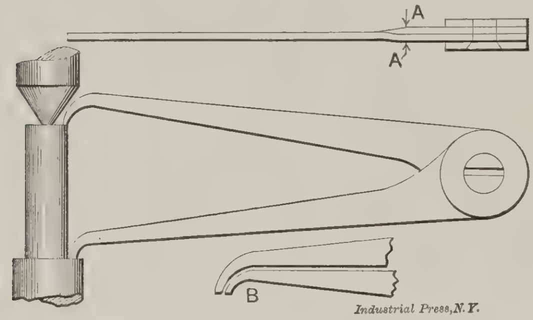
J. S. R. sends a sketch illustrating how a universal chuck can be used on a drill press for work which requires a boring bar, or for any cylindrical work which is to be drilled or bored. This arrangement has been in use for several years, and has proved to be very satisfactory. The attention of the reader is directed to the stud-plate *A*, which is the principal part of the arrangement. This plate has a projection on the bottom side which is turned to fit the hole in the center of the drill press platen, and a projection on the top side which is bored as large as the conditions will allow, and threaded on the outside to fit the threaded part of the faceplate of a universal chuck. This stud-plate is secured to the drill press platen by two bolts, as shown at *B* and *C*.



The bushing *E* is bored so as to be a good working fit on the boring bar *D*, and made to rotate with the bar by means of a key, which is fast in the bushing, but must slide freely in the keyway in the boring bar. If the boring bar has more than one mortise in it for cutters, the keyway should be cut from the lower end of the bar to the highest mortise. This bushing is turned on the outside so as to be a good working fit in the stud-plate, and should have a collar as shown at the upper end, which will, to a large extent, prevent dust and fine chips from getting into the working joint. By this arrangement the boring bar is supported at both ends, which insures greater rigidity, increase of feed, more stock removed in a given time, a greater variety of work, and as a consequence, more work done.

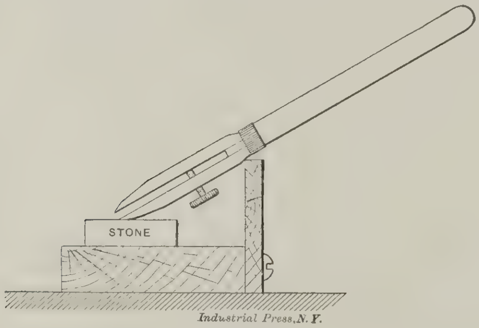
HOME-MADE SHOULDER CALIPERS.

V. H. M. sends a sketch of a pair of shop-made calipers which, he writes, have proved very handy in measuring work from shoulder to shoulder or from a shoulder to the end of the piece. For this purpose they are much handier and more accurate than the ordinary "hermaphrodites." The legs are bent at *A A* so as to lie flat and thus bring the point of the long leg directly behind the short one which "nests" into it, as at *B*, so that the calipers may be used for short measurements as well as for the long ones.



PEN SHARPENING ARRANGEMENT.

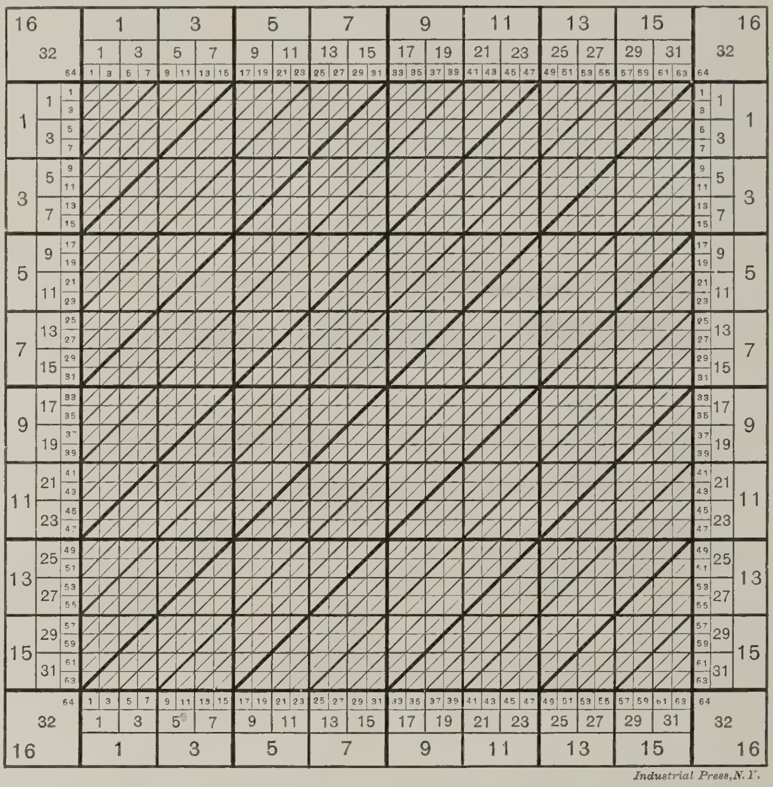
W. T. S. sends a drawing of a little arrangement that should prove very convenient in every drawing room. This is a device which he has used to facilitate the sharpening of drawing pens. A small wooden block, to which is attached a back, is all that is required. The stone is placed in any position desired and moved away from or toward the vertical back in order to bring the pen in contact at any angle that is wanted. The stone is held in place by the left hand, and the pen, held by the thumb and forefinger of the right hand, is moved backward and forward and at the same time given a rocking motion so as to grind all of the point. In this way first one and then the other nib of the pen are given an ideal finish.



ADDITION AND SUBTRACTION CHART.

L. S. Burbank, Worcester, Mass., sends us a chart that will prove of assistance to draftsmen and others in the addition and subtraction of fractional parts of an inch. The numbers in the smallest rows are 64ths of an inch and in the next larger rows 32ds and 16ths respectively, 8ths and larger fractions being located without indicating. One of the fractions to be added is located on the top of the chart, and the next number located on the left; trace the lines from these numbers vertically and horizontally to their intersection and then follow the intersecting diagonal line to the nearest side. The number there found is the sum of the two fractions. If this sum occurs on the right or bottom side of the chart, 1 must be added to the result. All numbers are traced on the line except 64ths, which, to simplify the chart, are traced between the lines.

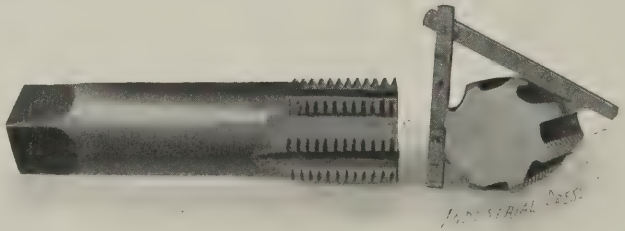
Example: Add 1¼ + 7-32 + 2⅛ + 53-64. The sum of the more easily computed numbers (1¼ + 2⅛) is found by inspection to be 3⅜. Continuing from here, find ⅜ on top of the chart, on third vertical line from the left. Note this point and find 7 in the 32ds row on the left; trace these horizontally and vertically to their intersection and then trace the intersecting diagonal, either way, to the edge of the chart, in this case pointing to 19 in the 32ds row. The result is now 3 19-32, but without stopping to learn this, note the point and find 53 in the 64ths row at the top. Trace similarly to their intersections, then the diagonal to 27, which is found in the 64ths row. As this occurs on the right or bottom of the chart, 1 must be added, making the required sum 4 27-64.



Any number of fractions may be added without stopping to learn the individual results, very much in the same way in which continuous calculations are performed upon the slide rule. As it does not matter from which side of the chart the numbers are found, the nearest one may be used for convenience. To subtract, trace *diagonally* from the larger number and *horizontally* from the smaller. Then from their intersection trace *vertically* to the same side on which the larger number is chosen.

ANNEALING A TAP.

H. H. E. sends us the accompanying photograph of a tap which was broken during the process of hardening. It was designed for a finishing tap, 4¼ inches in diameter and 22 inches long, and weighed 65 pounds. The forging was made from a bar of 4¼-inch carbon steel which was upset to a diameter of 4½ inches and thoroughly annealed. It was then machined to finished size without a second annealing but when the attempt was made to harden it, it broke in two, as illustrated. While there may be some difference of opinion as to just what caused this break there is but little doubt that the upsetting of a bar of steel is usually attended with disap-



pointing if not serious results in the finished tool. Where the nature of the work is such as to require that a tool like this be made from the solid bar, too much care cannot be exercised in forging and annealing the steel.

* * *

SPEEDS AND FEEDS.

E. R. MARKHAM.

For many years it has been a matter of study with the writer to harden tools in a manner that made it possible to run them at speeds, and to apply feeds, that insured the maximum amount of product. Many times, however, the matter of speed is given a great amount of attention, while other factors fully as important are lost sight of. I remember visiting a shop at one time where one man was running three lathes on very short cuts. The work being turned was run at a very high rate of speed. The foreman informed me that he had succeeded in getting a steel that would stand up when the work was run at more than double the speed he had formerly considered possible. Observation soon showed that the work was traveling at so high a speed that the entire length of the machined portion was traversed some little time before it was possible for the operator to tend to the other machines and get back to this one. Of course I realized that the proper method to pursue would have been to run the lathes at as high a speed as possible and then have sufficient help to take care of them as soon as the cut was across; provided there was enough work to keep all hands busy. But if an extra man had been provided there would not have been enough for either of them, so it was advisable to let one man do it all, and have him get around as rapidly as possible. The question naturally arises "Why run at such extremely high speed and have to wait at the end of cut?" As much work would have been accomplished had the speed been gaged so that the cut would be completed just before the workman got around; and the tools would have stood up much longer. The bearings on the machine would not have worn out as rapidly, neither would it have taken as much power to run.

The number of feet per minute at which a cutter runs should not be the only thing taken into consideration, but also the speed at which it is necessary to run the cutter—or the stock as the case may be—in order to produce the maximum amount of work possible on a machine, in a given length of time. A shop owning a large number of milling machines considered installing enough more to enable them to increase their product 50 per cent. They were advised, instead, to harden their cutters by a process entirely different from that which they were using, with the result that they were able to speed their machines up and get from their equipment the desired increase in output without the extra expense of *new* equipment. When it is possible to increase the amount of work turned out by a machine by increasing the speed, it should be done, provided, it *will* increase the output of the machine; but if the increased speed necessitates grinding the cutters so often that the output is curtailed rather than increased, then it is folly.

To enable them to run at high speed, some shops harden their tools by methods that insure the desired results. When speeds greater than it is possible to obtain with ordinary carbon steels are desired, it becomes necessary to use the high-speed steels. The various high-speed steels can be procured in almost any form—either in the shape of bars, blocks, or blanks for milling machine cutters. They can be obtained in the annealed state, so they can be machined to shape very readily, or they may be annealed on the premises.

Many times a *high speed* is used to turn out an increased amount of work when the result might have been attained by the use of *coarser feeds*, and the cutters would have retained their edge much longer. It is a mistake oftentimes to feed *too* slowly.

While the matter of increased feeds is being treated there are several things that must be considered. First, the strength of the machine must be taken into consideration; then the strength of the arbor—if the machine be a milling machine; the strength of the cutting portion of the tool, and whether it will be able to resist the additional strain without breaking or springing; the ability of the piece of work or the fixtures holding it to resist the added pressure, etc. A lathe tool if made of light stock or if the cutting portion is too light, will not turn a piece of steel having an irregular surface true if heavy cuts or feeds are used. A milling machine cutter whose teeth are too light cannot be subjected to coarse feeds, for the teeth will spring, dig into the surface of the work, and probably catch and break. A milling machine cutter, or similar tool, whose teeth are too fine cannot be given a coarse feed, as the spaces between the teeth do not furnish sufficient room for the chips; and again, being filled with chips the lubricant cannot get to the teeth, so they will heat and dull very quickly.

The writer recalls an instance of a milling machine cutter of the form shown in Fig. 1 which had 42 teeth. The cutter was 3½ inches in diameter, and was used in milling a handle bar binder for a bicycle. It was not possible to mill more than 20 or 22 of these pieces in a day. A *formed* cutter having only 9 teeth was made and it was found that 120 pieces could be milled per day on the same machine. The difference in results was due to the much heavier feeds it was found possible to use when the cutter teeth were strong and there was sufficient room for the chips and lubricant.

Sometimes a forming cutter for use in a lathe or screw machine is made very light as shown in Fig. 2. To produce a smooth cut it is found necessary to run the machine very slowly, and to support the tool as shown in Fig. 3, possibly even to do both, *i. e.*, to run slowly and support the tool. Now were the tool made sufficiently stiff it would not be necessary to run as slowly and it could be fed much faster.

Reamers and taps are oftentimes made with the teeth or lands so weak that it is found impossible to do a satisfactory amount of work with them. In the case of a tap, the lands when light will spring and consequently open out into the work, unless it is handled very carefully. And the operator is obliged to turn but a very little, then back out a little, and so continue doing until the hole is tapped, which is very slow work, and generally very unsatisfactory. A reamer whose teeth are light is also a source of much annoyance, as only the finest feeds can be used or the teeth spring out, gouging into the work, break the reamer teeth and produce a ragged, uneven hole. It is of course necessary in the case of a tap or reamer to provide sufficient space for the chips, and to give a chance for the lubricant to get at the cutting edges, which can be done by properly designing the tooth.

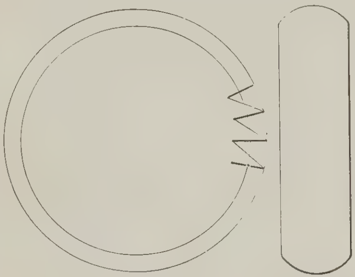


Fig.1

Industrial Press, N.Y.

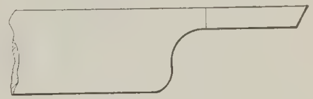

Fig. 2

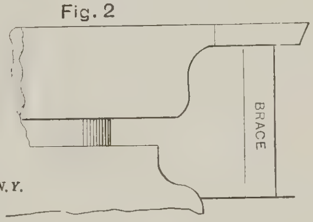

Fig. 3

While the design of the cutting tool has much to do with its success, yet it cannot possibly do the amount of work it should unless properly hardened. If steel is not given the proper heat when hardened it is not in a condition for running at a high rate of speed; and if it is overheated the tool is weak—and if subjected to coarse feeds, the cutting portion will break.

Tools made of carbon tool steel are capable of higher speeds if hardened by the method known as "Pack Hardening;" then again, being much stronger, they are capable of resisting coarser feeds than if hardened by the ordinary methods.

In these days of competition, when speeds and feeds are a matter of vital importance, every phase of the subject must be considered to get the most possible work. It is of course possible to accomplish *something* on a machine that is too light for the purpose, but much more can be accomplished if the machine and tools are adapted to the work in hand. The modern high-speed steels are doing a great deal to revolutionize shop practices, yet much better results can be obtained with carbon steels than is often the case.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

6. R. M. S.—In making a peculiar form of self-oiling, babbitted journal box, we wish to core an oil pocket between the cast iron box and the babbitt shell. Have tried to use a sand core, but without success, owing to the shape of the pocket. Is there anything that can be used for a core in such a place?

A.—For work of this kind a core made of common beeswax will be found to work very satisfactorily. By warming it gently it can be formed into any shape desired. When the babbitt is poured it hardens so quickly that the wax does not have time to melt, so that a perfect core is formed. The wax can then be removed by slowly heating the box and pouring it out as it melts, care being taken not to heat the box hot enough to melt the babbitt.

7. F. R. H.—To run a 20 horse power motor on 220 volt circuit according to the maker's catalog requires 85 amperes. Figuring this by the formula given in Kent's Mechanical Engineers' Pocket Book, $\text{H. P.} = \dfrac{\text{Volts} \times \text{amperes}}{746}$ it should require about 68 amperes. Is the motor rating or the formula at fault?

A.—The formula to which you refer does not take into consideration the efficiency of the motor, which is generally but 75 to 80 per cent. of the result obtained by the formula as given. For practical purposes the formula should read H. P. $= \dfrac{\text{Volts} \times \text{amperes}}{746} \times f$, in which $f =$ the efficiency of the motor. Suiting this to your case and allowing an efficiency of 80 per cent. we have:

$$\text{H. P.} = \frac{220 \times 85}{746} \times .80 = 20, \text{ which agrees with your rating.}$$

8. A. E. H.: Will you please explain what is meant by "Eastern" hose thread, "California" thread and regular hose thread? Please give table of standard of sizes and pitch of threads.

A. We are informed by the Allen Fire Department Supply Co., Providence, R. I., that hose threads, in use by the fire departments of the different cities, all vary more or less, hardly any two in the country being exactly the same. For example: New York has a standard of its own, which is 8 threads to the inch; Providence has one of 7½ threads per inch; while Raleigh, N. C., has 6 threads per inch, 3 5-16 inch outside diameter. Burlington, Vt., has 2½ × 3 threads, and San Francisco and Sacramento, Cal., have 2½ × 7½ threads, but this is not the same as the Providence standard, which has the same number of threads but a different outside diameter. The same discrepancy also applies to the threads used on the smaller sizes of hose, such as garden hose. Thus it is impossible to present a table of hose threads that could be considered in any way as representing any generally adopted "standard."

9. G. C. N.: In cutting a spur gear for a pattern, when it is desired to cut the space wider than the thickness of the cutter, would it be correct, after the cutter has been once through the blank, to turn the blank so as to take the entire amount of extra cut from one side of the space; or should it be turned first forward and then backward and an equal amount of stock cut from each side of the space? The idea being to keep the shape of both sides of the space alike. 2. Does it materially change the shape of the tooth to set over the dividing head one or two holes?

A. The former method, that of removing all of the stock from one side of the space, would be the only practical way to cut the pattern teeth. By taking one-half of the amount of the metal from each side of the space we would obtain exactly the same results but more work would be entailed. The cutters, as made, will cut the correct form of tooth only when their center line is in line with that of the blank and so long as this condition is fulfilled it makes no difference with the shape of the teeth forming the sides of a space, whether stock is taken from one side or both. 2. Setting over the dividing head one or two holes would only turn the blank on its center and would not affect the position of the blank center as regards that of the cutter, consequently the form of the tooth would not be changed otherwise than to be thinner than standard by the amount that the blank was turned.

* * *

DRAWING WORM THREADS.

Regarding the method for drawing a 29-degree thread that was described in answer to question 2 of the "How and Why" department, "Draftsman" writes: While this method is, of course, perfectly correct I have found the method described in Brown & Sharpe's "Treatise on Gearing" to be much more convenient to use. To draw the sides of a 29-degree thread by this method, upon a horizontal line *A A* draw a semicircle with any convenient radius. Then from the point *B*, where the semicircle intersects the line *A A*, draw an arc with a radius equal to one-half that with which the semicircle was drawn and this intersects the semicircle at the point *C*. A line drawn through the points *C* and *B* will make an angle with the line *A A* of 75½ degrees and consequently with the vertical axis *D D* it makes the required angle of 14½ degrees, which is the angle of the side of the worm or "Acme" thread tooth.

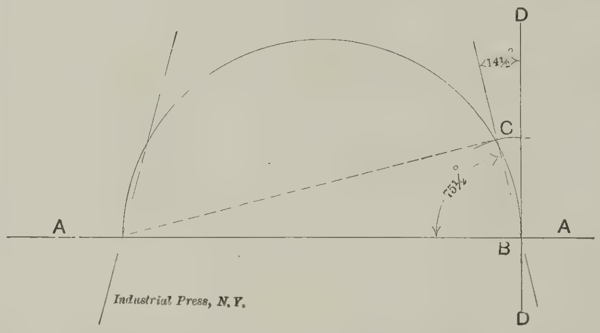

Fig. 1. Laying Out 75 1-2 Degree Angle.

In proof of this method, in the triangle *A B C*, $AB = 4\,CB$, by construction, and the angle *A C B* is a right angle since it is inscribed in a semicircle, consequently the cosine of the angle $ABC = \frac{1}{4} = .2500$. The cosine of $75\frac{1}{2} = .2504$, so that this method is seen to possess the same degree of accuracy as that previously described.

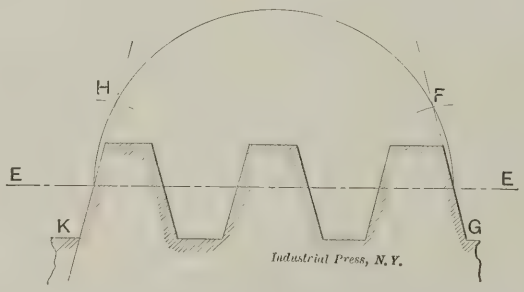

Fig. 2. Application of above Method to laying Out 290 Threads.

In drawing the teeth of a worm or an "Acme" standard thread this method is conveniently applied, as illustrated in Fig. 2. Here the semicircle is drawn on the pitch line *E E* with a diameter equal to the distance from the front of one tooth to the back of another. Then when the lines *F G* and *H K* are drawn, by the above construction, they will form respectively the right- and left-hand faces of the thread teeth. It is then an easy matter to draw the faces of the other teeth from these by the use of the triangle and T-square.

* * *

Errata: According to the present common acceptation of the term in the United States, the expression "diametral pitch" was incorrectly used in the answer to "F. H.," Question 30, August issue. It should be changed to read "diameter pitch."

In the answer to question 33, in the same issue, in the formula by Prof. Carpenter for the flow of steam through pipes, the denominator of the equation should read $7{,}500\ Dd^5$ instead of $7{,}500\ Dd^2$ as there printed.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

STOCKBRIDGE ELECTRICALLY-DRIVEN SHAPER.

We illustrate herewith, in Figs. 1 and 2, a new electrically operated shaper which is the product of the Stockbridge Machine Co., Worcester, Mass. This shaper has a stroke of 24 inches, is back-geared and has a 4 to 1 quick return stroke. The ram is driven by a combination crank motion, which is a new and very powerful mechanical movement and gives an even cutting speed throughout the entire length of the stroke. Especial attention has been paid to the packing for the ram, and the taper packing which has been adopted does away with packing screws and makes it impossible for the ram to get out of alignment. The length of the stroke may be readily changed from the front of the machine and is indicated by an index and pointer so placed as to be in plain view. The head has a travel of 9 inches, and is fitted with a very simple automatic feed operated by an adjustable dog and pawl shown on the side of the machine in Fig. 1. The feeding is done at the end of the return stroke, so that the tool is not dragged back over the scale nor does it require any great amount of clearance to feed in. The length of the feed at each stroke can be readily adjusted to suit the work.

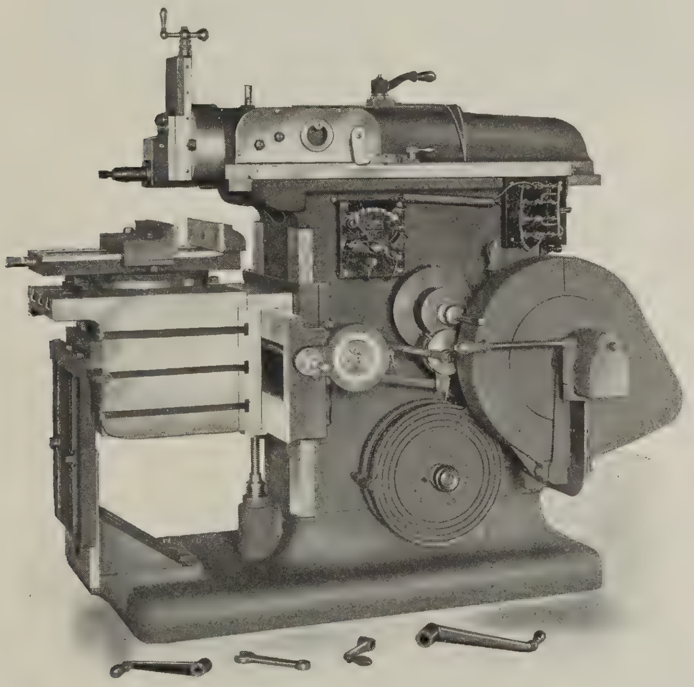

Fig. 1. Stockbridge Shaper with Motor Drive.

The table has a vertical motion of 15 inches and is operated by bevel gears and double screw so that it becomes unnecessary to cut any hole in the floor for the screw to pass through, thus permitting the machine to be set on concrete floors. Ball bearings are employed to facilitate the operation of the elevating screw. The cross-feed is 30 inches in length and automatic in either direction. It is operated through a rod which adjusts itself to any position of the bar, and the screw is fitted with a graduated collar reading to 64ths inch, the same as the down-feed screw.

The machine is operated by a 3 horse power Storey motor, which, by means of rheostat speed controller, may be made to impart a driving speed to the machine varying through a range of 300 per cent. The power is transmitted from the motor to the machine by means of a Morse flexible chain, which provides a quiet and positive driving mechanism that has proved very satisfactory. The shaper is started and stopped while the motor is still running, by means of the clutch lever which is placed at the outer end of the driving shaft. The levers for operating the back gearing, changing length of stroke, feeds, etc., and the switch for starting and stopping the motor, together with the speed controlling mechanism, are all placed where they may be easily reached by the operator without leaving the position ordinarily occupied when running the machine. A circuit breaker, mounted on the back of the column, is shown in the rear view, Fig. 2.

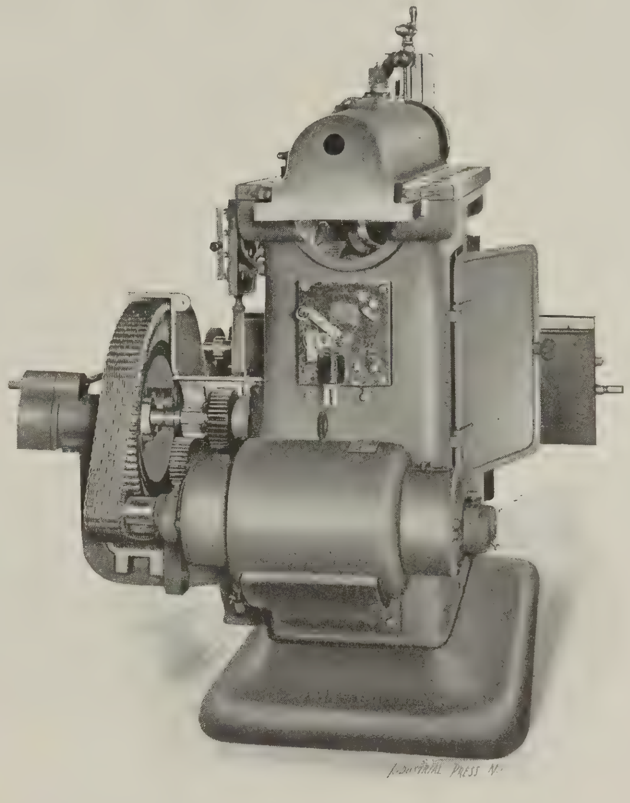

Fig. 2. Rear View of Stockbridge Shaper, showing Motor.

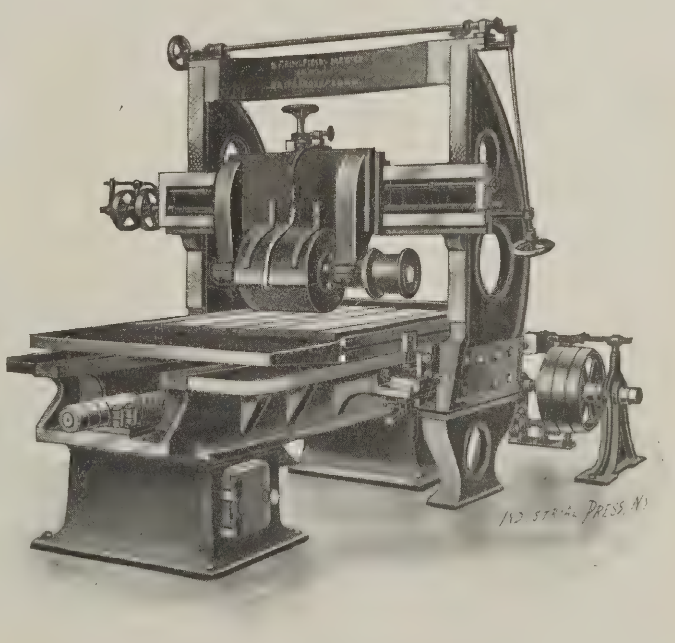
"SPRINGFIELD" SURFACE GRINDER.

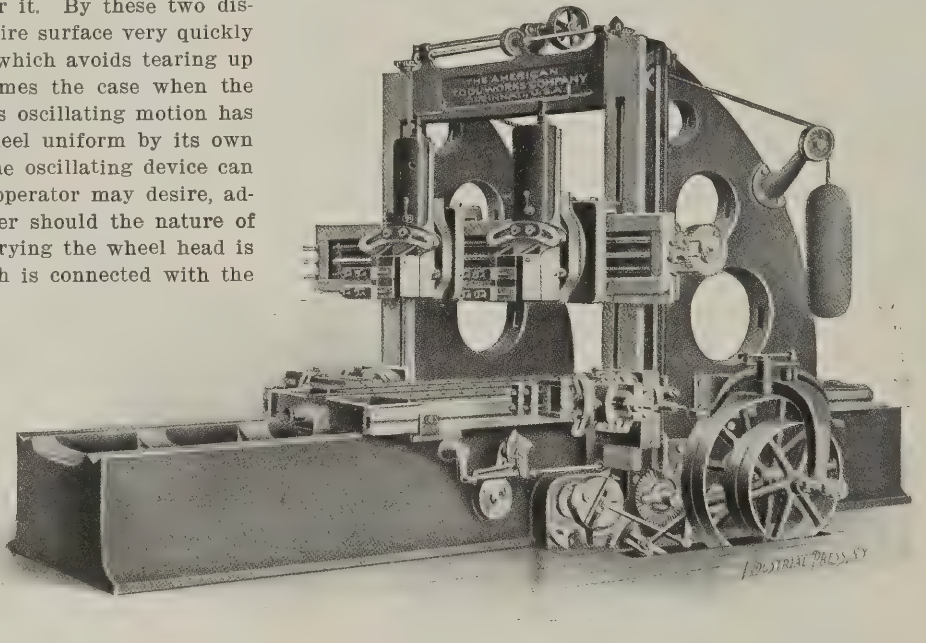
The Springfield Manufacturing Co., Bridgeport, Conn., have added to their line of grinding machines the surface grinding machine that is illustrated in the accompanying half-tone. This will be known as their No. 7 surface grinder. The machine shown in the illustration is designed for surfacing work 5 feet long by 4 feet wide and is adapted for grinding one large surface or several small surfaces at one time. This grinder is especially constructed for the use of water, which is believed by the builders to be a prime factor in rapid and accurate surface grinding. The bed and platen are provided



"Springfield" Automatic Surface Grinder.

with proper aprons to confine the water to the machine, and there are also receptacles in which the water settles before being forced back onto the wheel by the rotary pump. The carriage is operated by a leadscrew, the power being transmitted to the same by a worm and worm gear which has proved very effective in overcoming any chattering.

The emery wheel, which is 16 inches in diameter and has a 16-inch face, oscillates across the platen between the housings while the platen is passing under it. By these two distinct motions the wheel covers the entire surface very quickly and produces the diagonal or file cut which avoids tearing up the fine fibers of metal, as is sometimes the case when the wheel runs parallel to the work. This oscillating motion has also the advantage of keeping the wheel uniform by its own operation. By a simple attachment the oscillating device can be thrown out at any point that the operator may desire, admitting of grinding close to a shoulder should the nature of the work demand. The cross rail carrying the wheel head is easily adjusted by a hand wheel which is connected with the elevating screws by the use of bevel gears. The wheel head has also a micrometer adjustment allowing the wheel to be adjusted to one-quarter of a thousandth of an inch. An idler is provided to automatically adjust the belts on the emery wheel and cross rail. The builders of this machine are prepared to furnish it for any desired capacity, from 2 feet long by 14 inches wide up to 20 feet long by 10 feet wide



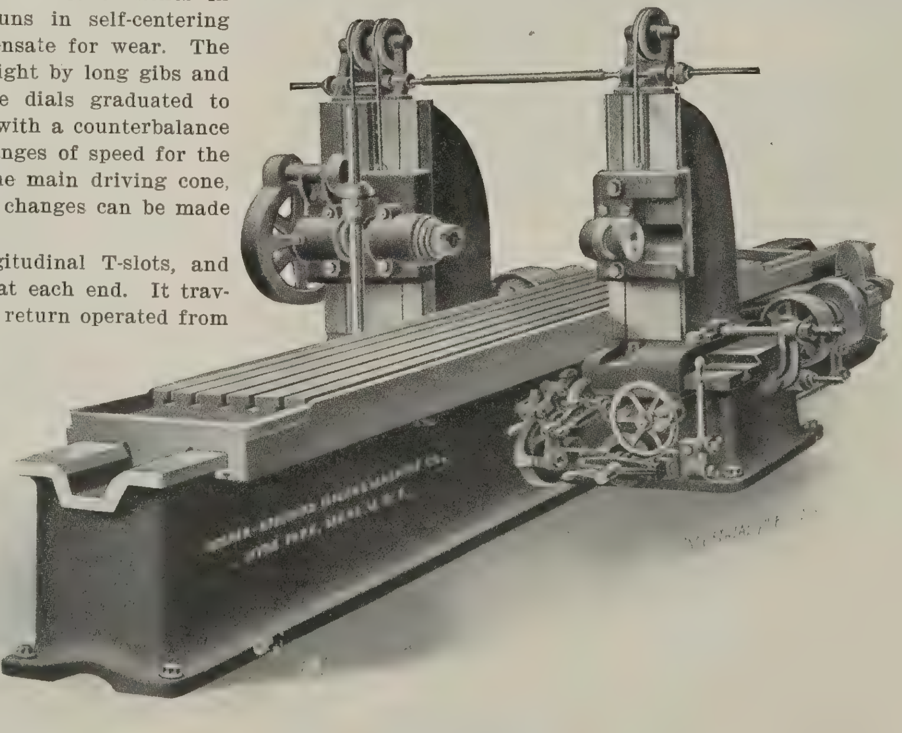
"American" 48-inch Planer.

BECKER-BRAINARD PLANER TYPE MILLING MACHINE.

The Becker-Brainard Milling Machine Co., Hyde Park, Mass., have just added to their line of milling machines the 32-inch x 26-inch x 10-foot planer-type machine that is shown in the accompanying half-tone. This machine is designed for strength, rigidity and power, with special provisions for ease of operation and the demands of modern milling machine practice. The crucible steel spindle, which is 5 inches in diameter, has a threaded nose and runs in self-centering boxes with nut and check nut to compensate for wear. The spindle carrier is held firmly to the upright by long gibs and is elevated by a screw with adjustable dials graduated to thousandths of an inch. It is provided with a counterbalance for ease of operation. There are 20 changes of speed for the cutter spindle obtained by gearing in the main driving cone, operated by clutch and lever so that all changes can be made instantly.

The table is provided with five longitudinal T-slots, and has an oil channel the full length and at each end. It travels on flat gibbed ways, and has a quick return operated from a separate countershaft. It can also be moved by the usual hand wheel. The platen has a working surface of 120 x 26 inches, with a longitudinal feed, automatic in either direction, of 120 inches. The feed of the table is operated through gearing from the spindle by means of a belt running on a five-step cone and giving a range of feed, through eight changes, from 3-64 to ⅜ inch. The changes of feed can be effected instantly by a lever, without stopping the machine.

The head may be adjusted in either direction from either side of the machine so that it is not necessary to take the cutters off from the arbor in order to change their position in relation to the work. The greatest distance from the center of the spindle to the table is 28 inches and the least is 2 inches. The bed is of extra depth, extending to the floor and making a solid foundation. It can be made of any length desired. The weight of the machine, with the 10-foot bed, is about 25,000 pounds.



Becker-Brainard Type Milling Machine.

NEW "AMERICAN" PLANERS.

The American Tool Works Co., Cincinnati, Ohio, have thoroughly redesigned their entire line of planers, from 22 to 48-inch sizes, with the purpose of adapting them to the increased duties imposed by modern shop practice. Every condition influencing modern planer work has been given careful consideration with a view to increasing the efficiency of the machines and adapting them to the use of high-speed steels. Strength and rigidity being the foremost aims, the bed has accordingly been made very heavy and of unusual length in proportion to the table, so that there will be but a slight overhang of the table when planing to full length.

The table has a new shifting mechanism which reverses the belt from one pulley before the return belt engages the other, thus obviating any disagreeable shrieking of the belts. A safety locking device prevents the table from starting before the operator is ready, while it may be easily run from under the tool for an examination of the work. The housings are of the double-webbed cored-section type, with wide bearings for the cross rail which is raised and lowered rapidly by power. The heads on the rail are made right and left to permit them to work close together, and the saddles are graduated for angular planing.

The feeds are all automatic and can be operated from either side of the machine. The down feed is of exceptional length and equipped with micrometer adjustment. The side heads are of the compound slide type, are counterbalanced and can be run below the level of the table when not in use. Each shaft is so arranged that it can be readily removed, when necessary, without disturbing the rest of the machine, and all of the gearing is located on the inside of the bed.

THE MOTOR-DRIVE AS APPLIED TO MILLING MACHINES.

Figs. 1 and 2 illustrate one of the latest steps in the adaptation of the electric motor to the purpose of machine tool operation. These milling machines, made respectively by the Brown & Sharpe Mfg. Co. and the Cincinnati Milling Machine Co., are operated by Crocker-Wheeler shunt-wound motors. The regulation of speed is obtained by the use of a Crocker-Wheeler, 12-point controller, designed to operate on a 4-wire multiple voltage system of current supply, and gives six speeds by voltages ranging from 40 to 240, by steps of 40 volts each. An equal number of intermediate speeds is secured by the use of resistance, giving in all 12 speeds in either direction.

The motor is located directly over the machine, where it is enabled to drive the spindle at a point between the bearings, and at the same time it in no way increases the amount of floor space occupied. Power is transmitted from the motor to the spindle of the machine by a Morse rocker-joint chain which is much more satisfactory than a belt, owing to the extremely short distance between the centers of the shafts. In its operation the chain is positive and noiseless, and the pull exerted between the motor shaft and the spindle is only that necessary to transmit the power required. The sprockets and the chain are entirely encased in light guards which are easily removed when necessary, but which normally protect the chain from dirt and the workman from injury.

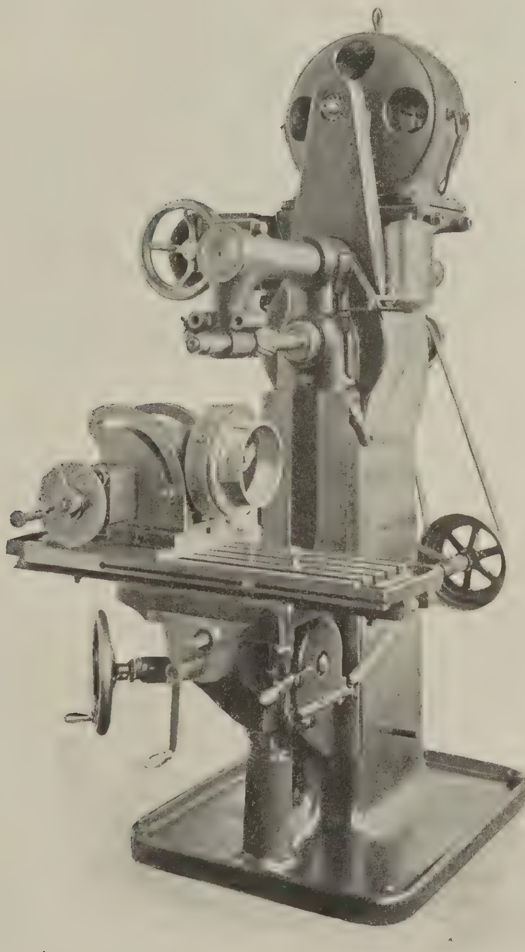


Fig. 1. Brown & Sharpe Milling Machine with Motor Drive.

The Brown & Sharpe machine, being designed for light work, is fitted with a 3 horse power motor, which is connected to the spindle of the machine by a speed reduction of about 3½ to 1. The highest speed of the motor drives the spindle at 276 revolutions per minute, and the slowest speed at 44. The height of the machine and motor over all is but 6 feet 4 inches, so that the motor is readily accessible for adjustment or examination.

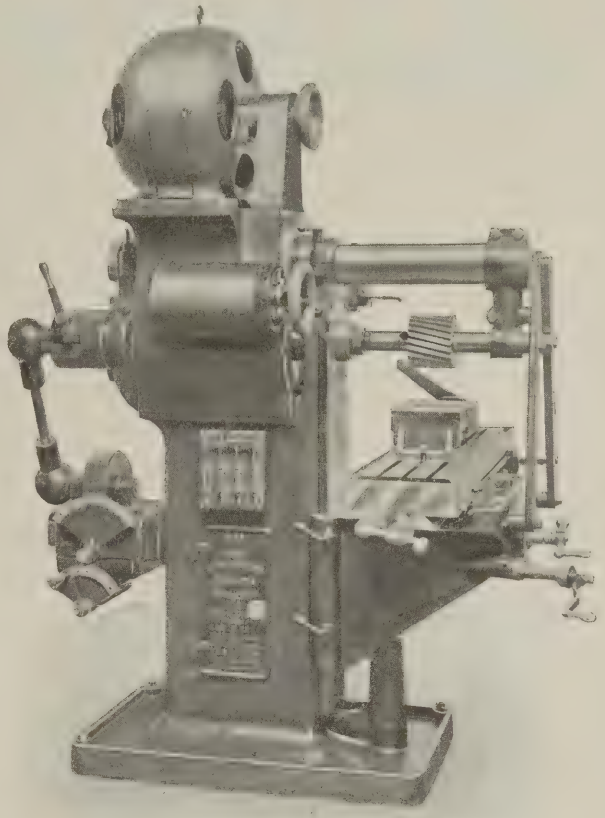

Fig. 2. Cincinnati Milling Machine with Motor Drive.

The Cincinnati machine is built for rather heavy service, and is fitted with a 7½ horse power motor. This machine is provided with a powerful feed changing mechanism, covering an exceptionally wide range. Sixteen feeds are available, and they may be changed instantly from one to another without stopping the machine and regardless of the speed of the spindle. Beside the 12 different speeds secured by the motor, 24 more may be obtained by the use of back gear combinations. The greatest available speed of the spindle is 278, and the least 14 revolutions per minute. The hand wheel, shown on the extension of the motor shaft, is for turning the motor by hand when the power is shut off, so as to permit the teeth to intermesh when changing the back gear combinations. All gears, chain, or other dangerous moving parts are carefully inclosed and every precaution has been taken for the protection of the operator against accident.

NEW CLAMPING DEVICE FOR MICROMETER CALIPERS.

The Brown & Sharpe Mfg. Co., Providence, R. I., have recently placed upon the market an improved device for clamping the spindle of micrometer calipers, which is very simple and efficient, a slight movement of a knurled nut being all that is required for clamping the measuring spindle firmly. After a measurement has been taken it is often desirable to lock the spindle to retain the measurement, and it is important that the spindle should not be rotated or moved longitudinally in order that the original measurement be not altered. The construction of this device is such that the possibility of disturbing the adjustment is entirely avoided. Its general appearance, as applied to the calipers, is shown in Fig. 1, on next page, while the details of its construction are clearly illustrated by the drawings in Figs. 2 to 5, the operation of the mechanism being as follows: The split ring, *B*, Fig. 2, fits the measuring spindle with a sliding fit when open, thus insuring a longer bearing for the spindle than has been possible with the devices heretofore used for this purpose. The ring is held firmly from rotating by the lug, *D*, which fits into a recess in the slot, *K*, Fig. 5. The roller, *C*, Fig. 2, which moves upon the inclined surface cut in the periphery of the ring, is actuated by the ring, *A*, Fig. 3. The clamping ring, with the roller at the lowest point, fits into the ring, *A*, with a sliding fit; and as the clamping ring is held from rotating, the movement of the actuating ring, *A*, to the right forces the roller up the inclined surface, *E*, and closes the ring concentrically around the measuring spindle. The slot in the caliper frame, Fig. 5, receives the two rings together with the roller, and the spindle is passed through the clamping ring. It will be seen that as the clamping ring closes concentrically there is no opportunity for dirt or grit to get into the device, and spindle cannot be thrown out of alignment when clamping. The clamping ring cannot be taken out of the frame until the spindle has been run out sufficiently to clear the recess, and this prevents the device from being accidentally lost, as is many times the case with a nut and split bushing that fits over the end of the spindle.

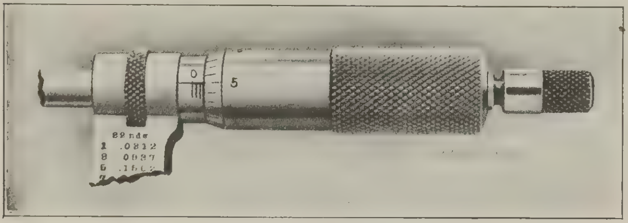

Fig. 1. Clamping Device for Micrometer Calipers.

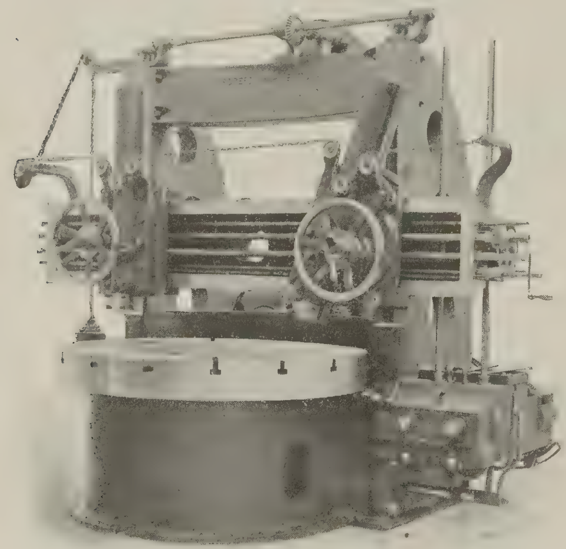

Fig. 1. Rogers Boring Mill—Front View.

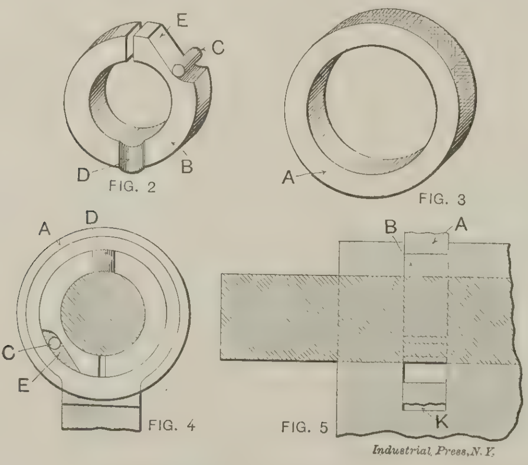

Details of Micrometer Clamp.

Another new feature of this device is that the tension of the measuring spindle can be adjusted without disturbing the threaded portion of the screw and nut. This is a valuable feature when measuring a number of pieces for comparison, as sufficient tension can be put on the spindle to prevent its turning when the work is passed between the measuring points and at the same time the spindle can be left sufficiently free to allow of slight adjustments. When the clamping ring has been set to exert a certain tension, the rotation of the spindle cannot alter it, for the reason that the clamping ring is held stationary and forms part of the bearing of the spindle.

ROGERS BORING AND TURNING MILL.

The accompanying photographs, Figs. 1 and 2, show the front and rear view of a 62-inch boring and turning mill built by the Rogers Machine Tool Co., Alfred, N. Y., who have entirely redesigned their line of these machines in order to meet the demands of modern boring mill practice and qualify them for the use of high-speed steel. An important feature of this machine is the fact that it can be changed from belt to motor drive at a very small expense, as the driving arrangement is composed of a cluster of gears that are so proportioned as to give a great range of speed and large number of speed changes. The change is accomplished by replacing the driving pulley with a gear, which is shown in the rear view, Fig. 2. In this case the motor is mounted on a bracket securely fastened to the frame.

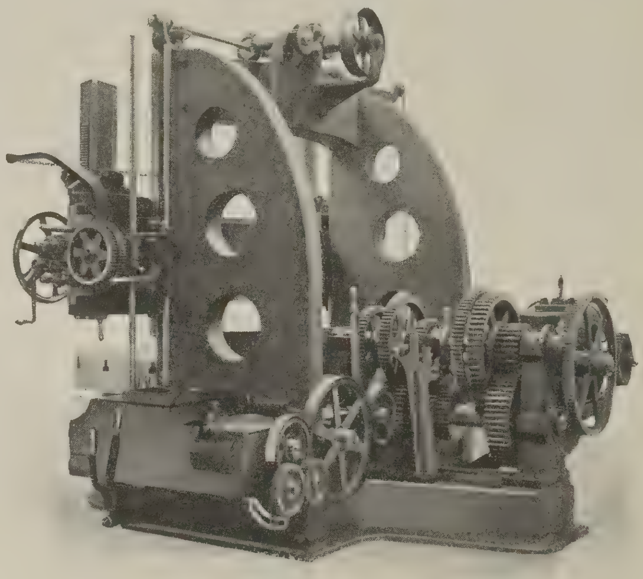

Fig. 2. Rogers Boring Mill—Rear View.

The table is supported by a spindle with V-shaped bearings of large diameter, and the foot brake, which is one of the features that have been retained from the earlier machines, enables the operator to stop the table in any desired position. The cross rail has a belt lift so arranged that only the pulley shaft need be run when raising or lowering the rail. Positive gear feeds are used, which are operated by levers, and each head is independent in amount and direction of feed. The feeds are easily operated, the levers being convenient to the operator's hand. The machine can, at any time, be fitted with screw cutting or drum grooving attachment.

THE "CHICAGO" ADJUSTABLE BORING TOOL HOLDER.

The "Chicago" adjustable boring tool holder has been designed to meet the demand for a holder for use with self-hardening tool steels, and one that shall be quickly adjustable to the different sizes of lathes upon which it may be used. In using this holder the tool post is removed from the lathe and the holder clamped to the cross slide. This provides, in reality, two tool posts five inches apart which furnish a very rigid support for the boring bar. The bar itself is secured in the holder by two clamps, operated by setscrews, and the cutter can be swung to any desired height at which it is clamped by a setscrew on the side of the holder. The form of clamp used for holding the bar, together with the provision for adjusting the height of the cutter, permit the use of any size of bar within the limits of the holder.

MACHINERY.

November, 1903.

MACHINE SHOP EQUIPMENT.—3.

PLANS FOR THE DRAWING ROOM AND ITS EQUIPMENT.

OSCAR E. PERRIGO.

Brains are more important than hands; ideas are more sought after than things; the conception of that which we are to do, of that which we are to develop or to build, to produce and to sell, are first in the natural order of conducting all manufacturing operations, or of entering into any line of the world's trade and commerce. The *plan* is the first and important matter, and to plan well and wisely we must have the best ideas obtainable. These ideas and conceptions have many and far-reaching results and consequences, both as to a matter of mechanical and of financial success. Good ideas, properly developed and elaborated, may mean the beginning of years of business success to the owners or the promoters of the enterprise; while defective and ill-considered plans may mean practical ruin or thousands of dollars wasted in fruitless work.

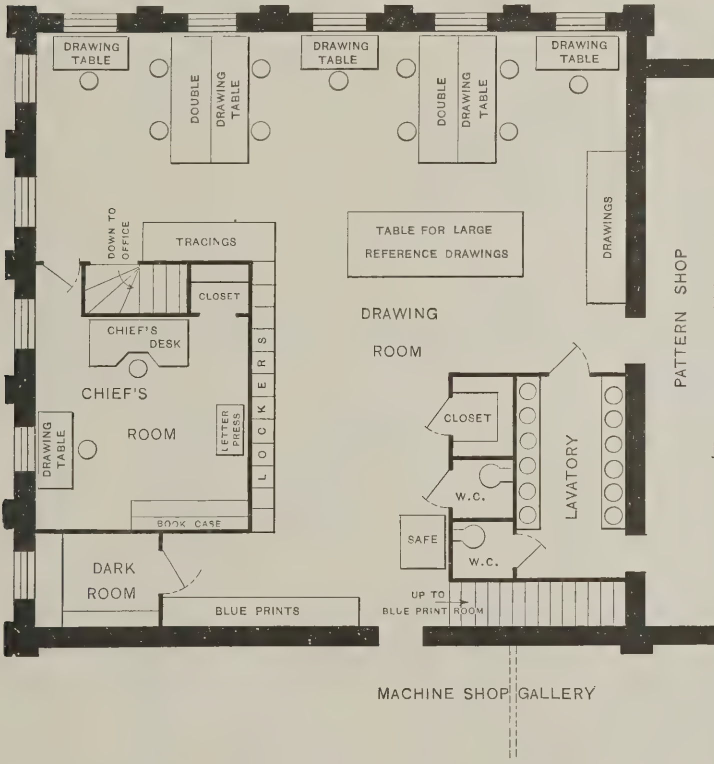

Fig. 1. Drawing Room and its Arrangement.

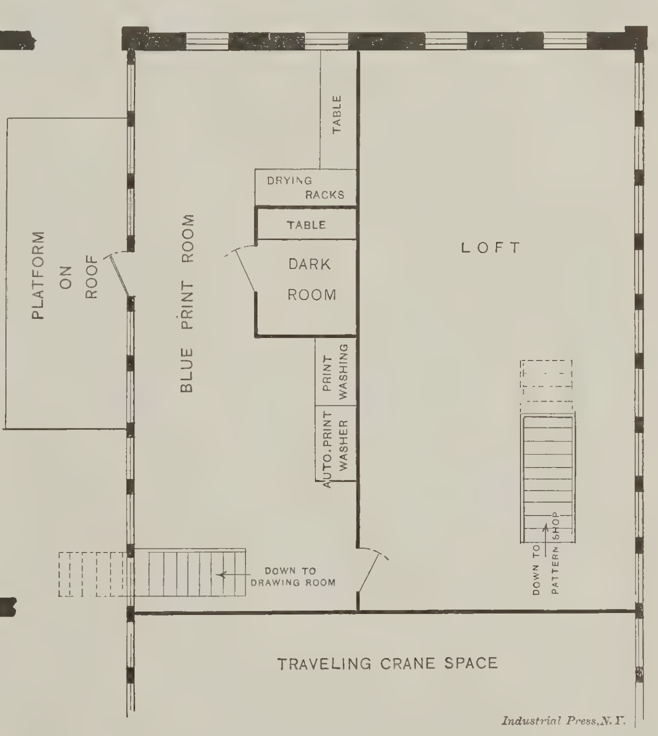

Industrial Press, N. Y.

Fig. 2. Blueprint Room.

But to plan well, to bring out the best ideas of the men whose duty in life is to study and think and plan the work that others are to perform, men should be placed in proper and congenial surroundings, which may inspire them to conceive and bring out the very best ideas of which they are capable, just as in any other line of human effort we make the conditions as favorable to success as we can if we are to expect good results.

The drawing room of the machine shop has often been facetiously called "the brain room," by those who have little conception of its real usefulness in the manufacturing establishment. Yet this is precisely what it should be, if it is properly organized, equipped, and has the right quality of men in its working force. And nowhere in the whole establishment is there more need of men of original thought; of men with ability to "see the point," to grasp the situation and make practical use of ideas and suggestions as they present themselves; and to take apparently worthless plans or devices and develop them into that which is mechanically good and financially profitable. These conditions making the drawing department one of the most important in the whole establishment, it naturally follows that in its location and equipment much thought and care should be exercised so that all the conditions and surroundings should be of the best, as to their kind and their adaptation to the particular class of product which the establishment is to turn out. By this we do not mean that the drawing room should be expensively or luxuriously fitted up. Its design may be comparatively plain and yet architecturally and artistically correct and agreeable. Its furniture may be simple and yet appropriate, and serve its purpose as well as that costing several times as much. Dark-colored woods should not be used owing to the fact that their color absorbs so much light. We should choose, rather, light-colored woods such as oak, ash, birch, or even white pine varnished, according to the amount available for the work. The walls may be wainscoted or sheathed up to about the height of the tables, but above this line they should be finished with a plain, white surface. The ceilings should also be white. A hard finish of what the plasterers call "adamant" is very durable and may be rendered still more so by painting with oil paint, several coats of which should be put on, in preference to kalsomining.

The windows should extend from the height of the drawing tables entirely to the ceiling. They should be provided with two curtains, one reaching from the top of the window down to the center, and a second one reaching from the center down to the bottom. The men working directly in front of the windows should only handle the lower curtain; and those in the center of the room have charge of the upper curtain. The curtains should be white, or nearly so. Instead of curtains some prefer ribbed glass, as it does not admit a glaring light in any one place, but is very useful in diffusing the light over the whole room, and the appearance of the room is much better than where curtains are used. Some prefer plain glass for the lower portion of the window and ribbed glass for the upper portion.

Electricity is the favorite artificial light, and the incandescent lamp seems to be the proper one. The question of whether we shall use enough of these, placed high up, to flood the whole room with light, or have them low down and under the control of each individual, is still discussed with fairly good reasons on both sides. Probably a majority of draftsmen will prefer the individual lamps which they can place in any position best calculated to aid them in the particular kind of work in hand.

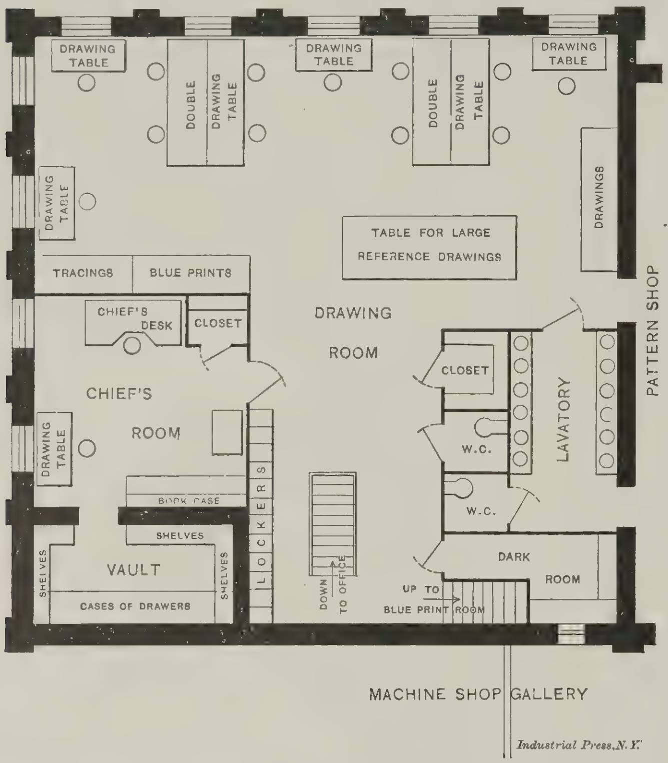

Fig. 3. Drawing Room Arranged for Storage Vault in one corner.

Some of the more important conditions in reference to the location and construction of the drawing room are these: It should be away from the noise and bustle of the machine shop, yet near enough to make the latter readily accessible. It should be directly connected with the pattern shop as it is so intimately associated with it in many of the preliminary operations. It should be readily accessible from the offices. It should have plenty of fresh air and be well ventilated at all seasons of the year. In winter the heating system should be such as to maintain as even a temperature as possible. It should be well lighted, by natural light by day, and a proper artificial light during the hours which make it necessary. It should be provided with proper facilities for photographing machines, or any of the articles produced by the shops. It should have connected with it, but not installed in it, facilities for blueprinting, where an abundance of light is available at all hours of the day. It should be provided with proper facilities, not only for making drawings and tracings, but for indexing them, for issuing and receiving them, and for safely preserving them from fire or other injury. In the descriptive matter which follows and the drawings illustrating it, the effort has been made to meet all of these conditions in a practical and economical manner, and on such a plan as will provide drawings, tracings, blueprints, etc., for small or large plants, or for a large variety in the product to be manufactured; as will be pointed out in detail later on in this article.

In the drawings, Fig. 1, is a plan of the drawing room, located above the offices and well lighted by ten large windows, as shown. It is reached from the latter by a broad flight of stairs. Along the front are located the drawing tables, providing for eleven draftsmen. The arrangement is so made that three of the single or regular tables are for the draftsmen making the general drawings, their tables facing the windows. Between them the two double tables are placed, with their ends toward the windows. These tables accommodate four men each, who do the detail work and the tracings. The circles in front of the tables indicate the positions of the men.

The single drawing tables are shown in perspective in Fig. 5. These are of the plainest construction consistent with usefulness. The top inclines one inch to the foot, and is three by six feet, which is ample for most general drawing work. They may be made with vertical legs, but the crossed legs here shown are more rigid. Braces extend from the crossing of the legs to the center beneath the drawers, to support the top as well as to act as braces to insure stiffness. Foot rests are provided, ten inches from the floor. The height of the tables in front is thirty-seven inches. Three drawers are supplied for holding instruments, books, memoranda, etc.

Many more or less complicated forms of drawing tables as well as other equipments for the drawing room, have been devised, described, illustrated, built, used, and in many cases discarded; and it has come to be the opinion of many of the older draftsmen that while each of the more complicated devices has its peculiar merits, the simpler forms are, in the long run, best adapted for every-day work. The double drawing tables are shown in Fig. 6. They are six feet by ten, and are the same height and inclination of top as the single tables. Three drawers are provided for each draftsman, and a convenient shelf is placed over the center, within the reach of all the men, for holding instruments and many small articles that it is desired to place out of hand but within reach. Foot rests are provided the same as in the single tables. These tables are of the proper height to permit the draftsmen either to sit or stand at their work, as a change of position is much easier than maintaining either one of these positions for hours at a time.

The chief draftsman has a separate room and he is provided with one draftsman whose duty will be that of working out special devices that come more particularly under the constant supervision of the chief. The desk of the chief is shown in Fig. 7, and is identical with one used several years by the writer and found to be a very useful and practical desk and drawing table combined. The top is thirty inches

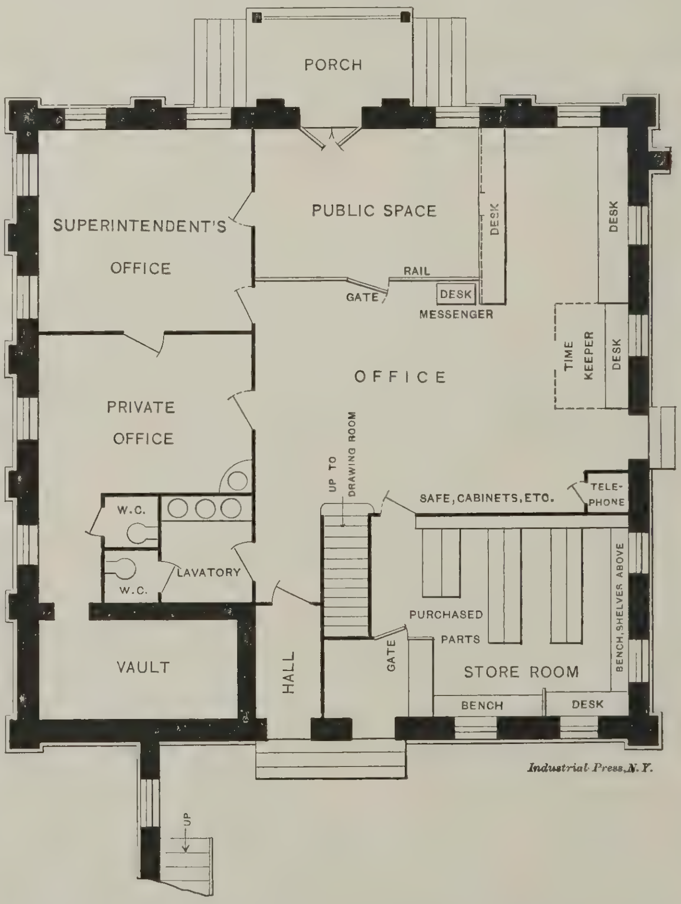

Fig. 4. Arrangement of Offices under Drawing Room, when there is a Vault.

high, and thirty-four inches wide by six feet long. The center of the top at the front is cut out in a semicircular or hexagonal form of a recess to enable the draftsman to sit in close to his work and at the same time to have ample table room at the right and left. Two boards drawing out under the top, one at each side, add to this space, so that a practically continuous table on three sides of the draftsman is provided. This arrangement is very useful where many reference drawings, books or catalogues are to be consulted. Four drawers on each side and one directly in front furnish ample filing space. A shelf at the back is convenient for books or for supporting instruments or other small articles not in use at the moment. The chief's room is provided with a convenient closet, and it has a table with drawers beneath and a bookcase above, as well as a letter-copying press for making letter-press copies of sketches, memoranda and similar matter sent into the shop or to those outside of it. The drawing table used by the chief's assistant is the same as the single tables in the large room.

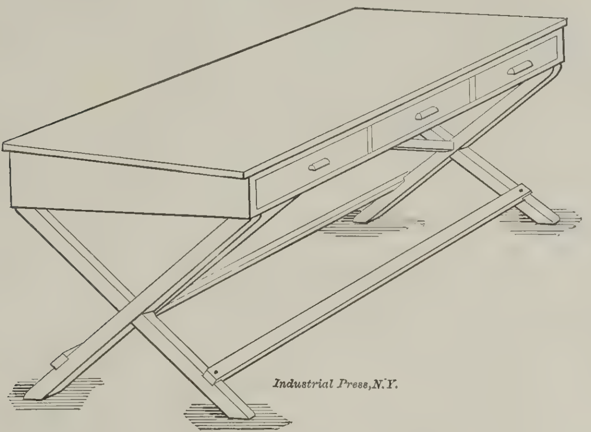

Fig. 5. Drawing Table for one Draftsman.

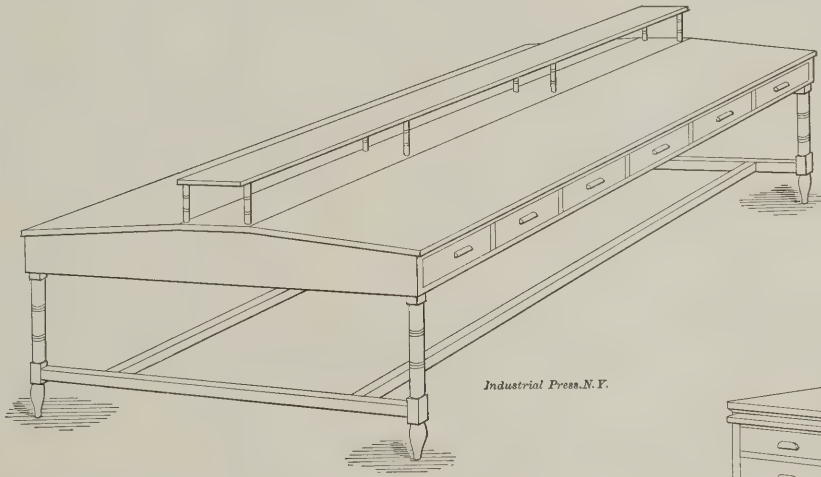

Fig. 6. Double Drawing Table for Detail Draftsmen.

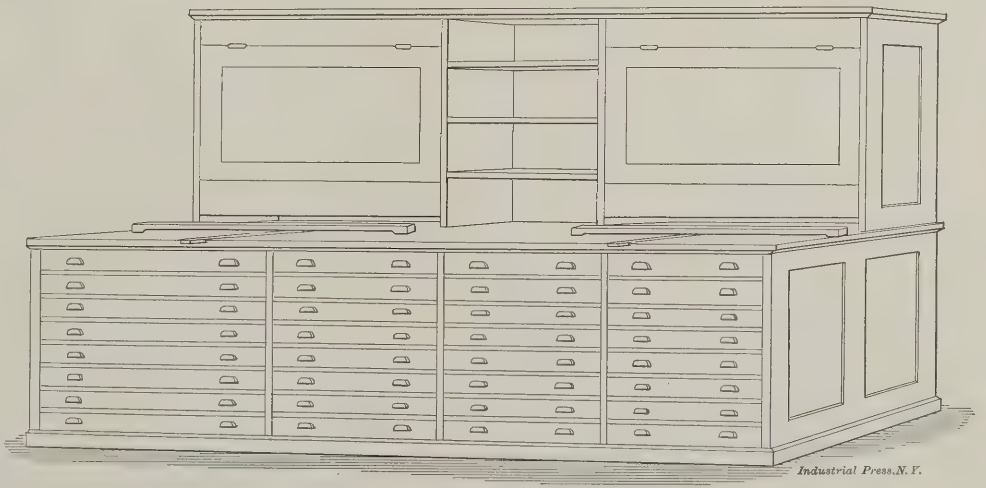

Fig. 8. Case for Filing Drawings and Tracings.

In Fig. 8 is shown a very convenient filing case for drawings. It has drawers for general drawings and detail drawings, made of different sizes to suit their dimensions. These drawers should have a fixed horizontal strip, say ⅜ inch thick and 5 inches wide, running along the back of the drawer at the top, to prevent drawings from curling up and sliding over the back edge of the drawer. In the front part of the drawer a similar strip, pivoted, or hinged so as to turn down over the front edge of the drawings, or back out of the way when the drawings are to be examined, removed or replaced, will be found very useful. In the center of the front each drawer should have a metal label holder, in which a lettered card, readily removed and changed when necessary, describes the contents of the drawer. Usually each drawer is devoted to the drawings of one machine. Above the table are two cases in which are to be kept rolls of drawing paper of different widths or qualities, tracing cloth, tracing paper, etc. Doors hinged at the top and provided with spring catches at the bottom, afford convenient access. The ends of the rolls of paper are brought down at the back and out the front under a guide bar, as shown, and along a sliding scale-of-inches, let into the top covering the drawers, and by which any length or width of sheets are measured, and may be cut off with a knife guided by the guide bar. So far as we know, this is the most practical and convenient method of keeping and cutting up drawing papers; and the plan of purchasing drawing paper in rolls and cutting it up into any desired size of sheets seems to be preferable to purchasing the paper in sheets of odd sizes and trimming it to the dimensions required. In the center, between the two drawing paper cases, are shelves for holding books, catalogues, etc. This case is located against the wall dividing the drawing room from the pattern shop, and convenient of access for the draftsmen.

At the opposite side of the room, and against the stationary partition, is the case for filing tracings; and against the wall next to the machine shop a similar case is used for finished blueprints. It is of the form shown in Fig. 9, and has drawers constructed in the same manner as those in the case for drawings shown in Fig. 8. It is built higher than the latter to increase its capacity, although, of course, it may contain any number of drawings required for the work.

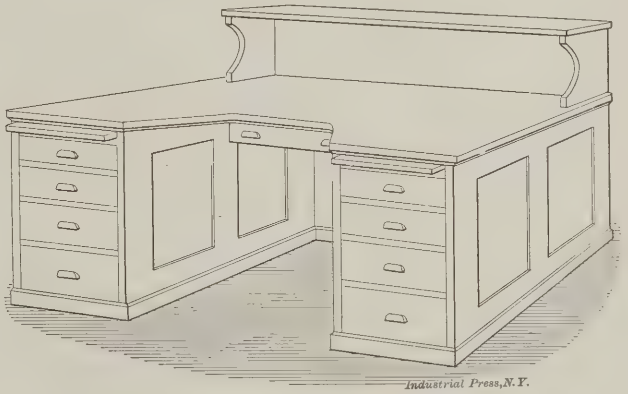

Fig. 7. Chief Draftsman's Desk.

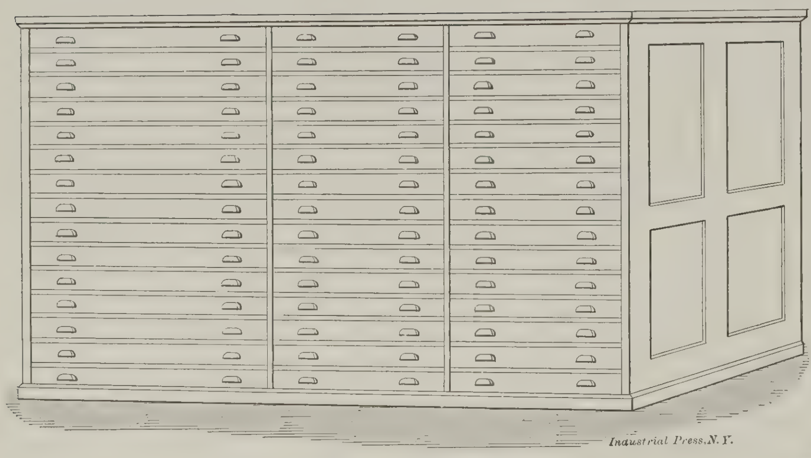
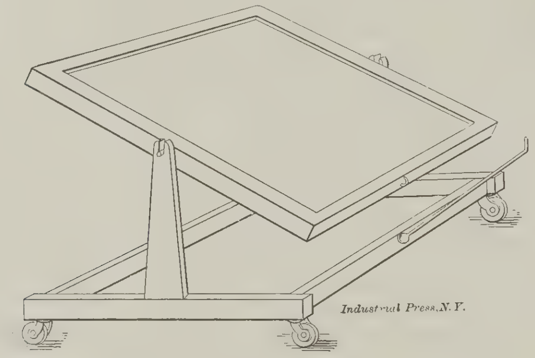
Many systems for filing and preserving drawings, tracings and blueprints have been devised, but here again, simplicity will be found best in practice, and by devoting one drawer to each machine and properly indexing the drawings and tracings, the desired sheet may be quickly found, taken out and replaced, with little disturbance to the others. Where the variety of the work makes it necessary to have a great num-



Industrial Press, N.Y.

Fig. 9. Case for Filing Blueprints.

ber of classes it will be found that a more elaborate system is needed, but the plan proposed will be sufficient for a large majority of establishments. In filing tracings it is well to lay in a sheet of thin straw board between every ten or twelve tracings, or to divide the tracings of a machine into divisions representing the groups of parts of the machine, as, for instance, of a lathe, the headstock, tailstock, carriage, apron, etc. This helps to keep the tracings lying flat without wrinkles and aids in quickly finding the one needed.

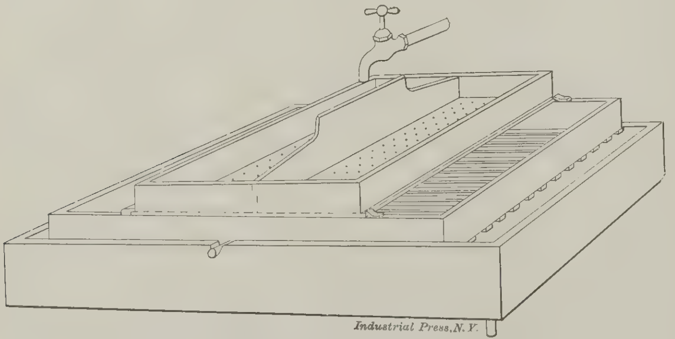


Industrial Press, N.Y.

Fig. 10. Large Blueprint Frame.

Next to the chief's room a dark room is provided for photographic work, as every modern drawing room is expected to be able to make photographs of machinery and similar articles; and this branch of work should not be done in connection with blueprinting, owing to failures that may result from carelessness in handling the necessary chemicals.

In the opposite corner of the drawing room and next to the pattern shop is arranged a lavatory provided with twelve bowls for the use of the draftsmen and patternmakers. In connection with this are two water closets, one of which opens out of the lavatory and is used by the patternmakers; the other opening from the drawing room is for the draftsmen's use. A large storage closet is included in the space devoted to the above purposes and between this space and the rear wall is the stairway leading to the blueprint room above. A fire-proof safe of sufficient size should be provided for storing such records and original drawings of special devices as cannot be readily replaced, and such valuable papers as always accumulate in the drawing room.



Industrial Press, N.Y.

Fig. 13. Automatic Washer for Blueprints.

In the central space of the room is a table five feet by fourteen, for large reference drawings and similar purposes. Drawers under this table are convenient for holding large construction sheets which cannot be filed in the regular cases without folding.

Against the partition of the chief's room is a row of lockers, one for each man. These should never be constructed of boards, or in any way tightly enclosed, but, as a matter of fire protection and sanitary cleanliness, should be open to a free circulation of air; and nothing which we have seen fulfills the conditions better, or perhaps as well, as what is generally known as the "expanded metal" used in many establishments for this purpose.

The above arrangement of the drawing room and its equipment is intended for cases where there does not seem to be the need of an expensive vault in which to store drawings, tracings, blueprints, etc. Still the want of this means of safety to such valuable records in case of fire has of late years been gaining in importance and would seem, in most cases perhaps, a good investment from the point of view of insurance. Hence an arrangement of the plans of both offices and drawing room has been made with this end in view, and is shown in Figs. 3 and 4. As a matter of economy the vault is built in a corner of the structure, the walls of which form two of its sides. For this purpose the superintendent's public and private offices are placed next to each other and the lavatory located between the latter and the vault, while the stairway leading to the drawing room is placed between the hall and the "Purchased Parts" store room. This permits the vault in the drawing room to be built directly over the one in the offices and next to the chief's room, out of which it opens, without disarranging the plans to any considerable extent. The dark room is placed under the stairs leading to the blueprint room. The vault is provided with cases of drawers similar to those in the drawing room, and with racks for holding negatives, as well as shelves upon which may be stored any valuable records, memoranda and similar articles. These vaults are eight feet wide and sixteen feet long, and have masonry floors and brick arches overhead. The walls should be sixteen inches thick, exclusive of an air space of 1½ inches in the center of the walls. Steel should not be used in their construction unless it is completely covered by brick work, on account of its tendency to warp from the excessive heat of a fire. Double fire-proof doors should be provided,

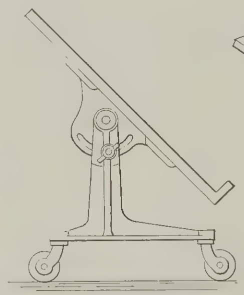


Fig. 11.

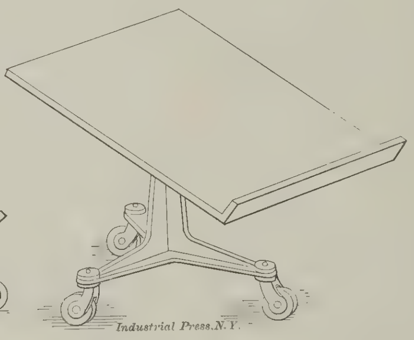
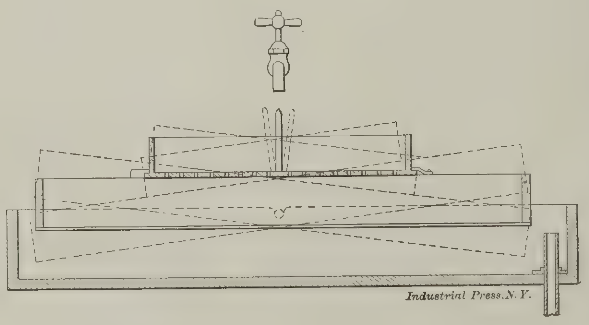


Industrial Press, N.Y.

Fig. 12. Stand for Supporting Blueprint Frame.

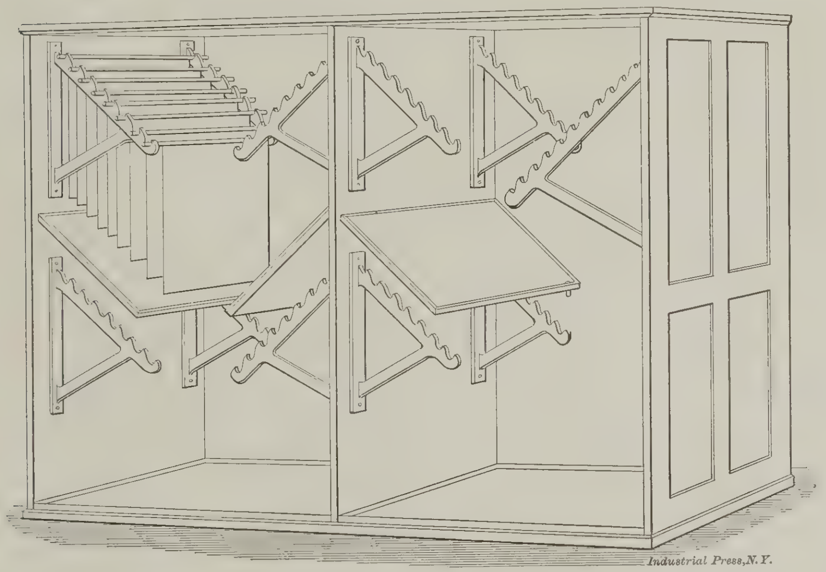


Industrial Press, N.Y.

Fig. 14. Cross Section of Automatic Washers.

similar to those used in safes. The hinges should be held by bolts passing entirely through the walls, as should also be the case with bolts securing the door frames.

The blueprint room is located in the monitor roof in the center of the building, and thus over both the drawing room and the pattern shop. The space available is eighteen feet wide. It is well lighted along one side and across the front end. In it are built a large dark room and other facilities and appliances for print washing and drying, as is shown in Fig. 2. The blueprint frames are opened and filled in the dark room and the smaller ones carried out the door to a platform built over the roof and on a level with the floor of the blueprint room. Instead of being supported by any kind of a rack, they are placed upon an adjustable blueprinting stand, as shown in Figs. 11 and 12. This may be easily turned to face the sun and the supporting board adjusted to whatever altitude the sun may happen to be at the time. The stand is made with a cast-iron standard rising from the base which is supported on three caster wheels of not less than three inches in diameter. A cast-iron support is pivoted between jaws formed in the standard, to which it is clamped in any desired position by a bolt and hand nut, as shown in Fig. 11. The board is attached to this support. When in the room the board may be brought to a nearly vertical position, thereby occupying less space. These stands may be kept in the room and the boards placed upon them and rolled out on the platform, if heavy printing frames are used, but this is not usually necessary.



Industrial Press,N.Y.

Fig. 15. Blueprint Drying Racks.

Fig 10, shows a device for supporting large printing frames. This rests on four caster wheels of not less than four inches in diameter. Trunnions are fixed on the sides of the printing frame in a position to exactly balance it, and either the collars of these trunnions should press tightly against the standards, or the trunnions should be considerably larger than those shown, so that the friction will hold the frame in any desired position for printing. The printing frame may be held in a horizontal position for filling by means of the rod pivoted at one end of the frame and having at the other a hook formed upon it which engages a staple in the end of the frame. When in use this frame is rolled to the door of the dark room, the tracing and blueprint paper put in, closed up and rolled out on the platform, thus avoiding much of the usual manual labor in carrying heavy printing frames. Where printing must be done out of a window various forms of tracks and frames must be resorted to, but there are many advantages in so locating the blueprint room as to utilize the roof for supporting a large, level platform, as here described. In cases where no monitor roof or similar facilities are offered, and the roof is nearly level, or with a slight pitch, it will be best to build a printing room on the roof with a platform outside of it, so as to be operated as here described.

A simple washing box is provided for soaking blueprints in the usual way. Also, an automatic print washer, as shown in Figs. 13 and 14. In this device a fixed box has pivoted in it a smaller box, whose bottom is composed of light slats. Upon this box is attached, but so as to be removable, a smaller box with a perforated bottom and divided by a transverse partition set exactly in the center. The operation of the device is as follows: The top box being removed by turning the buttons securing it, the blueprints are laid upon the slats, as many as six or eight at a time, and the top box replaced. The water is turned on at the faucet and one end of the pivoted box is depressed to either of the positions shown by dotted lines in Fig. 14, which will throw the water into the compartment at the higher end of the smallest box. A considerable portion of the water will trickle through the small holes of the top box and upon the blueprints, while the opposite ends of the prints are immersed in the water of the lower box, which is maintained at a constant height by the overflow pipe, as shown in Fig. 14. The perforations in the bottom of the top box not being sufficient to carry off all the water, it gradually fills up that compartment and the pivoted box, thus weighted, is depressed, and the water from the faucet flows into the other compartment and the operation is repeated. The frequency of this rocking movement is easily regulated by the amount of water that flows from the faucet. The operation is not only entirely automatic, but very thorough in its action, as the prints lying upon each other are separated and the upper ones float whenever that end is depressed into the water. The water constantly flowing in and out of the lower box readily eliminates the chemicals that are to be washed out of the prints. So far as he knows, the writer originated this method for washing blueprints and photograph prints and used it with much satisfaction. The boxes may be made of wood and kept well painted; or may be of galvanized iron or zinc protected by paint. The original one was made of white pine, the lower box of 1¼ inch, the pivoted box of ⅞ inch and the top one of ½ inch stuff, and painted with white lead.

For drying blueprints various devices have been used, but so far as the writer knows, nothing is more economical or better adapted to the purpose than the drying case shown in Fig. 15. The plan is to attach the blueprints to small, round sticks by means of small wooden spring clips and hang them on supporting brackets. The brackets are of light cast-iron or wood, as may be preferred, and should incline on an angle of 45 degrees, so that any print may be conveniently reached and removed without removing those in front of it. Two pairs of these brackets are located, one above the other, for medium-sized prints, say 18 x 24 inches, as on the left of the engraving, or one pair for large prints, as shown on the right. The upper section of prints drip the water into a zinc tray supported by a wooden shelf fixed at an angle of 45 degrees, from the lower corner of which, at the back, a short pipe carries the water into a similar tray resting on the floor, and from which suitable pipes carry the water to the waste pipes coming from the print-washing apparatus. The drying of blueprints may, of course, be hastened by the application of artificial heat. For this purpose doors may be added to the drying case and a small steam coil be placed in the bottom or near the back of the case. But to use artificial heat, or any temperature over about one hundred degrees has a tendency to cause the prints to be distorted by unequal shrinkage, and marred by wrinkles, while drying them by the natural temperature of the room, and suspended as in this case, will cause them to come out in good condition.

To adapt this plan of constructing and equipping a drawing room to the wants of larger establishments requiring a larger force of draftsmen it is only necessary to extend its length so as to provide for a greater number of the single and double drawing tables, to any extent required. The capacity for filing drawings, tracings and blueprints should be increased in proportion. One or more large tables for reference drawings will be needed, and the number of lockers increased to accommodate the added force of draftsmen.

Otherwise the same arrangement of the plan need not be disturbed, as the chief's room, photographic dark room, vault and all the other accessories will be either ample, or very easily adapted to an increase to any reasonable extent that may be desired.

* * *

LET US FIRST LEARN TO FLY.

"I wonder if the inventors who are worrying their brains over the solution of the problem of aerial navigation ever give the legal side of the subject a thought?" said an attorney to a New York Tribune reporter. "Probably not, and probably few lawyers have ever thought of their profession in connection with flying through the air; and yet, if we assume that the means of locomotion through the air are equally perfect with those on land and water, it becomes evident at once that there will have to be considerable new legislation to protect both the public and those who engage in transporting passengers and freight through the air. One of the first problems to be settled will be the question of the right of way.

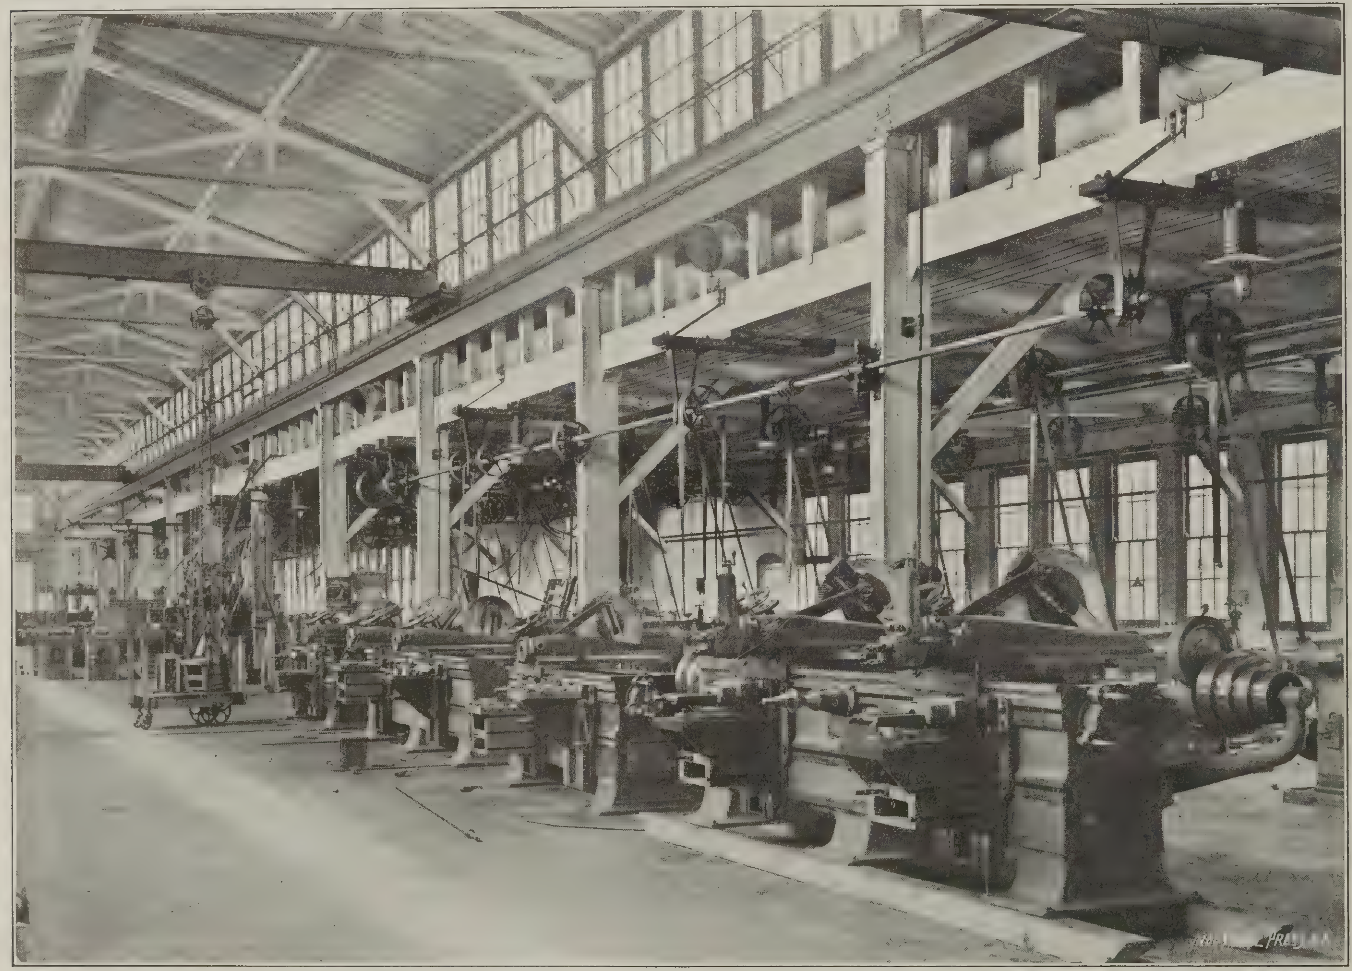


Fig. 1. Interior View of Cincinnati Shaper Co.'s Shop, showing Clearstory Roof Construction, Hand Traveling Cranes, etc.

"Would an aerial line passing over a definite course, at whatever altitude, be a nuisance to an owner of subjacent land, and therefore entitle him to damages for the injury or to compensation for taking of his property? If not, then at what proximity would traffic begin to infringe on his rights? These are important questions and would have to be settled by the lawmakers before a chartered company could run an air line between any two points.

"It might be that the aerial navigators could be sued for trespass, as the common law looks upon the ownership of land as extending to the sky. Consequently a statutory law would have to be passed abrogating the right of the property holder under the common law. Then, too, there is the danger of something falling from the airship, or sky train; and if any loss of life should ensue, or there should be any damage to property, the law must be so framed that the property holder could recover adequate damages. In such an accident it would be difficult to prove contributory negligence."

NEW SHOP OF THE CINCINNATI SHAPER CO.

The great development of the machine tool industry in Cincinnati within the past few years, has, as every one knows, been quite generally along the lines of specialism, most of the makers of this class of machinery in the "Queen" city confining their product to one type of machine tool only. While this tendency has by no means been confined to Cincinnati, this city probably has more shops conducted on these lines than any other. In the census report for 1900 the tendency toward specialism is commented on, from which the following statement is taken:

"This tendency has prevailed in Cincinnati, perhaps, more than in any other city, and has been one of the characteristic features of the rapid expansion of the machine tool industry in that city during the past ten years. During the census year there were in Cincinnati thirty establishments devoted to the manufacture of metal-working machinery, almost exclusively of the classes generally designated as machine tools, and their aggregate product amounted to $3,375,436. In seven shops engine lathes only were made, two (?) were devoted exclusively to planers, two made milling machines only, drilling machines formed the sole product of five establishments, and in three shops shapers only were made. Several other manufacturers made only two or more of these classes of tools, but for the most part the industry was very strikingly specialized."

The Cincinnati Shaper Co., as the firm name denotes, is one of the machine tool specialists referred to, its product consisting solely of crank, geared and traverse shapers. In 1902 the firm erected a new shop in the machine tool district that now stretches along Mill Creek Valley from Eighth Street to Winton Station, and has occupied it since about the first of this year. The shop is of the three-bay, clear-story or monitor roof construction and, of course, is typical of the large class of modern machine shops built along these lines to secure traveling crane facilities and good light. It is a shop, however, that should interest concerns building machinery up to, say, 15 tons (which is the weight of their heavy traverse shapers), who desire a moderate-size shop built with a conservative regard for cost, convenience and efficiency.

The new shop is located on a plot of land 389 x 415 feet, on Beard and Elam Streets, just off Colerain Avenue, and is near the tracks of the B. & O. S.-W. and Big Four railroads, from one of which a switch will eventually be laid to it. The plan is shown in Fig. 2. The total length is 290 feet 10½ inches, and the width, 92 feet 10 inches. A wing was erected at about the middle of the north side for the engine, generator and boiler, and it also contains a wash room, locker room and compartment for the shop heating apparatus. A forge and casehardening furnace are located in the boiler room. The engine is belted to the main lineshaft in the north bay, which is about 220 feet long. The two testing lineshafts, each 90 feet long, are driven by the main lineshaft through belts and friction clutch pulleys. The engine is also belted to a Jantz & Leist 50 K. W. generator which supplies the lighting circuit and the power circuits for the south bay. The electric cables for this section are carried in a conduit under the floor so there is nothing to interfere with the free movement of the traveling cranes along the full length of the erecting floor.

Fig. 3. Details of Foundation and Floor Construction.

The best floor for a machine shop is a problem that has puzzled many builders, and perhaps the solution has not yet been reached. But where lumber is comparatively cheap, there seems to be nothing yet used that equals it in the matter of cost and general utility. It is not badly damaged by ordinary falls of machinery parts, and the parts themselves do not usually suffer. It is comfortable to work on, and when repairs become necessary they are easily made. The floor of this shop is made of one-inch maple, laid on two-inch planks which are supported as shown in the detail, Fig. 3. The ground was first filled in some parts to a depth of 18 inches to make the surface level. The earth was pounded down and then rolled by a steam roller until it was as solidly compacted as it could be made, mechanically. To support the floor, 4 x 4 inch stakes, sharpened, were driven to refusal with heavy mauls, and the tops sawed off level. Upon each row 2 x 8 inch planks were laid flat and spiked fast, to support floor proper. Both these planks and the stakes were chemically treated to prevent rotting. The stakes were spaced 2 feet apart, center to center, in both directions. Upon and across the planks supported by the stakes, the floor planks were laid and on top of these the maple floor was laid diagonally. The machines are set directly on this floor, save some of the heavier tools which have concrete foundations, notably three Cincinnati No. 4 milling machines, upon which some record performances have been made.

A 15-ton platform scale, 8 x 18 feet, is located in the floor at the street entrance, on which castings brought on trucks can be weighed in bulk. The location of this scale will probably be changed to the opposite end of the shop when the railroad switch is laid, as then the castings will generally be delivered by rail. The plan of the shop and the location of the tools were designed with this condition in view, the casting cleaning department being at that end of the shop as well as the rough and finished material stock rooms. The locations of the machine tools determine the route of the various parts and, as stated, these have been laid down so that stock taken from the material stock room shall traverse its appointed course and return to the finished stock room with the least handling. From thence the parts required for the erection of each shaper are loaded on special trucks, one set only on a truck, and transported to the erecting floor. Of course an exception is made in the case of the heavy parts such as the frames, knees, etc. In connection with the stock room, the plan of keeping track of rough and finished castings is worth noting. Two blackboards, say 4 x 4 feet, are mounted in two pairs of vertical guides, back to back, and connected together by means of ropes running up over pulleys so that one counterbalances the other. When one board is down, the other one is up out of the way, making both sides of each board available for keeping accounts. One board is used for rough castings, and the other for finished stock. They are ruled vertically, two adjacent columns being headed "Patterns" and "Stock" respectively. Following the pattern numbers the number of pieces in stock are written in the column headed "Stock."

As intimated in a preceding paragraph the machinery in the south bay is motor driven. Two lineshafts have been erected, one being about 150 feet long, and the other 120 feet. The longer one was driven by a 15 horse power motor, and the shorter by a 10 horse power motor. Both are connected to the lineshafts by Renold chains. This installation is an instructive example of the great disparity in motor horse power required for individually-driven tools and group-driven tools.

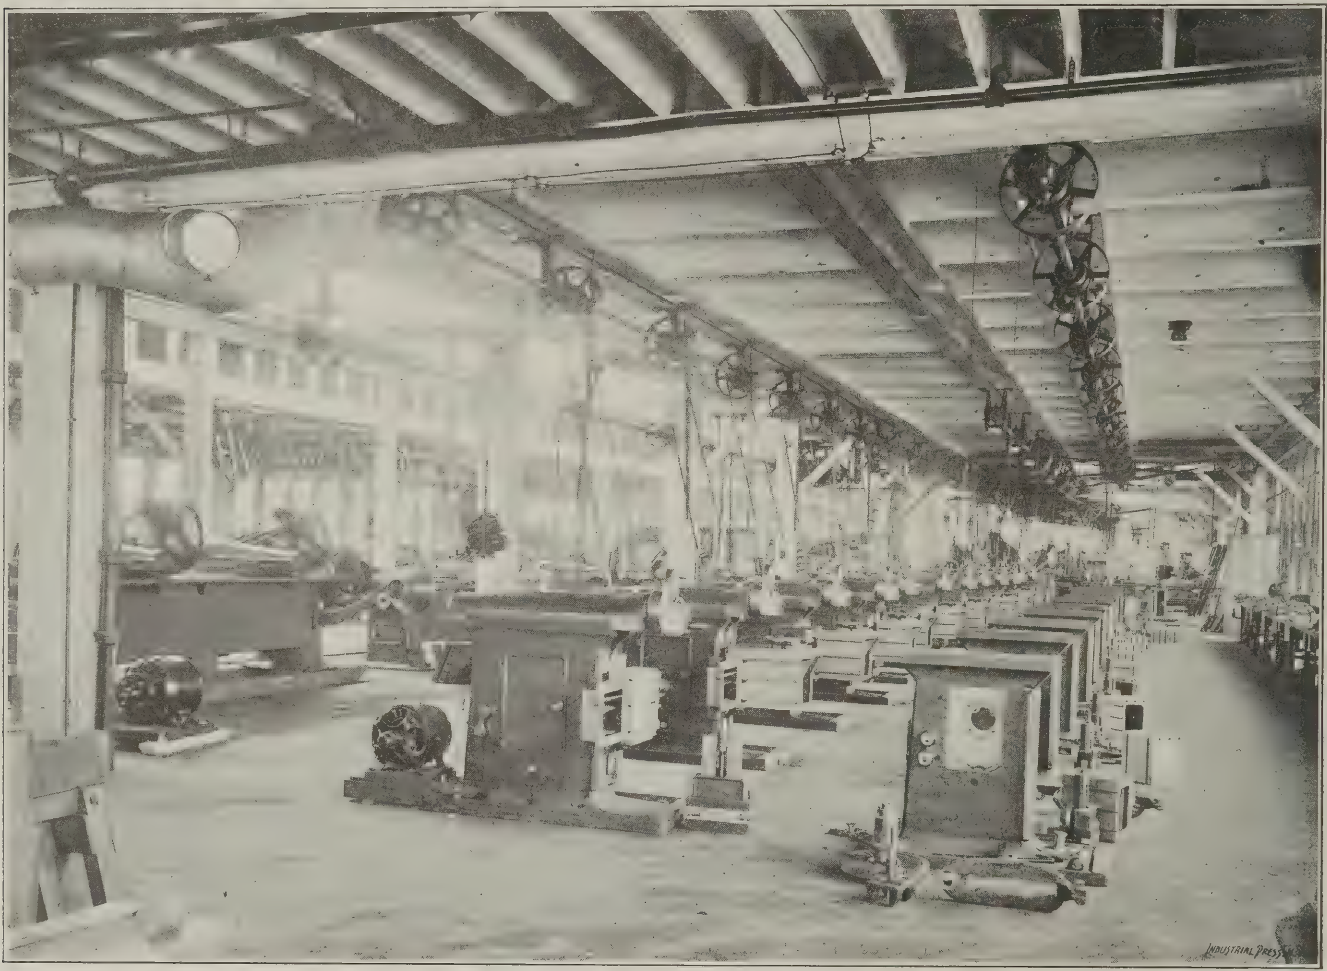

Fig. 4. View from Northeast Corner, showing Shaper Testing Department.

Lineshaft *A*, Fig. 5, drives 12 machine tools; and lineshaft *B*, 19 tools. The maximum power required for each tool was carefully estimated from available data, and the actual power requirement for each group was estimated to be not more than fifty per cent. of the total at any time. Most of the time it was expected that the percentage of power would be still less. The following table gives the estimated maximum power requirements for each group:

LINESHAFT A.

Number of machines.		Estimated H.P.
3	No. 4 plain milling machines, total	6
1	20-in. lever drill	1
1	20-in. chucking lathe	2
1	Jones & Lamson lathe	2
2	25-in. lathes, total	4
1	18-in. lathe	1¾
1	16-in. shaper	1¾
1	Cut-off saw	1
1	Centering machine	½
12	Total	20

LINESHAFT B.

Number of machines.		Estimated H.P.
1	30-in. gear cutter	1½
2	No. 3 plain milling machines, total	3
1	No. 2 Universal milling machine	1½
1	28-in. upright drill	2
1	24-in. upright drill	2
1	Sensitive drill	½
1	No. 2 Universal grinder	4½
1	Jones & Lamson lathe	2
1	15-in. lathe	1
2	16-in. lathes	2
1	14-in. lathe	1
2	19-in. lathes, total	3
1	24-in. shaper	2
1	22-in. planer	3
1	Cutter grinder	1
1	Twist drill grinder	1
19	Total	31

This motor equipment has carried the load quite satisfactorily, but certain changes have since made it necessary to replace the 10 horse power motor with a 15 horse power motor. The lineshafts are belted together so that if one motor is overloaded the other helps it out.

In the north bay are located the radial drills, planers, and the testing floor on which all shapers are run previous to shipment. Two lineshafts, each 90 feet long, are erected for the testing department, each lineshaft accommodating 12 shapers at a time. These lineshafts are driven from the main lineshaft by means of belts and friction pulleys so that either or both can be started and stopped at will without interfering with the main shaft. The testing lineshafts have two sets of pulleys for each shaper stand, so that both crank and geared shapers may be tested with one uniform speed of the lineshaft. Fig. 4 is a view of the testing department taken from the northeast corner of the bay.

The erecting floor or middle bay is 31 feet 4 inches wide. It is served by two hand traveling cranes, one of 2½ tons, and the other of 6 tons capacity. The sides of the monitor are almost solid glass, the window frames being set as closely as possible yet leaving space for the necessary supporting framework. The window frames are pivoted in the center and are connected to shafts operated by worms and wormwheels through vertical shafts from the floor so that the windows of any section may be readily opened for ventilation, etc.

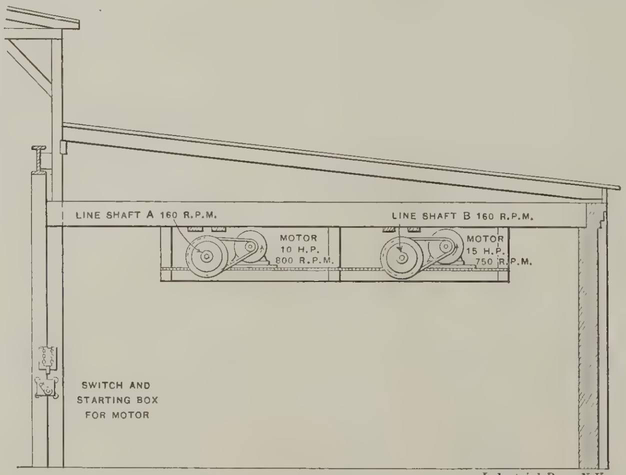

Fig. 5. Arrangement of Lineshaft Motors in South Bay.

Fig. 6 is a sectional elevation of the shop, looking toward the front. Fig. 7 shows the plan of the second floor of the office and a portion of the roof plan of the shop.

Shop Practice.

All shafts are ground to size on a Landis grinder, after having been roughed out in engine and turret lathes. All parts are jigged for drilling, boring and reaming with one important exception. This is the frame of the pillar shapers. For this work a special machine has been made which obviates the necessity for a jig. It consists of two Warner & Swasey boring machine heads, right- and left-hand patterns, mounted on a special frame connecting the two so that their spindles are dead in line. An elevating table with cross-feed makes a combination very similar to the Grand and Bogart double-spindle type of milling machine. A vertical and a horizontal scale gives means for measuring vertical and horizontal distances from certain datum lines, which are laid out on a special drawing for use in connection with this work. The operator sets the shaper frame to be bored so that it rests on the surfaces planed for the ram, which locate it vertically, and the location horizontally is determined from the face of the vertical slide. The location of the various holes is indicated on the special drawing, the distances being indicated from two datum lines which correspond with the zero marks on the scales when the casting is properly set. The holes are drilled and bored with end mills from the two sides simultaneously. The reaming is done from one side only as the reamers are run clear through both holes to insure their perfect alignment. This scheme seems to work satisfactorily in the matter of labor cost, and it must be fairly accurate since the shafts running in the holes bored in this manner carry gears meshing with fixed center distances. Even a slight variation under such circumstances will cause trouble.

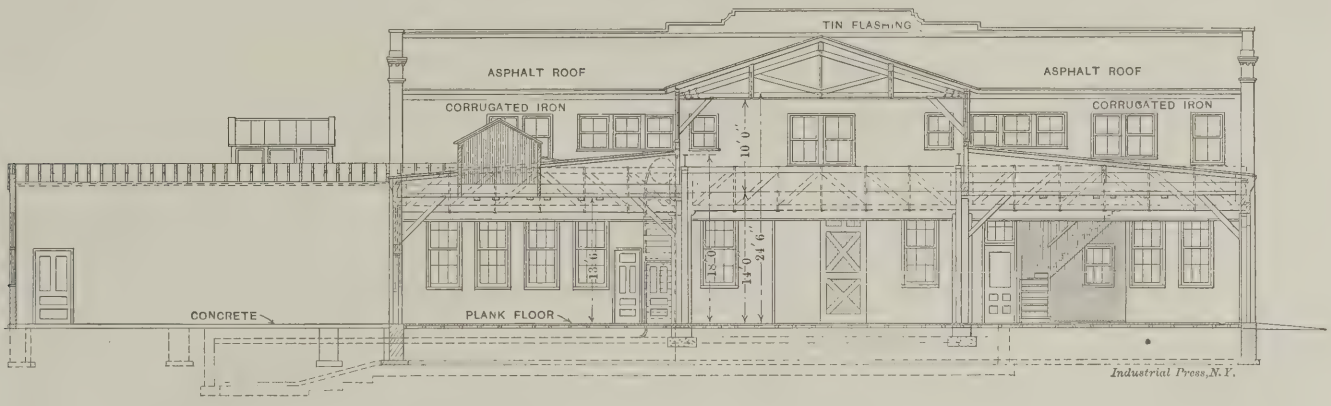

Fig. 6. Sectional Elevation of Shop, looking toward Front.

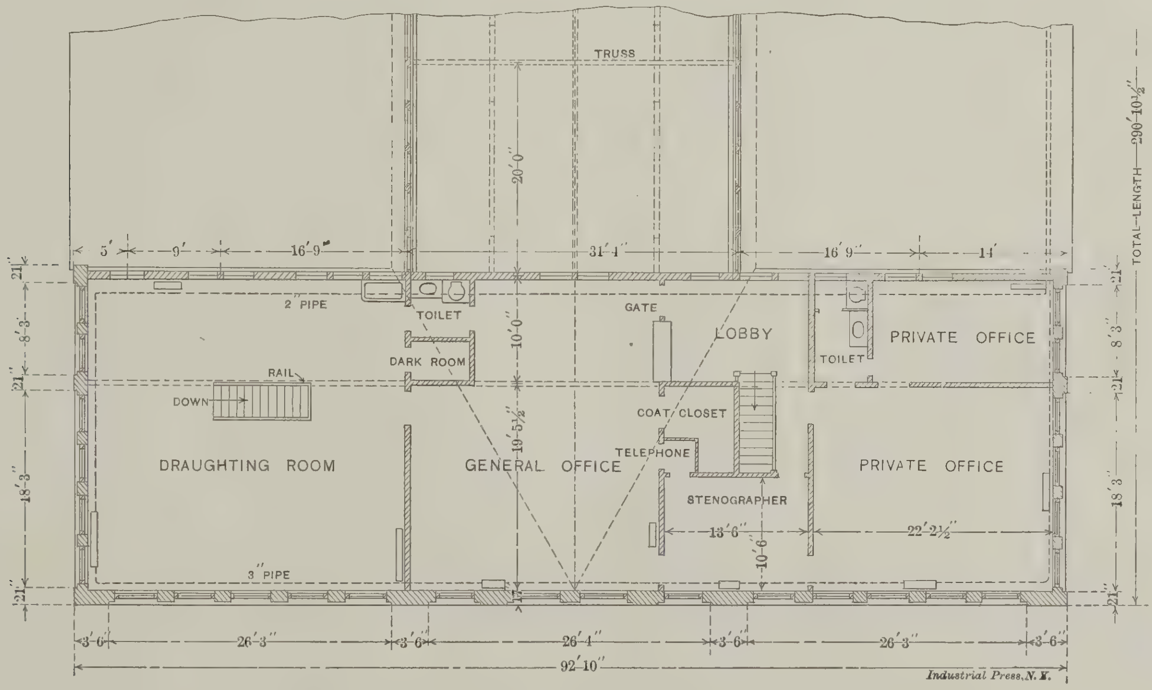

Fig. 7. Second Story Plan, showing Office and Portion of Roof.

A Putnam planer was noticed which has a feature not often found on planers, and that is two driving and two reversing belts, each having its own tight and loose pulleys. The object of this design, which was made to special order, is to give the driving power of a wide belt with the facility of shifting to be obtained only with a narrow belt. In this way a powerful drive can be obtained without the necessity of running at so high a belt speed as to cause disagreeable squeaking and slipping of belts at the reversals of the stroke. Another special feature of planer construction was noticed on another planer to enable the side heads to be used on both sides of shaper ram slides. With the side-heads extended sufficiently for such work, the overhang is so great that heavy cuts could not be taken. To support the slides a planed strip is bolted to the inside of each planer upright some distance back of the cross-rail. Two castings about three feet long with dove-tailed ends, are clamped in a horizontal position to the slides of the side-heads, with their opposite ends abutting against the strips bolted to the uprights. In this manner the thrust of the tools is transmitted to the uprights through the struts, thus relieving the side-heads of pratically all stress. Vertical movement, of course, is not interfered with since the ends of the struts abut against the vertical strips which offer no resistance to movement except in the direction of the thrust of the tools.

In the tool room special trucks are provided to transport the jigs and tools required on certain pieces, and each truck is reserved for that particular purpose. That is, instead of unloading a truck with all the attendant labor, whenever the jigs and tools are returned, it is left loaded until required for the next job and then all there is to do is to haul it to the drill-press where wanted. This plan would require considerable floor space in the tool room for the storage of all the trucks, but since a certain proportion are always out in the shop, this is not a serious objection. The convenience of handling jigs this way is apparent.

* * *

FIRST STEAM ENGINE IN AMERICA.

The first steam engine in America was imported in 1753 by Col. John Schuyler for use in pumping out his copper mine opposite Belleville, near Newark, N. J. This mine was rich in ore and was discovered by a curious chance. One of the Schuylers was plowing in a field when his negro slave found a large stone that was unusually heavy. His master saw that it contained copper and sent it to England for inspection, where it was pronounced 80 per cent. copper. Upon receiving the report Schuyler gave his negro his freedom and granted him three wishes. The old darky scratched his head and for the first wish chose to live with his master and have all the tobacco he could use; for his second wish, a dressing gown with brass buttons, like his master's; and for his third wish, more tobacco.

Col. Schuyler's mine had been worked as deep as hand and horse power could clear it of water. Its proprietor, having heard with what success steam engines, then called fire engines, were used in draining the mines of Cornwall, determined to have one in his own mine. He accordingly requested his London correspondent to procure an engine and to send out with it an engineer capable of putting it up and running it. A Hornblower engine was, accordingly, ordered, and Joseph Hornblower, one of the sons of the builder, became interested in the machine and came over to erect and operate it, expecting to return later. The voyage was a long and perilous one, and Mr. Hornblower's services proved so satisfactory that the proprietor induced him to remain—all the more willingly, probably, because the American girl had proved as attractive to him as she has to many other men from foreign lands, the girl in this instance being a Miss Kingsland, whom he married.

Josiah Hornblower's father, whose name was Joseph, had been engaged in the business of constructing steam engines in Cornwall from their first introduction in the mines there, about 1740; and had been an engineer and engine builder from the first use of steam engines in the arts, about 1720. The engines constructed by him and his sons were Newcomen engines, or Cornish engines, using steam at atmospheric pressure. There was an immense wooden walking beam, with a segment at each end from which hung chains; the chain from one end attaching to the pump rod and from the other end to the piston rod. The pump rod descended by its own weight and was pulled up again by the air pressure on top of the piston, the steam having been condensed under the piston by a spray of water, producing a partial vacuum.

At the time Hornblower's engines were built, Watt had not invented his separate condenser, nor discovered the use of high-pressure steam. After 1760 the Schuyler mine was worked for several years by Mr. Hornblower himself.

EXAMPLES OF INERTIA.

We are all familiar with many experiments to demonstrate the inertia of matter, sometimes called the passiveness of matter—its dislike to get into motion when at rest and its desire to keep moving when once in motion. One of these is the old trick of firing a candle through a door panel. The candle travels so rapidly that when it strikes the door its particles do not have time to slide one upon another, and the soft candle flatten out, as would be expected; but instead it will crash through the wooden door, if we are to believe our text books. Whether it actually would do this or not can only be told by those who have performed the experiment, which would seem to be rather a dangerous one, owing to the possibility of bursting the gun. It is known, moreover, that a person hunting in the winter-time should be careful not to run the muzzle of his gun into the snow, lest the end of the bore become filled with snow and the gun burst when fired. While the snow would be almost infinitesimal in weight, it would have to start instantly into motion, at the rate of perhaps a third of a mile a second, when the powder ignited. While it may be hard to realize it, more force would probably be required to accomplish this result than the strength of the gun barrel could stand and the barrel would rupture under the strain.

Examples like the foregoing are very familiar, but some other tests quite as instructive, but more out of the ordinary, have recently been explained before the Royal Society of London. The tests were first made with a copper sphere about 5 inches in diameter, in the center of which was a glass flask about 1 to 1½ inches diameter, retained in position by cotton packing. The sphere was perforated to allow water to enter its interior and then it was sunk in the ocean on the end of a sounding cord to a great depth. The pressure of the water increased, of course, as the sphere descended, until it became so great as to burst the glass flask, which was filled only with air. This gave a momentary relief to the high pressure within the sphere, and its copper walls collapsed. The inertia of the water was so great that it could not be set in motion quickly enough to fill the space occupied by the glass flask before the collapse of the outer sphere. Another similar test was made with a copper tube, open at the ends, and containing a small glass vial. When sunk sufficiently deep the vial crushed, relieved the pressure within the tube and the latter collapsed, before the water had time to run into the ends of the tube for the support of the metal walls. These tests are all the more striking when it is remembered that the water was under such high pressure at the depth of the sphere or tube, that it must have flowed at an extremely high velocity into the sphere or the ends of the tubes; but yet it was too late to prevent the action cited.

* * *

RAPID COAL HANDLING.

In the last number we published a brief item in regard to the coal handling machinery installed by the C. W. Hunt Company at the Lincoln Wharf Power Station of the Boston Elevated road, which marks a decided advance in the speed with which coal has heretofore been hoisted from barges, cracked to uniform size and delivered to storage pockets. The installation consists of two hoisting towers with the moving gear and coal cracker electrically driven and the hoisting engine direct-connected. The towers have to traverse overhead the whole length of the coal storage pocket and to move 30 feet at a time without changing steam connection. The boom of each tower has an overhang of 40 feet. With one of these towers run-of-mine bituminous coal was raised 90 feet above the tide water from one hatch of a vessel and delivered to the storage pockets, cracked to a mechanical-stoking size, at the rate of 320 tons per hour, by one tower.

To attain this end, the steam engines of fifty to one hundred combined horse power in common use have been replaced by machinery of three hundred horse power, and the coal-cracking machine attached to the tower cracks to the proper dimensions for automatic stokers, before passing to the pocket the enormous quantity of coal over five tons per minute, delivered to it from the hoisting machinery. The ordinary small steam shovel has been supplanted by an automatic one of two tons capacity at each lift.

The time occupied in raising two tons of coal from the hold of a vessel to the discharging hopper, nearly one hundred feet above, is only six seconds, while the round trip, involving the operations of lowering and moving the shovel out of the boom, opening the former, digging up two tons of coal, raising it to the level of the hopper and discharging it therein, is frequently performed in twenty-two seconds.

The work demanded of coal hoisting towers and their machinery is of the hardest description, both from the unskilled nature of the labor employed, and the shocks to the machinery incidental to the service; and it changes constantly with the nature and size of the coal, which may vary from a soft pea variety contained in open wooden barges, to a hard foreign product in cubes, two feet square, loaded in steel vessels with small hatches.

FOUNDRY AND PATTERN DEPARTMENTS OF THE B. F. STURTEVANT COMPANY.

In November of last year we published an outline of the preliminary plans for the new works of the B. F. Sturtevant Company, at Hyde Park, Mass. Since that time the plant has been nearly completed and occupied and we give herewith a general description of the pattern and foundry departments. The new works were commenced shortly after the destruction of the greater portion of the old works at Jamaica Plain, Mass., by a disastrous fire, and afford over double the space of the latter, an increase in facilities that was much needed by the rapidly growing business of the firm. The new plant comprises a commodious office building; a building devoted to the manufacture of blowers, heaters and galvanized iron work; a building for the electrical department, and for testing steam engines; a general machine shop, used mainly for engine building; a forge shop; foundry; pattern building, and power house.

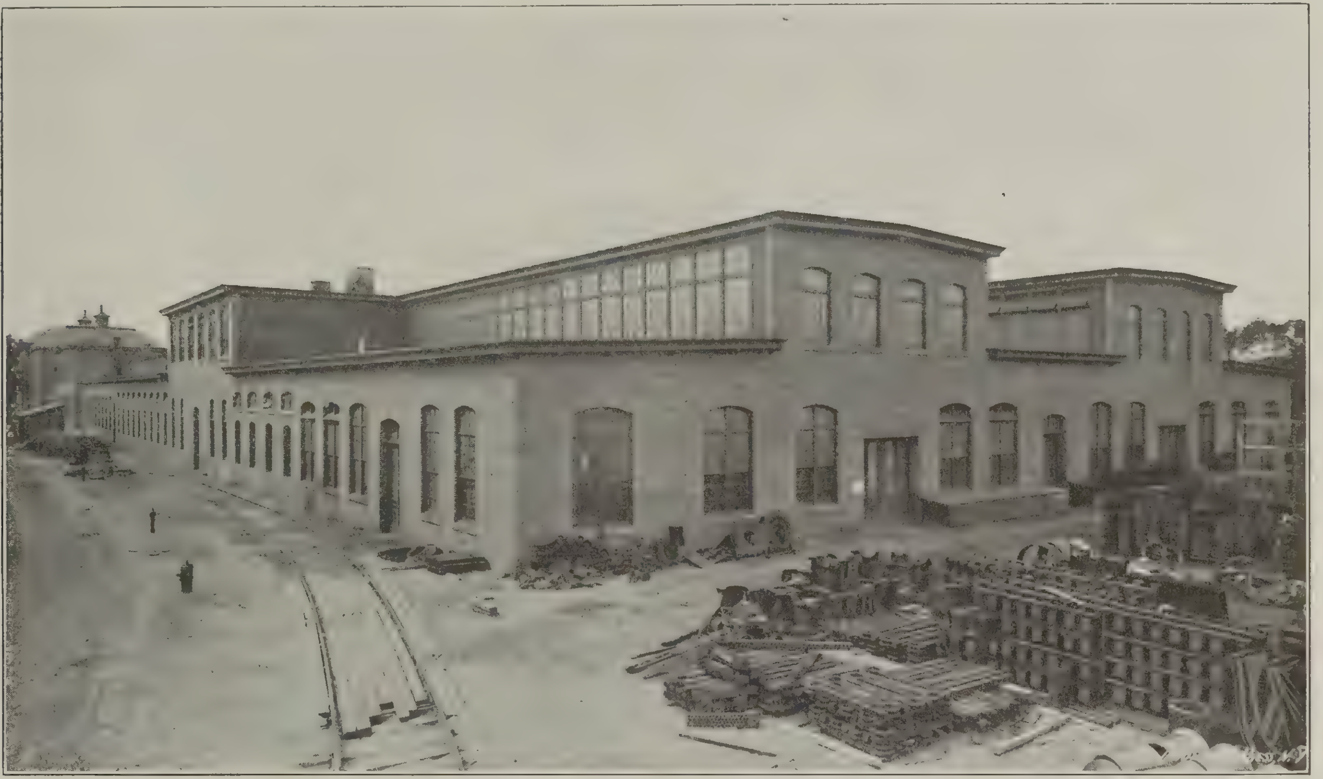

Fig. 1. New Foundry of the B. F. Sturtevant Company.

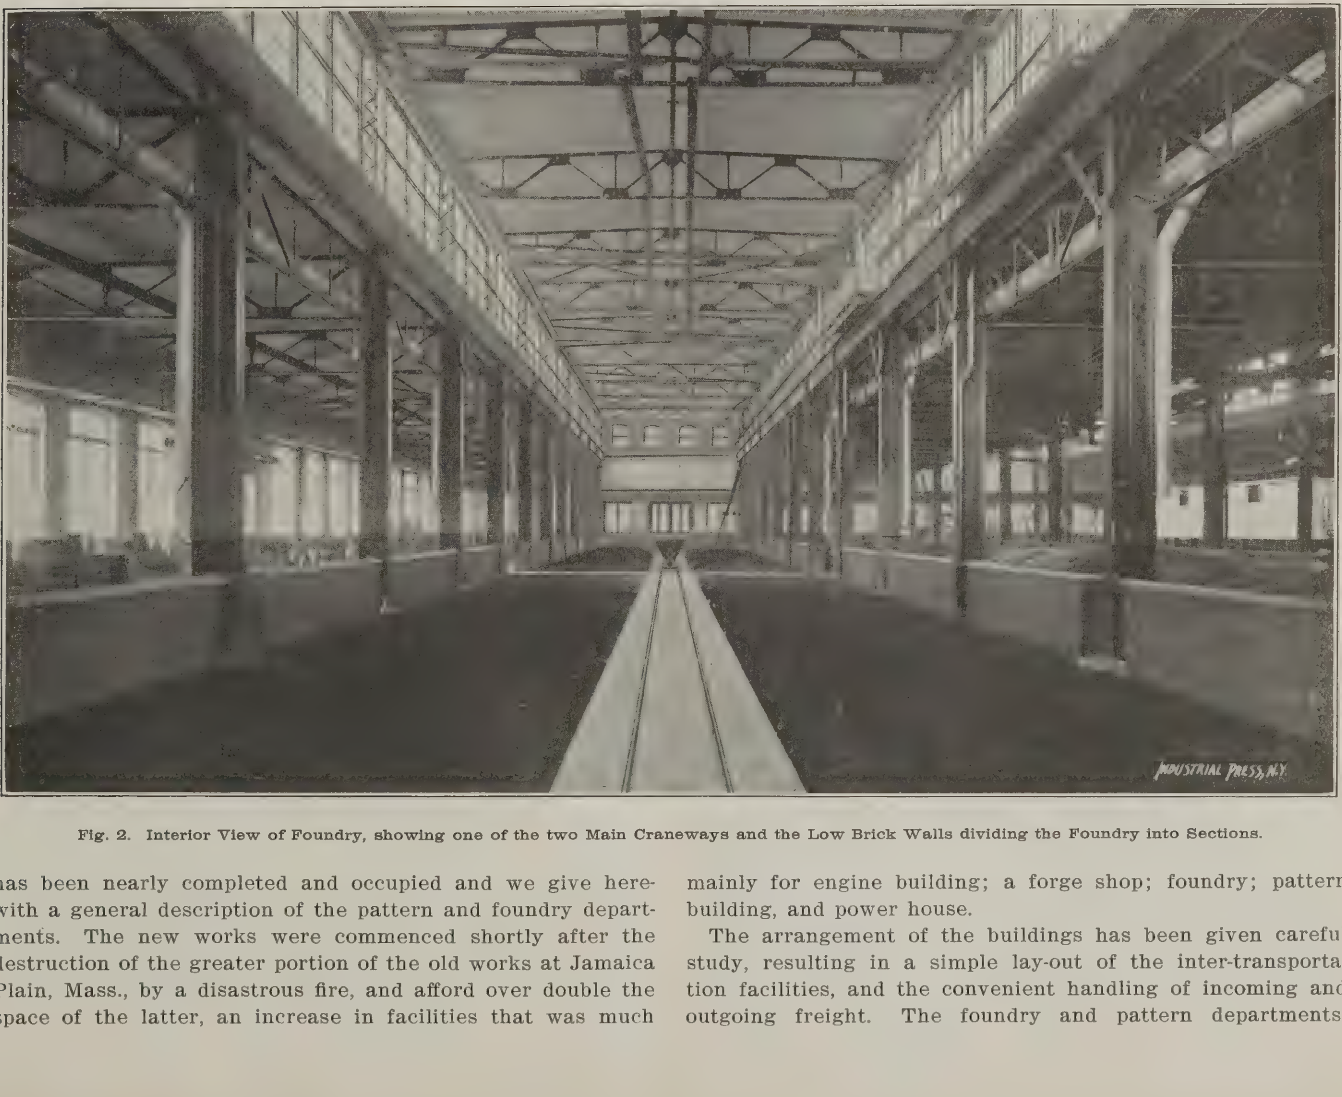

Fig. 2. Interior View of Foundry, showing one of the two Main Craneways and the Low Brick Walls dividing the Foundry into Sections.

The arrangement of the buildings has been given careful study, resulting in a simple lay-out of the inter-transportation facilities, and the convenient handling of incoming and outgoing freight. The foundry and pattern departments, which form the subject of this description were the first to be put in operation prior to the removal of the entire plant from Jamaica Plain.

The Pattern Building.

The pattern building is divided midway of its length by fire walls enclosing stairs, elevators, etc. One-half the building, with stories respectively 17 and 15 feet, is devoted to the flask and patternmaking rooms, while the other half, provided with intermediate floors, making four in all, is utilized for pattern storage. The spacing of the floors will be evident from the exterior view in Fig. 7.

The industrial railway runs directly into the flask shop from the foundry and together with an overhead transfer track reduces to a minimum the cost of handling flasks. The lumber is unloaded from cars directly in front of the building. This room also includes the metal patternmakers' department.

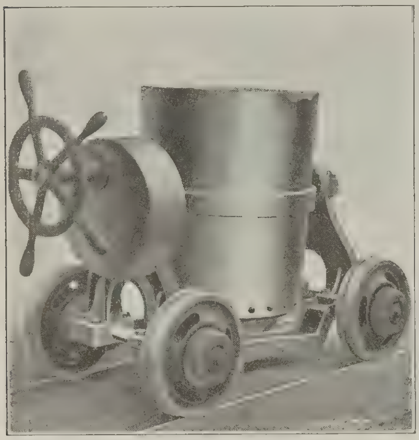

Fig. 3. One-ton Spur Gear Ladle Truck.

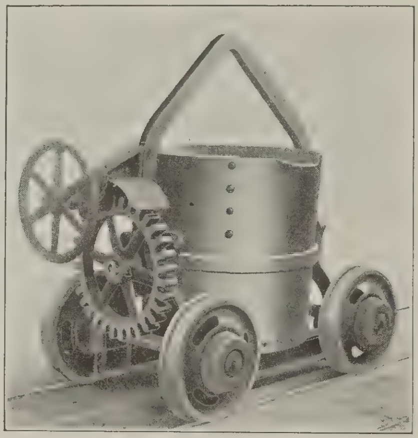

Fig. 4. Transfer Truck for Crane Ladle.

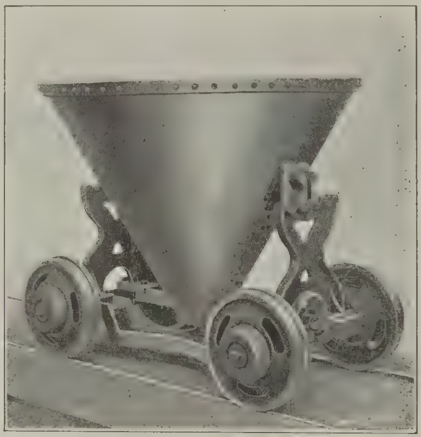

Fig. 5. Dump Car.

Immediately above the flask shop is the pattern shop, abundantly lighted upon three sides and equipped with a full complement of tools. The benches accommodate two men each and measure 2 feet 6 inches in width by 16 feet in length. They are so arranged along the sides of the building that the men all receive a left-shoulder light. Behind each bench is a working table 4 feet by 16 feet in dimensions. The benches are supported upon cast iron legs of special design which were built by the Sturtevant Company and are used throughout the plant. They are equipped with Emmert vises and their tops are of heavy maple plank. A warming chamber for glued work is provided which receives warm air through the heat flue. Sturtevant motors are employed in this building, in 10 horse power units, which provides for a relay in case of a breakdown.

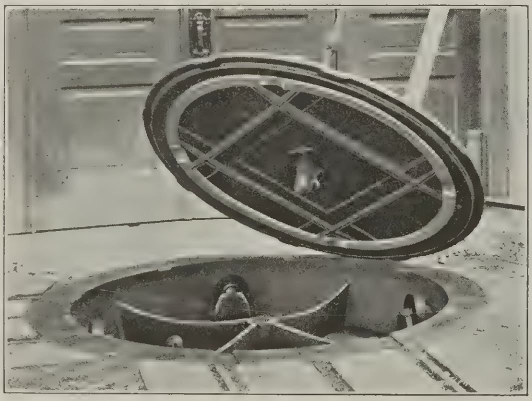

Fig. 6. Turntable for Industrial Railway, with Cover Lifted.

Around the pipe columns which support the floors of the pattern storage end of the building are clamped the pattern shelving brackets which are adjustable to any height. All patterns are consecutively numbered upon the drawings as made. When delivered to the pattern storage department proper locations are assigned, and records thereof made upon cards, one for each pattern. These cards are filed in the order of the pattern numbers. Four figures with the addition of a letter are in every case sufficient to locate a pattern. A given location, for instance, may be 2125B; that is, it is upon the second floor, as shown by the first numeral, "2"; it is in the twelfth row of shelves and the third division of that row, as shown by the succeeding numerals "125," and on the B level, the floor being designated A, and the letters B, C, D, etc., indicating the shelves in their order above.

The first floor is of concrete and is designed for the keeping of heavy cast iron patterns. It is served by an industrial railway and turntable which permits of transfer to the elevator and thence to other floors. Communication between the pattern shop and storage department is direct, while the fire risk is reduced to a minimum by a double system of fire doors.

The molder's written order to make a specified number of castings is issued by the foundry office, directly to the pattern keeper, who makes record thereon of the pattern location, attaches it to the pattern and sends both to the foundry. A metal clip placed upon the storage record card indicates that the pattern is out.

The Foundry.

The foundry consists essentially of two long craneways, each 35 feet in width, with center bent of the same width and side floors 30 feet wide. The brass foundry, core room and wash room are located at one end; the charging floor at one side, nearly midway of the length, and the cleaning room at the other end. The craneways are designed for 20-ton electric traveling cranes. Those already installed are of the Whiting Foundry Equipment Company's make and are equipped with Sturtevant motors.

A feature of the foundry arrangement is the location of two division walls 3½ feet high, so as to separate the floor into three divisions on the lines of the columns. Breaks in these walls occur at intervals, allowing passage from one division to another. The walls serve the purpose of dividing the foundry into different sections for different classes of work, without actually making several separate rooms or buildings, and also serve as extra wall space against which flasks or tools can be leaned.

In the center line of each of the craneways and in the bent between them runs an industrial railway with turntables connecting with the cross aisles which provides for the distribution of metal, etc., to all parts of the building. The floor between the craneways is supplied with a series of 1½-ton small traveling cranes of about 10-foot span equipped with Sturtevant electric hoists built especially for this work.

All materials are received from a track which runs along one side of the foundry and are delivered through wall openings to the bins which fill a portion of the side wing adjacent to the cupolas. These various features appear in the three interior views of the foundry herewith.

Lighting is secured through side windows and monitors. Each line of monitor transoms is operated in unison by a novel device installed by the G. Drouve Company. The western side of the foundry is given up to bench and small floor molding, the bench molders' floors being separated at the

VIEWS OF THE NEW B. F. STURTEVANT FOUNDRY AND PATTERN BUILDING.

bench ends by wooden partitions. The floors throughout this side of the building as well as those in the storage bins and center runways are of concrete. Alongside the industrial railway, which serves iron from ladle trucks to the bench floors, is a sunken trench laid with common brick as a suitable place for drippings and for the piling of hot castings.

The Cupola Arrangement.

An ingenious system of charging has been devised under which the charging cars pass at floor level in front of the bins, are there loaded with the requisite amounts, weighed, and passed to the elevator where they are raised to the charging floor. As each car is unloaded it is pushed forward and started down an incline whence it passes back in a direction opposite to that traversed while being loaded on the floor beneath. A novel apparatus gradually brings it to a standstill while yet upon the incline, and then releases it so that it may, by its own weight, roll onto an elevator which is automatically tripped and descends to the ground floor level. Here it is removed by one of the loading men and the elevator returned to its place above, ready to receive another load. A number of views are shown of the charging car in several positions.

The cupolas are two in number, of Whiting make, 54 and 72 inches in diameter, and the blast is secured by Sturtevant pressure blowers; a No. 8 and a No. 10 blower are driven respectively by a 30 and a 40 horse power belted motor, being supported upon the charging platform through which they discharge directly downward and thence to the cupolas. It is intended to make this installation the subject of critical experiment for the establishment of important principles.

The entire transportation equipment of the plant, including tracks, cars, trucks, etc., was designed and built by the Sturtevant Company. The tracks in the foundry are imbedded in the concrete runways and all changes of direction are secured by turntables, there being no switches in the works, and therefore no radial truck cars, all cars having rigid bases. The turntables are designed very heavy to avoid distortion or breakage and consist of a bottom frame with four roller wheels, Fig. 6, which are carried upon composition trunnions, and a cover, which is recessed for crossing tracks at right angles, and is provided on the underside with a chilled tread, with which the wheels come in contact. A small idler wheel is provided which automatically stops the turntable on each quarter, but readily releases it. The cover is accurately centered by a chilled conical bearing.

The cars are provided with a special type of ball bearing, practically devoid of machine work, but with chilled wearing surfaces. The ordinary flat cars, as well as the charging cars, are built up of structural steel. The geared ladle cars have malleable iron frames and enclosed spur gear mechanism. Similar construction is employed in the case of the transfer cars for geared crane ladles of medium size, while a simple low platform truck is utilized in the case of the largest crane ladles. The dump cars are in the form of inverted cones and so balanced as to be tipped with the utmost ease. The taper of the cone is such that these cars are practically self-dumping.

Brass Foundry.

The brass foundry, located at one corner of the main building, is provided with four crucible furnaces and a special form of reverberatory furnace designed principally for the melting of babbitt or similar soft metals. An overhead traveler with interlocking transfers on the side floors serves the entire area of the room.

In the middle of the end of the foundry is the core room. The ovens are six in number, three being 7 feet in diameter, of the reel type and three being respectively 4, 5 and 7 feet in width by 8 feet 10 inches in length, provided with cars. An overhead traveling crane serves these latter ovens and provides for the transfer of heavy cores to the industrial railway which passes through this room. A portion of the room is partitioned off and serves for the women core makers employed in this department. The floor is of concrete. The tops of the ovens are utilized for storage of cores upon a special rack of steel construction.

At the other end of the foundry is the cleaning room, through which run the longitudinal tracks from each main aisle of the foundry. A five-ton three-motor electric crane of the Whiting Foundry Equipment Company's manufacture equipped with Sturtevant motors serves the principal portion of the floor in this room. The tumbling barrels, six in number, are completely enclosed in housings of steel construction. These, together with a Sly cinder mill and several emery wheels are driven by a 30 horse power Sturtevant motion. A temporary air compressor, located in one corner, supplies air at 100 pounds pressure to chippers, stokers, hoists, etc., employed in connection with this work. The light and ventilation of this room are noticeably good.

Adjacent to the cleaning room is the pickle room, Fig. 10. The floors of both are of concrete. The pickle beds are of teeter board construction so designed that the acid may be drained back into the vats and the board subsequently teetered over for washing into the trench upon the other side of the room. The floor slopes for drainage. A pneumatic traveling crane serves this room.

One of the notable features of the equipment of this plant is to be found in the sanitary arrangements. Most generous provision has been made in the case of the foundry, which has a large locker and wash room. Expanded metal lockers to the number of 225 are already in position. Enameled iron sinks, six in number, are served with tempered water and are generously patronized by the employees. A series of slate partitioned shower baths has proved to be very acceptable during the past summer. The floor of this room is of tar concrete; the upper walls and ceilings which are white and fresh are in pleasing contrast with the steel work and base of the walls which are finished in rich dark green. Within the same room is installed the time-recording system, so placed that a double line of men pass, one upon either side of the board, as they go and come from the room. The foundry foreman has not been forgotten in the matter of convenience, and he with his assistants is provided with an attractive office, well lighted and susceptible of thorough ventilation from out of doors.

The entire plant is heated and ventilated by the Sturtevant system. In the case of the pattern building, the apparatus consisting of an engine-driven fan and steel pipe heater is placed close to the division wall and delivers the heated air into a vertical flue and thence to the various rooms. The foundry apparatus is located overhead in the end of one of the craneways and arranged to take fresh air from out of doors or return from the building and reheat it. Distribution of air is made through a system of overhead galvanized iron piping, discharging downward to the floor. Both apparatus utilize exhaust steam. A complete underground tunnel system is provided for distribution of steam, electricity, compressed air, etc., and return of condensation.

* * *

What is said to be the most dangerous railway in the world is that recently completed up the side of Mt. Vesuvius for the benefit of the many tourists that annually visit this famous volcano. It is a cable railway of the mono-rail type, the one car comprising the active rolling stock being supported by two wheels, one at each end of the car. The center of gravity of the car is below the top of the supporting rail so that it balances without the aid of supporting wheels at the sides. The railway line runs to within nominally 1,000 feet of the crater mouth, but the distance changes from day to day on account of the rapid changes that take place; accretions to the sides of the crater may materially increase the distance one day, and the fall of a huge slice into the seething gulf 500 feet below, may considerably lessen the distance the next day. The maintenance of the line in proper alignment is a difficult matter. Fissures opening, the flow of lava, falling cinders, and sliding of the roadbed require constant watchfulness and labor by gangs of laborers who constantly patrol it during the periods of operation. The "train" has no fixed time-table, the trips depending on the activity of the volcano and direction of the wind; some days they are entirely abandoned.

ALTERNATING CURRENT RAILWAY MOTOR.

United States Consul-General Mason, Berlin, Germany, has been more active in collecting and sending information to this country upon technical and engineering subjects than any of our foreign representatives. In a recent consular report he devotes considerable space to a general description of a new variable speed motor for electric cars operating with a single-phase alternating current of 6,000 volts, without conversion to a lower voltage or to direct current. A car equipped with one of these motors has been in operation on a Berlin suburban line and it is stated that its speed can be varied to any desired degree without cumbersome or expensive regulating devices. The motor was invented by a young Austrian electrician and built from his plans by the Union Electric Company, Berlin. If the motor should prove on extended trial to accomplish all claimed for it, it is an invention of great importance, for it apparently accomplishes a result not heretofore attained. Readers may possibly remember the description of the Arnold system of electric traction in the technical press about a year ago, in which system alternating current motors are employed. But Mr. Arnold found it necessary to provide a compressed-air storage reservoir and an air engine, connected with the electric motor and also the car axle by suitable mechanism, in order to obtain the full variation in speed desired. Various other systems, more or less complicated, have been worked out to avoid direct-current motors on electric cars and the consequent converter and transformer stations along the line of the road, in installations where alternating current is used for the transmission.

No information is at hand regarding details of the new Austrian motor, but Consul-General Mason's description and very intelligent comments are of interest. He says that alternating currents of high pressure, which are taken off at intervals by substations, as mentioned above, work very well for short suburban and city lines. But when the proposition is to extend the same practice to a standard railway, connecting two cities from 100 to 300 miles apart, the cost of the installation and working expenses become practically prohibitive. Besides the frequent substations equipped with converters and transformers capable of changing the high-voltage alternating current into a low-pressure continuous one, there is the question of heavy copper conductors throughout the line, and this, added to the fact that the transformers and rotary converters must stand idle except when the converted current is taken off and used by some passing train, has hitherto rendered the proposition economically untenable.

When the high-speed experiments were tried last year on the government railway line between Marienfelde and Zossen, an alternating three-phase current of 10,000 to 12 000 volts was carried along the line on three copper wires and conducted thence by trolleys to transformers carried under the floor of the car, whence it was transformed to 1,150 to 1,800 volts and passed into the three-phase induction motors. The car easily attained a speed of 140 to 150 kilometers an hour, at which pace the rails began to give way. The experiments had to be postponed until a more solid and substantial track could be provided, but have recently been conducted successfully.

The present experiment has therefore a wholly different purpose. It involves no question of extreme high speed, but rather the transmission of a single-phase alternating current at a voltage sufficient to carry it over a long line on a small and relatively inexpensive wire, and the direct use of the current, without transformation, by a motor capable of running economically at any desirable speed and which fulfills all the other requirements of electric traction. The point demonstrated by the tests now in progress is the effectiveness of the new motor for the special purpose to which it is applied. No sparking or other technical difficulty appears thus far to shadow the success of the experiments. The system eliminates the expensive substations, with their heavy initial outlay and operating expenses, and is so simple and direct in its working that it may, at least in theory, be applied to lines several hundred miles in length. If the distances are very great, of course the power may be transmitted from a distant waterfall or steam plant at any desired pressure—say, 20,000 or 50,000 volts—and then reduced in ordinary transformers, requiring no especial care, to the working-line voltage of, say, 6,000 or more. The present tests are over a line of 3 or 4 miles in extent, the length being immaterial. There may be encountered new technical difficulties when this distance is increased to as many hundred miles, but such difficulties are only such as may be met in any long-distance transmission and such as electrical science at its present stage is fully prepared to overcome.

OF HISTORICAL INTEREST.

In a brief paper read before the Engineers' Society of Western Pennsylvania on early experiences in transportation, Mr. Antes Snyder referred to the regulations promulgated for the control of traffic on the State railways of Pennsylvania. When the commonwealth opened the Philadelphia and Columbia Railway, the theory was that the State furnish the roadway, and that any one who pleased could furnish his own vehicle and motive power and use the railway whenever he wished, by paying the State tolls for its use, just as the turnpikes of the day were used. But it was soon discovered that a certain character of vehicle was necessary and that rules and regulations as to times and manner of using the railways were absolutely necessary to effect their successful operation. The ordinary shippers found it too expensive to fit themselves with the necessary plant, and that they could get this transportation done by large and well-equipped shippers much more cheaply than they could do it themselves, so that in pracice the business drifted into the hands of a few individuals and companies, who did this service for the many. The railway as constructed was intended for the horse as motive power, though the locomotive was being introduced as an experiment shortly after the railway was completed. The following, among the rules and regulations adopted by the Canal Commission for the regulation of the railway, may be of interest:

"Section 92.—No car shall carry a greater load than three tons on the Columbia and Philadelphia Railway, nor more than three and one-half tons on the Portage Railway, nor shall any burden car travel at a greater speed than five miles per hour, unless the car body and load shall be supported on good steel springs.

"Section 108.—It shall be the duty of the conductors of cars moving with less speed upon the railways, upon notice by ringing a bell, blowing a horn, or otherwise, of the approach of a locomotive engine or other cars moving in the same direction at a greater speed, to proceed with all possible dispatch to the first switch in the course of their passage and pass off said track until said locomotive engine or other cars moving at greater speed can pass by. The conductors of the slower cars are directed to open and close the switches so as to leave them in proper order. Any person who shall refuse or neglect to comply with the provisions of this regulation shall, for every offense, forfeit and pay the sum of ten dollars."

It must have been a very interesting and novel sight, indeed, when the horse and the locomotive were used indiscriminately on the same track and were struggling for supremacy as the future motive power of our railroads, and the approacn of a locomotive was heralded by the tooting of a horn. Even at that time the right of way was given to the fast horse.

* * *

What is said to be the largest and most powerful towboat ever built for the Mississippi River was recently constructed at Dubuque, Iowa, to the order of the Monongahela River Consolidated Coal and Coke Company, Pittsburg, for use in taking down river the immense fleets of coal barges. She is the usual stern-wheel type of steamer which predominates on the Western rivers, but in size is very much larger than any boats yet built, her "over all" length being 318 feet. The hull is built of steel from the boiler deck down, the general dimensions being as follows: Length of deck, 277 feet; beam, 61 feet; depth, 7 feet. To give sufficient strength to this long and very shallow vessel 3 fore-and-aft bulkheads are fitted, and a system of chains and braces, similar to the hog frame in side-wheel steamers, is built to take up the strains due to the heavy weights resulting from placing the boilers forward and the engines aft.

MACHINERY
DESIGN—CONSTRUCTION—OPERATION.
PUBLISHED MONTHLY BY
THE INDUSTRIAL PRESS,
66 WEST BROADWAY, NEW YORK CITY.
CHICAGO—1462 Monadnock Block. BOSTON—620 Atlantic Ave.

LESTER G. FRENCH, Editor.
FRED E. ROGERS and GEO. H. HALL, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

NOVEMBER, 1903.

NET CIRCULATION FOR OCTOBER, 1903,—25,769 COPIES.

MACHINERY is issued in three editions—the Engineering Edition, printed on coated paper throughout, each volume comprising 650 or more reading pages and forty-eight 6 x 9 data sheets—price $2.00 a year; the Shop Edition, printed on super-calendered paper, comprising 430 or more reading pages, devoted to practical shop matter—price $1.00; and the Foreign Edition, which comprises the same matter as the Engineering but is printed on thin paper for transmission abroad—price $3.00 a year.

The growth of the oil industry in the United States has developed a highly skilled class of operators known as drillers, who are able to rapidly and cheaply sink bore-holes into the earth to depths of 1,000 to 2,000 feet, and more. But in these operations it is rare that a bit as large as 12 inches is used; the usual size being under 8 inches diameter. What then would the average driller think of sinking a shaft 9 feet diameter by the jump-drill operation? It would certainly be regarded as a big contract by most of them. At the present time, however, a colliery shaft is being sunk at Dover, England, by the Kind-Chaudron system which uses a special cutting tool called a "trepan" attached to a very heavy walking-beam by pitch-pine rods. The trepan is 9 feet across the cutting edge, which consists of 19 steel bits in line, each weighing over 100 pounds. This process has been used in Continental countries for some years in sinking mine shafts through ground in which extensive water strata is met with, but beneath which an impervious stratum will be encountered. When this strata has been reached by the "trepanning" operation the shaft is lined or "tubbed" with heavy iron rings tightly packed at the lower end by a "moss-box" to exclude the water.

* * *

The three-cornered muddle over the contracts to be let for the new battleships, in which the Bethlehem, Carnegie, and Midvale Steel companies are participating, promises to introduce a new point in law that is of considerable interest to manufacturers. The Bethlehem and Carnegie companies both have large and complete plants for producing armor plate by the Krupp process, and these two companies claim to control the rights for the use of this process in the United States, and exact a royalty from the government on the plate made at government plants. The Midvale company have not yet completed their plant for the manufacture of armor plate, and it is not known what process they intend to use; but it is surmised that it will be the Krupp process, also. The Bethlehem and Carnegie companies not only claim that the Midvale company will not be able to complete its contract, if it secures it, within the time specified, but further assert that they will compel the government to pay royalties on all the plate furnished by the Midvale company, inasmuch as it will infringe on the rights to the Krupp process, which the former concerns control. The peculiar part of the situation is, however, that there is no patent on the Krupp process, and that propriety rights with regard to it are held solely in virtue of its being a secret process and one that has been developed at great cost and has required the establishment of immense plants for its production. Will the courts decide that there is property in a secret process, even after it has been discovered by other persons and put to use by them? Apparently there is a new point of law involved which it has heretofore been supposed did not exist—and probably would not exist except for the millions of vested interests involved in the equipment of the plants. It remains for the courts to say, however, that this makes the tenure of the process itself any the more secure.

* * *

ONE WAY TO KEEP UP THE DEMAND.

Not long ago a prominent manufacturer and inventor of special machinery was relating his experiences and cited a certain product which he had developed some 20 years ago and was ready to put on the market. The product was for machine shop use, and inasmuch as the publication of its name would at once indicate at least one of the principals in the incident to be mentioned, it will answer our purpose to call this particular product a new brand of hack-saw blades, which, however, it was not.

The blades which this gentleman produced had remarkable qualities, particularly in the matter of durability. This was obtained in part by using a superior quality of steel, but mainly by the method of manufacture, which involved a forging process, by means of a special machine built for the purpose. The process gave to the steel a peculiar density and toughness previous to its being converted into saw blades, and it was found upon repeated tests that a blade produced by this means would outwear any four blades as usually made. The invention also included methods for nicking the teeth and finishing the blades, which reduced the cost of production to such an extent that blades could be manufactured by the new method at considerably less cost than any other blades had ever been produced for.

Now, Jones & Co. were the largest manufacturers of hack-saw blades in the country; so large, in fact, that they practically supplied the trade and had all they could do to keep up with their orders. They in some way heard of the work of the inventor and made overtures for the purchase of the invention. The inventor stipulated that if it were disposed of, the sale must be effected without the purchaser seeing the machine, or any of the apparatus; that cash must be paid; and that on his part he would guarantee the method to be all he claimed for it and the machine to be well constructed and free from trappy features. He furthermore agreed that in case the machine would not do what was claimed for it, he would refund the money, the question of refunding to be decided by a committee selected from the employees of Jones & Co., the prospective purchasers. Although these conditions were very unusual, the invention was apparently so valuable that the price of $25,000 was paid outright, and there never was a question raised as to the refunding of the money.

This sale, however, was the end of the invention, and it never after saw the light of day. Jones & Co. believed that if saw blades were put on the market which would outwear four times as many blades of their own manufacture, there would then not be as many people to buy saw blades, and that their production would be cut down to so great an extent as to be ruinous to their business. Although the new blades could be made cheaper and sold for a lower figure, or at the same figure at a greater profit, they still thought it to their interest to shelve the invention and so compel people to use blades of inferior quality and buy more of them.

There have been many firms who have held to the same mistaken and ancient views as Jones & Co., but fortunate it is that they have not been in the majority. It was perfectly natural that this company should have desired to control the best processes for making hack-saw blades, and should have purchased the invention of our friend; but if they had also made an effort to produce the best article that could be made, and had put it on the market at a fair price, they would have been more in line with present-day practice, for the best foundation for any business is the reputation for the best goods at a fair price.

Dr. Th. Goldschmidt, the well-known German chemist and discoverer of thermit, will give a lecture on this compound and make a demonstration of the thermit welding process at Columbia University some time during the second week in November. Further information may be obtained from Mr. Ernest Stutz at the Murray Hill Hotel, New York.

Gordon McKay, the millionaire inventor of shoe machinery, died on October 19. McKay was born in Pittsfield, Mass., and when a small boy showed a talent for mechanics. His first employment was with the Lowell (Mass.) Machine Company, where he helped in building the first locomotives for the Boston & Maine Railroad. Early in his life he became associated with L. R Blake, of Arbington, Mass., who invented a shoe-sewing machine, which eventually proved a failure. McKay saw its possibilities, however, and bought the patent rights. Then he inserted the necessary improvements and began to make his millions. He later invented a heeler, lasting machine, and shoe-nailing machine, and through the use of these was the only manufacturer in a position to offer to make shoes for the Union Army. The fortune that he amassed can only be estimated. At one time he was receiving a commission of from ½ to 4 cents on every shoe manufactured with the aid of his inventions, from Maine to California, in addition to enormous royalties from his British patents. Harvard University will now receive $4,000,000 of McKay's fortune, which was placed in a trust fund for the university in 1893, but at the time of his death it was not known to whom the balance, and probably the greater part of his fortune, would go.

THE DATA SHEET FOR THE CURRENT ISSUE.

The tables comprising the data sheet for this month have been furnished us by the Garry Iron and Steel Co., Cleveland, Ohio, and represent the practice followed in their engineering department for the design of round shafting. They consist of diagrams by means of which may be solved graphically the formulas for round shafts when subjected to twisting moments, bending moments, or to a combination of both twisting and bending moments.

Table 1 is calculated on the formula $T = \frac{Sd^3}{5.1}$, and consequently for a given twisting moment, T, the diameter of the shaft $d = \sqrt[3]{\frac{5.1\ T}{S}}$. In this formula S represents the fiber strain per square inch and the diagram is arranged for values of S from 4,000 to 24,000 pounds per square inch.

Table 2 is arranged to give the diameter of shafts subjected to bending moments. The formula for shafts loaded in this manner is $M = \frac{S\ d^3}{10.2}$ giving a value for the diameter $d = \sqrt[3]{\frac{10.2\ M}{S}}$. In the diagram seven values of S are given, ranging from 5,000 to 30,000 pounds per square inch.

Table 3 is used for determining the size of shafts that are subjected to a combined twisting and bending moment. Upon the horizontal base are denoted the twisting moments and upon the vertical side the bending moments. By following vertically and horizontally the respective lines representing the given moments, their point of intersection will fall upon a line which represents the diameter of a shaft of suitable size to sustain the combined load. This diagram is calculated by the well-known formula:

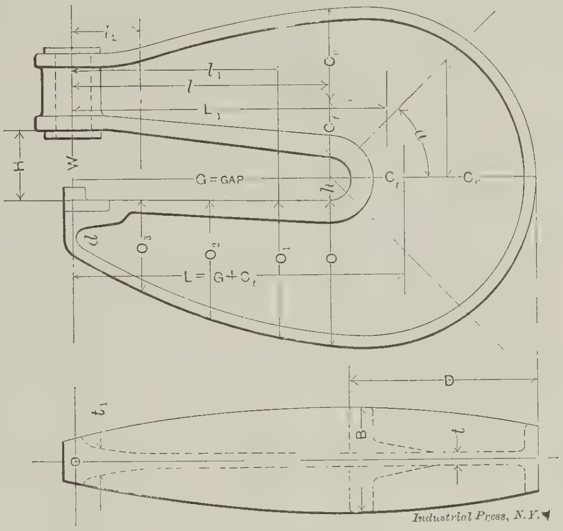
Combined moment $= M + \sqrt{M^2 + T^2}$
in which $M =$ bending moment,
$T =$ twisting moment.

The results of this diagram are based on a tensile strength of 7,500, and a shearing strength of 6,000 pounds per square inch. If we desire to find the diameter for any other tensile strength we first find it from Fig. 3 and then, by referring to Fig. 4, find a new diameter for any desired fiber strain from 5,000 to 30,000 pounds per square inch.

DESIGN OF PUNCH AND RIVETER FRAMES.

JOHN S. MYERS.

In the design of a punch, riveter or shear frame the depth of throat or gap G, and the height of the throat H and h, Fig. 1, are determined by the size and character of the work to be done. In riveters the stake is usually fixed by the smallest shell that is to be riveted, and dimension O must consequently be less than the internal diameter of this shell. It is customary, when thus limited, to make the section of the stake as shown in Fig. 2 in order to obtain as deep a section as possible. The strength of similar sections varies as the cube of the depth while the area varies as the square of the depth, so that ordinarily, a deep section is more economic of material than a shallow one. If, however, the depth D is great in proportion to the gap G, as shown in Fig. 3, the length of the compression flange is increased to such an extent that the entire frame is heavier than it would be if a shallower section were used. A machine of one hundred and eighty tons capacity, having a gap G of 9¼ inches was found, when made of steel castings, to be considerably lighter with a depth D of 16½ inches than when this depth was made 22 inches.



Industrial Press, N.Y.

Fig. 1

In riveters of long gap the spring or deflection is an important factor. This varies as the cube of the length and inversely as the moment of inertia of the section. For similar sections the moment of inertia varies as the fourth power of the depth; hence the adaptability in riveters of deep gap of the form of section shown in Fig. 2, keeping the depth of section as great as is consistent with the work to be done.

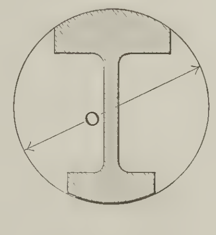


Fig. 2.

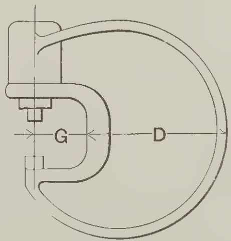

Industrial Press, N.Y.

Fig. 3.

In designing punches and shears, the dimensions O, D, B and t are selected according to the judgment of the designer. The frames are usually made of cast-iron as a more rigid frame can thus be produced for less money than if it were made of steel. If it is portable, however, weight becomes the main factor and steel may then be used advantageously. The thickness of the web t is mostly a consideration of what will cast well and for this reason it should be thickened where it joins the heavy tension flange at the end of the throat. This thickening also takes care of the rapid transition of stresses that takes place at this point. At t_1, Fig. 1, it should usually be thickened to carry the shear, as little of the shear is carried by the flanges, and the web is shallow at this point.

In punching large holes in thin plates with a flat-ended punch, the plate gives way at a certain point with a snap. If the head of the machine is heavy and the spring considerable, the kick, due to inertia, reverses the stresses when the plate gives way, suddenly releasing the frame. While this would probably never be enough to endanger the compression flange, yet the reversal of stresses weakens the tension flange.

After having decided upon the material to be used and the allowable stresses in tension, compression and shear, the usual method is to assume the proportions of the main section and calculate for the stress. If the results are not reasonably near the chosen ones, correct the first assumptions and recalculate.

The frame is acted upon by a force *W*, which produces a bending moment equal to the force times the length of the lever arm. On the main section the lever arm is the perpendicular distance from the line of action of the force *W* to the center of gravity of the section, and equals $G + Ct$, Fig. 1.

Let:

L, L_1, l, l_1, l_2, etc = lengths of lever arms, in inches, to various sections.

Ct and *Cc* = distance from center of gravity of section under consideration to extreme fiber of tension and compression flanges respectively.

W = Force, in pounds, applied at the die. (If a hydraulic machine, this is taken equal to the effective area of the ram multiplied by the working pressure per square inch.)

S = Uniformly distributed tensile stress due to force *W*.

Ss = Shearing stress carried mainly by the web of section.

St = Tensile stress due to moment of force *W*.

Sc = Compressive stress due to moment of force *W*.

Smt = Maximum or combined tensile stress.

Smc = Maximum or combined compressive stress.

A = Area of section under consideration.

I = Moment of inertia of section.

M = Bending moment, in inch pounds.

a = Angle of section with center line of frame.

Then:

$M = WL, WL_1, Wl, Wl_1, Wl_2$, etc.

$$S = \frac{W \cos a}{A}$$

for main section, where $a = o$; $S = \dfrac{W}{A}$

$$Ss = \frac{W}{\text{area of web}}$$

$$St = \frac{M\,Ct}{I}$$

$$Sc = \frac{M\,Cc}{I}$$

$$Smt = St + S$$

$$Smc = Sc - S$$

The dimensions of the main section being assumed, to determine the center of gravity and moment of inertia: Take the moments of the different areas of the section about some line of reference and divide the algebraic sum of the moments by the total area, which gives the distance of the center of gravity from this line. The neutral axis passes through the center of gravity of the section. The moment of inertia is equal to the sum of the product of each area by the square of its distance from the neutral axis, plus its moment of inertia about its own neutral axis.

As an example, we will consider the design of a 150-ton punch frame, which is to be quite rigid, but as light as consistent with good design; being mounted upon a carriage, gap to reach the center of an 8-foot plate. We will make this frame of a steel casting, of I-section, quite deep, and with medium stresses to insure rigidity. Then

W = 300,000 pounds, and assume:
Smt = 6,000 pounds per square inch.
Smc = 8,000 pounds per square inch.

For main section, referring to Fig. 4:

$$\begin{array}{lll}
5\tfrac{1}{2} \times 22 = 121 \text{ sq. ins.} \times 21 & = & +\ 2541 \\
2 \times 36\tfrac{1}{2} = 73 \text{ sq. ins.} \times 0 & = & 00 \\
3 \times 12 = 36 \text{ sq. ins.} \times 19.75 & = & -\ 711 \\
\hline
A = 230 \text{ sq. ins.} & & \dfrac{1830}{230} = 7.96
\end{array}$$

$$121 \times 13.04^2 + \frac{22 \times 5.5^3}{12} = \begin{cases} 20,600 \\ 304 \end{cases}$$

$$73 \times 7.96^2 + \frac{2 \times 36.5^3}{12} = \begin{cases} 4,616 \\ 8,100 \end{cases}$$

$$36 \times 27.71^2 + \frac{12 \times 3^3}{12} = \begin{cases} 27,600 \\ 27 \end{cases}$$

Moment of inertia, I = 61,247

$L = G + Ct = 50 + 15.79 = 65.79$

$M = WL = 300,000 \times 65.79 =$ 19,737,000 inch pounds.

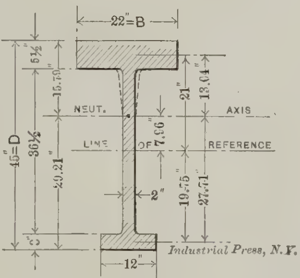

Fig. 4.

$$S = \frac{W}{A} = \frac{300,000}{230} = 1,305$$

$$St = \frac{M\,Ct}{I} = \frac{19,737,000 \times 15.79}{61,247} = 5,085$$

$Smt = S + St = 5,085 + 1,305 = 6,390$

$$Sc = \frac{M\,Cc}{I} = \frac{19,737,000 \times 29.21}{61,247} = 9,420$$

$Smc = Sc - S = 9,420 - 1,305 = 8,115$

These stresses are, therefore, found to be sufficiently near to those which were assumed.

The vertical section is figured likewise, except that there is no direct tension S to combine, but the shear on the web. The section at an angle a has $S = \dfrac{W \times \cos a}{A}$ to combine. The moment on this section is $M = W L_1$. The vertical section having been determined, the others may be proportioned from it thus: $l : l_1 :: O^3 : O_1^3$, or $O_1 = \sqrt[3]{\dfrac{l_1 O^3}{l}}$ and all of the other dimensions in like proportion.

Calculate the ordinates O_1, O_2, O_3, etc., and lay them out. The curve found will not be a very pleasing one, and will have to be varied somewhat. Keep the web of a uniform thickness, and taper the flanges in straight lines, keeping the area of the flanges the same as if proportioned from the above formula. Check two or three sections for St and Sc by finding center of gravity and moment of inertia, by method given above. Allow a somewhat lower stress on tension flange of the 45 deg. section and use large fillets for steel.

It is very often the case that two or more sections have to be calculated before the proper sizes are determined, and this becomes a tedious job. In the table herewith are given the elements of fifty different sections reduced to a uniform depth of 10 inches, showing their relative proportions, from which sections may be proportioned to suit almost any condition. From our known values, M, St, and Sc, we get $\dfrac{M}{St} = \dfrac{I}{Ct}$ and $\dfrac{M}{Sc} = \dfrac{I}{Cc}$. From the columns headed $\dfrac{I}{Ct}$ and $\dfrac{I}{Cc}$, we get the value of these quantities for the chosen section at a depth of 10 inches and our new depth will then be 10 times the cube root of the required value, divided by the tabulated value. The depth being determined, all of the other dimensions can be readily figured by direct proportion. If the required depth were 25¼ inches, multiply all of the dimensions in the table by $\dfrac{25.25}{10} = 2.525$.

Remembering that the dimensions vary as the depth, the area as the square of the depth, the sectional modulus as the cube of the depth, and the moment of inertia as the fourth power of the depth, any of these elements can be readily obtained.

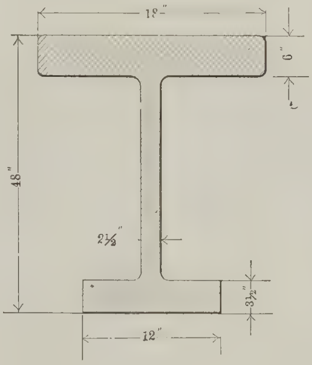

Fig. 5.

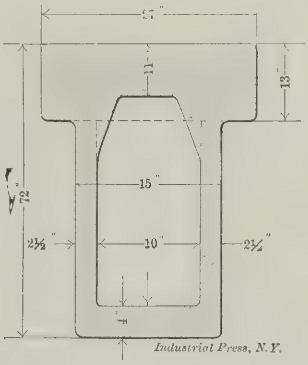

Fig. 6.

The section figured above as an example is No. 16 in the table. No. 35 was originally 48 inches deep. $B = 4.8 \times 3.75 = 18$ inches. $H = 4.8 \times 1.25 = 6$ inches. $b = 4.8 \times 2.5 = 12$ inches. $h = 4.8 \times .729 = 3\tfrac{1}{2}$ inches. $t = 4.8 \times .521 = 2\tfrac{1}{2}$ inches. All as shown in Fig. 5. This was the main section of a 100-inch, 50-ton riveter. The maximum stresses are given in the table.

Fig. 6 shows section No. 17 as it was originally built. It was for the main section of a 60-inch gap shear having an 18-inch ram at a working pressure of 1,500 pounds per square inch. The section was calculated as if the tension flange were 27 x 13 inches, the small amount of metal cut out being assumed to be replaced by the thickening up of the side web plates in front.

Sections Nos. 37 and 38 were main sections of an 18-inch 100-ton punch and a 50-inch, 100-ton punch, respectively. No. 45 was a beam 15 feet 6 inches long, carrying a uniformly distributed load of 1,130 tons. In the column headed "location of section," Par. means that the plane on which the section was taken is parallel to the direction of the force at the die; Per. similarly means perpendicular to the direction of this force.

* * *

Another use for cement construction is for curtain walls of expanded metal and cement or plaster to prevent the rapid spread of flame. At the Deering Harvester Plant, Hamilton, Ont., the roof trusses are lathed on both sides with expanded metal, the wall being carried up three feet above the roof, and the laths then covered with one inch of cement mortar.

THE NEWPORT (R. I.) STEAM TURBINE STATION

The first vertical Curtis steam turbine to be installed in this country is a 500 K. W. machine, at Newport, R. I. In the March, 1903, number of the Engineering Edition was a brief description of the Newport plant, with a line-drawing, showing the arrangement of the machinery in the engine room. We are now able to show two illustrations from photographs of this plant, together with detail drawings of the Schmidt independent superheater, with which the plant is equipped. This superheater is of unusual interest, as the work done by William Schmidt in the use of superheated steam in Germany has attracted the attention of engineers all over the world. The superheater of this design is now made in this country by the Providence Engineering Works, who control the patent rights for the United States, and installed the apparatus at the Newport station.

The Newport station is one of several controlled by the Massachusetts Electric Companies, who operate about 900 miles of electric street railways and have already contracted for 33,000 horse power in steam turbines. Three of these are 500 K. W. machines, and will be installed at Newport, while the others will be placed in stations at Fall River and Quincy Point, Mass., and will be much larger units.

The Newport turbine, at present in operation, runs at 1,800 revolutions per minute, taking steam at 140 pounds pressure at the turbine nozzles. Alternating current of 2,500 volts is generated. The turbine is 7 feet 8 inches in diameter at the base, and 12 feet 6 inches high. The station plans call for four turbines in all. The boiler room is equipped with the Schmidt superheater, which may be used or not at will, the intention being to carefully experiment and note the action of the turbines with both saturated and superheated steam. Four 350 horse power Aultman & Taylor water-tube boilers, fitted with Green economizers, will be installed at first. The separately fired superheater stands at one end of the line of boilers, and the arrangement of the steam piping is such that steam can be taken through the superheater or direct from the boilers.

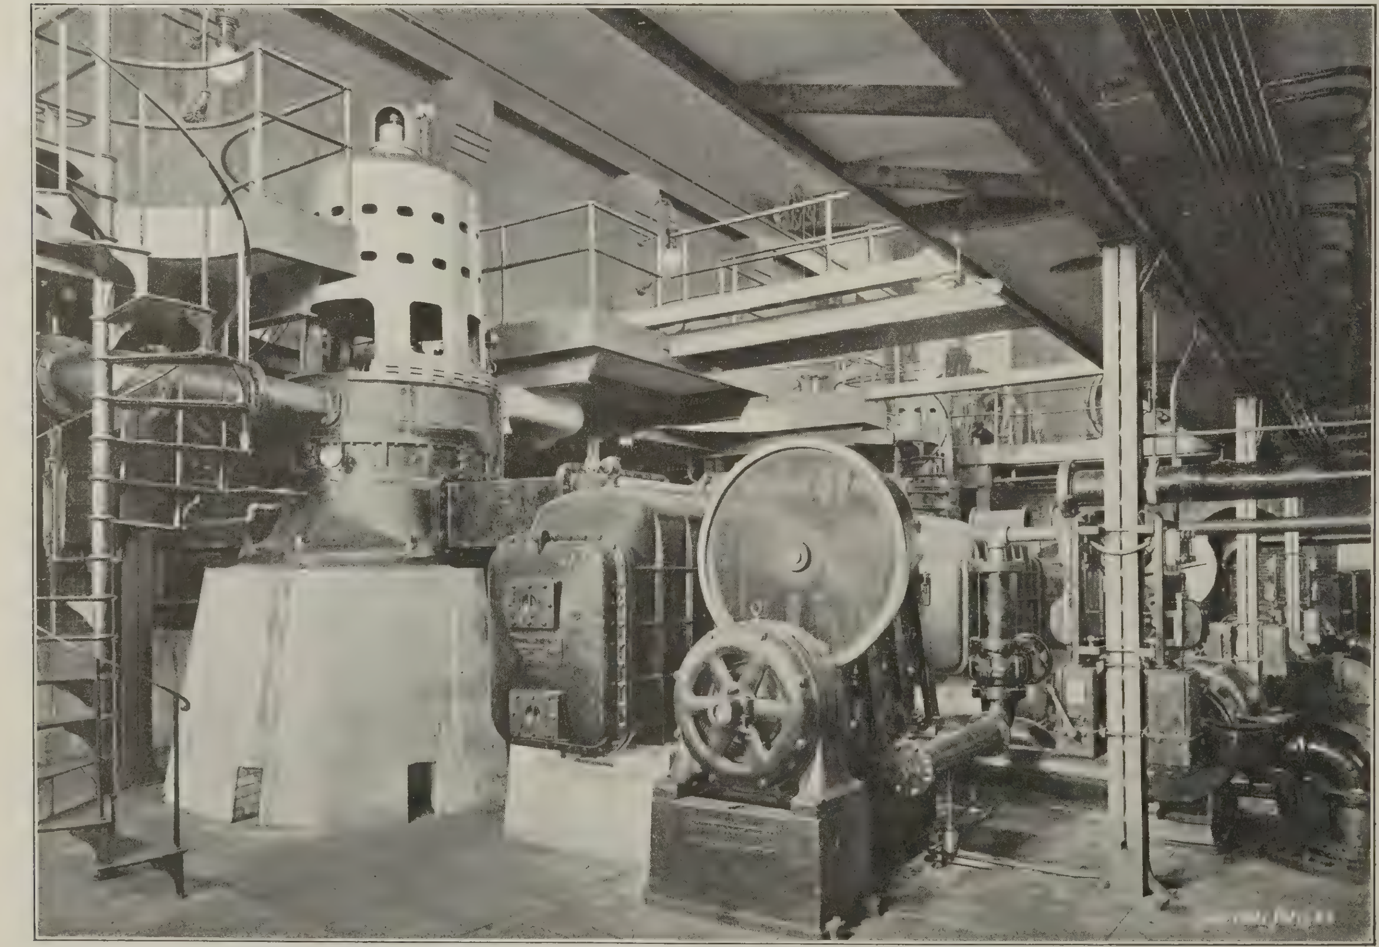

Fig. 1. The New Steam Turbine Station at Newport, R. I.

It will be noted in the illustrations that the engine room floor level is above the turbine proper, the generator only being above the floor. A heavy foundation of brick is provided for each unit, the dimensions being 9 feet square at the top, 11 feet at the bottom, and 5½ feet high. Beneath this is an 18-inch bed of concrete.

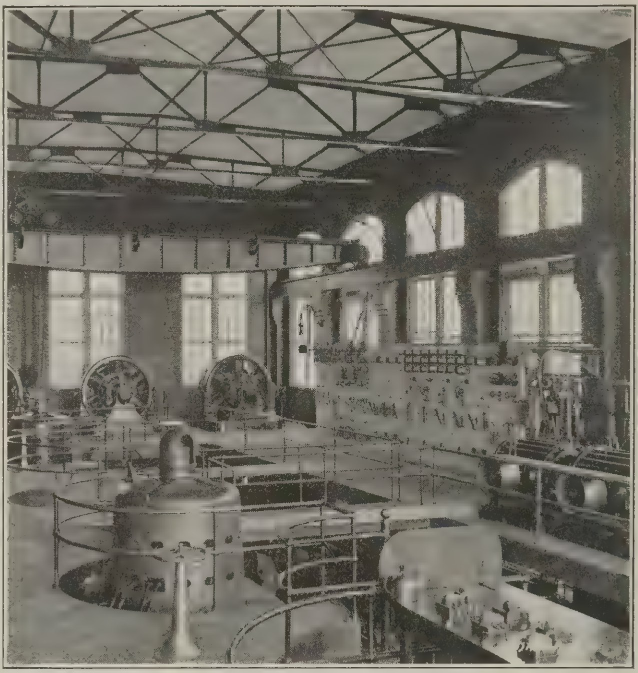

Fig. 2. View of Gallery in Power Station.

In explanation of the drawing of the superheater, saturated steam enters through the inlet valve, *A*, and passes through the cast-iron cross pipe, *B*, at the top of the superheater, to which the two upper sets of coils are connected. The satu-

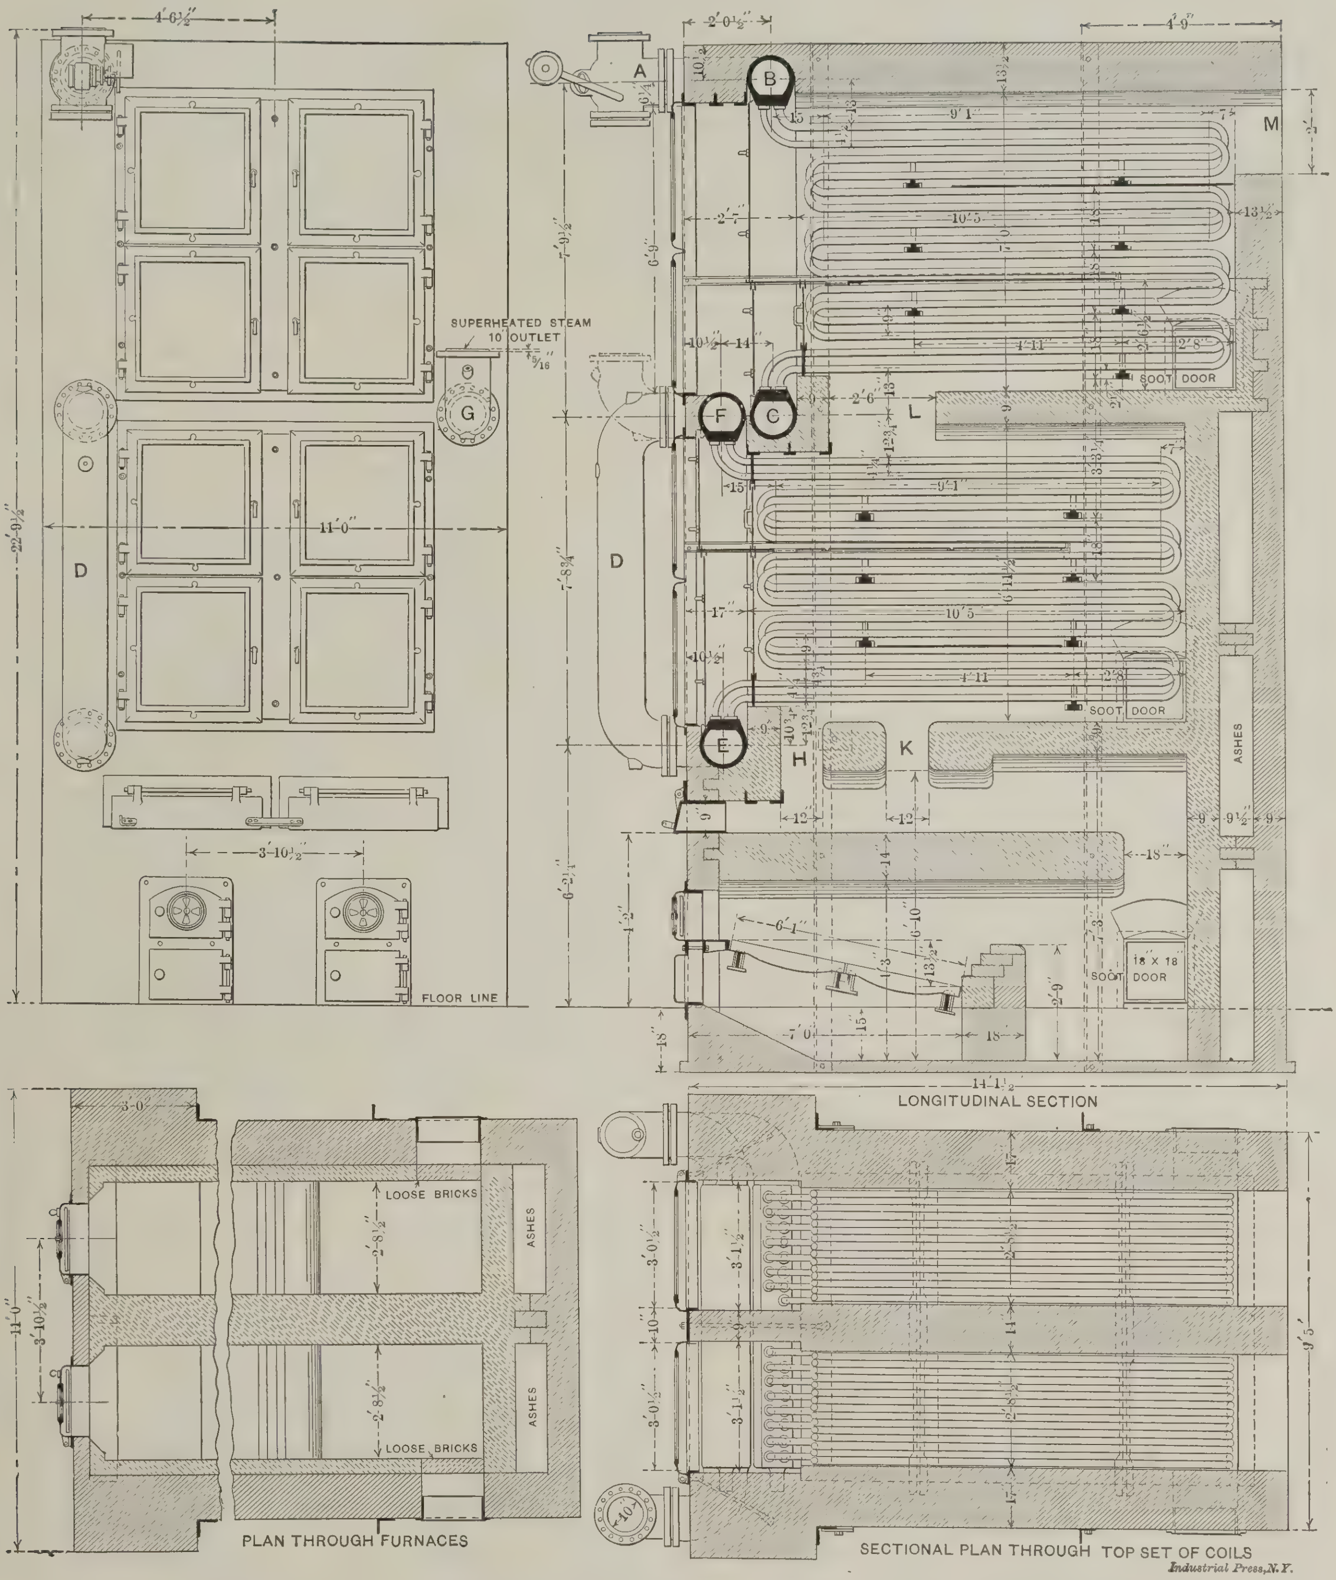

Fig. 3. Details of the Independent-fired Schmidt Superheater at the Newport Station; built by Providence Engineering Works.

rated steam then passes down through these two coils, becoming superheated on the way to the cross pipe, *C*; thence to the pipe, *D*, on the outside of the apparatus, which carries the steam to the bottom of the two lower sets of coils. The steam here enters cross pipe, *E*, and thence passes upward through the lower coils, where it comes in contact with gases at a higher temperature. The superheated steam outlet is at *G*, near the center of the superheater. The object of locating the outlet at this point is to secure as low a temperature of the escaping gases as possible, and at the same time have the heat transmitted to the steam efficiently. This method is a compromise between having steam enter at the top and leave at the bottom, or have it enter at the bottom and leave at the top. The former arrangement would give rather slow interchange of heat and the latter would send the gases up the flue at too high a temperature.

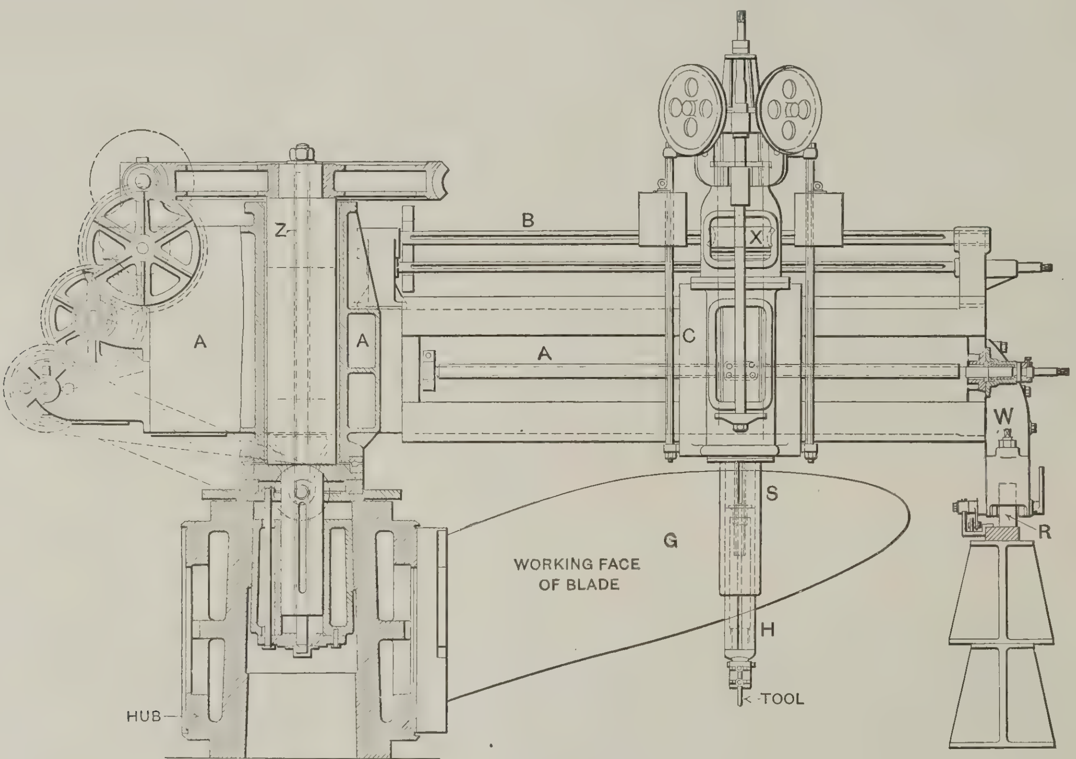
Tests upon this turbine were recently quoted by Mr. A. R. Dodge, in a paper read before the New England Cotton Manufacturers' Association. The tests were run at 140 pounds gage pressure, 250 degrees of superheat, and with the turbine connected to operate condensing. At a load of 500 K. W. the steam consumption was slightly less than 18 pounds per K. W. hour, and it remained nearly constant at this figure for increased loads, up to 800 K. W. At a load of 200 K. W. the consumption was about 20 pounds.

The motors required to operate the circulating and air pumps for the condenser are driven from the turbine generator and this power, about 20 K. W., is included in the output of the machine. Analysis of the velocities obtained indicate that this result from the first vertical unit will be materially reduced. Lighting, railway, and arc load are all carried on the same unit without difficulty.

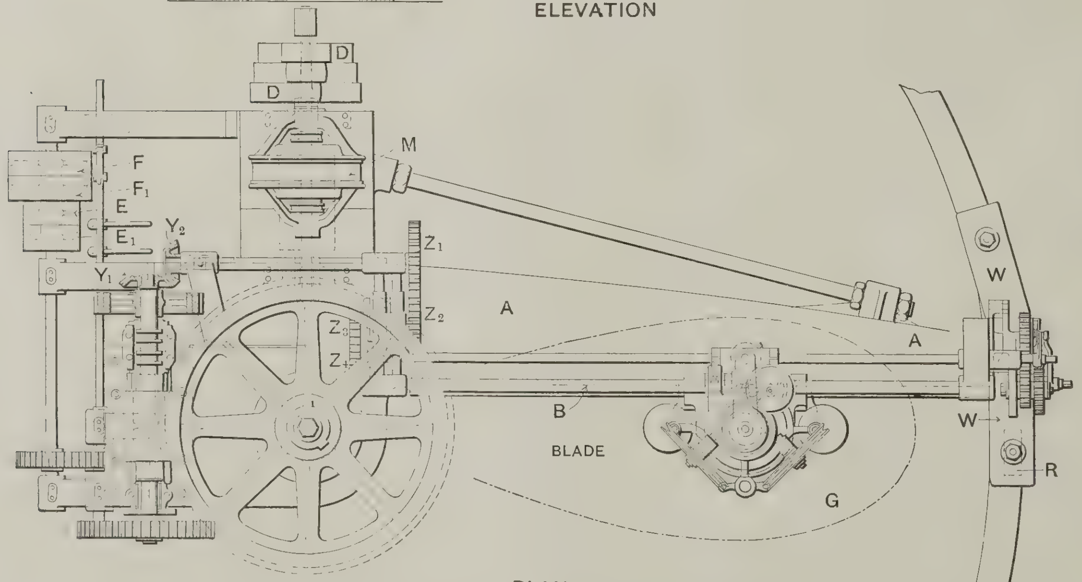
BAUER PROPELLER-BLADE SHAPING MACHINE.*

The propeller blades of the *Kronprinz Wilhelm* and the *Kaiser Wilhelm II.*, of the North German Lloyd Steamship Company, were shaped to the theoretically correct working face by a shaping machine invented by Dr. G. Bauer, and constructed by the Stettiner Maschinenbau Actien-Gesellschaft, Stettin, Germany, of which concern Dr. Bauer is the chief engineer. The importance of accurately shaped propeller blades has long been recognized, but up to the inception of this machine there has been no means for producing a more accurate surface on large propellers than can be obtained by casting. As an illustration of the need for an accurate shaping machine, a diagram of a propeller blade of the *Kaiser Wilhelm II.* was shown (not reproduced), the inequalities being marked plus or minus according as they are above or below the theoretical working face. As an example, two adjacent points about two feet apart, are noted, one of which was something over one-half inch above the theoretical plane, and the other as much below it, making the total inequality over one inch.

The object aimed at is attained in the machine, illustrated in Figs. 1, 2, and 3, by a planing tool which is reciprocated in helical lines over the blade and progressively fed along its radius after the completion of a cutting and return stroke, as in ordinary planer practice. In this manner a correct helical surface is shaped by concentric helical cuts. The method is applicable for shaping propeller blades to any generating lines. The generating line may be at right angles to the axis or inclined to it, as shown by lines *xy* in *A* and *B*, Fig. 4. It may also be a broken line, with different inclinations to its axis in its different portions.



ELEVATION



PLAN

Industrial Press, N.Y.

Figs. 1 and 2. Plan and Elevation of Propeller Shaping Machines.

The half-tone, Fig. 3, shows the machine at work on one of the blades for the *Kaiser Wilhelm II.* The hub is mounted on a cast-iron floor-plate, and the blades are bolted fast in the same manner as they are in actual service, with the working face upward. The stump or pivot, *Z*, Fig. 1 upon which the radial arm, *A*, swings, is fixed in the hub by being bolted to a cone which fits the bore of the hub. The outer end of the heavy arm, *A*, is supported by a carriage *W* provided with two wheels on a guide-path. The rotation of the arm is produced by a worm-wheel, keyed to *Z*, and a worm which is mounted on the arm together with the motor, *M*. The driving mechanism comprises the pulleys, EE_1, FF_1, the step cones, *D*, and the gear trains.

---

* This, from "Engineering" (London), is a description of a machine of great interest, and especially at this time, supplementing, as it does, the article upon the propeller planer in the last number.—EDITOR.

The tool, an ordinary planing steel, is, for reasons presently to be explained, not directly mounted on the tool-holder, *S*, but in a sliding piece, *H*. The tool-holder *S*, moves up and down, and is borne by a carriage, *C*, which travels along the radial arm, *A*. In shaping the propeller blades, *G*, the tool describes helical lines, as was already pointed out. Having made one cut, the tool travels back to the starting point of its operating stroke, following the same path. The forward feed is then imparted to the tool, which now makes a fresh cut, is taken back and again advanced, and so on. The operation is therefore the same as in a shaping machine, except that this new machine moves in helical and not in straight lines. This helical motion is produced by the combination of the up-and-down movement with the rotary movement of the arm, and the pitch of the helix depends upon the adjustable ratio of the two velocities. The vertical movement of the tool is obtained with the aid of a helical thread, cut upon the tool-holder, *S*; this thread engages with the worm-wheel, *X*, fixed in the carriage, *C*. The worm-wheel is driven through the intermediation of the shaft, *B*, the toothed wheels, Z_1, Z_2, Z_3, etc., and the bevel wheels, Y_1, Y_2, from the main worm which rotates the arm, *A*. It will thus be clear that the two movements of the tool—the vertical movement of *S* and the rotation of the whole arm, *A*—are independent of each other, and that the ratio of the two velocities can be varied with the help of the change-wheels, Z_1, Z_2, etc. It is in this way that the machine is set for cutting helical surfaces of different pitches. The reversing mechanism of the machine, which returns the tool to the starting point of its stroke, does not differ from the construction usually to be met with in large modern planing machines.

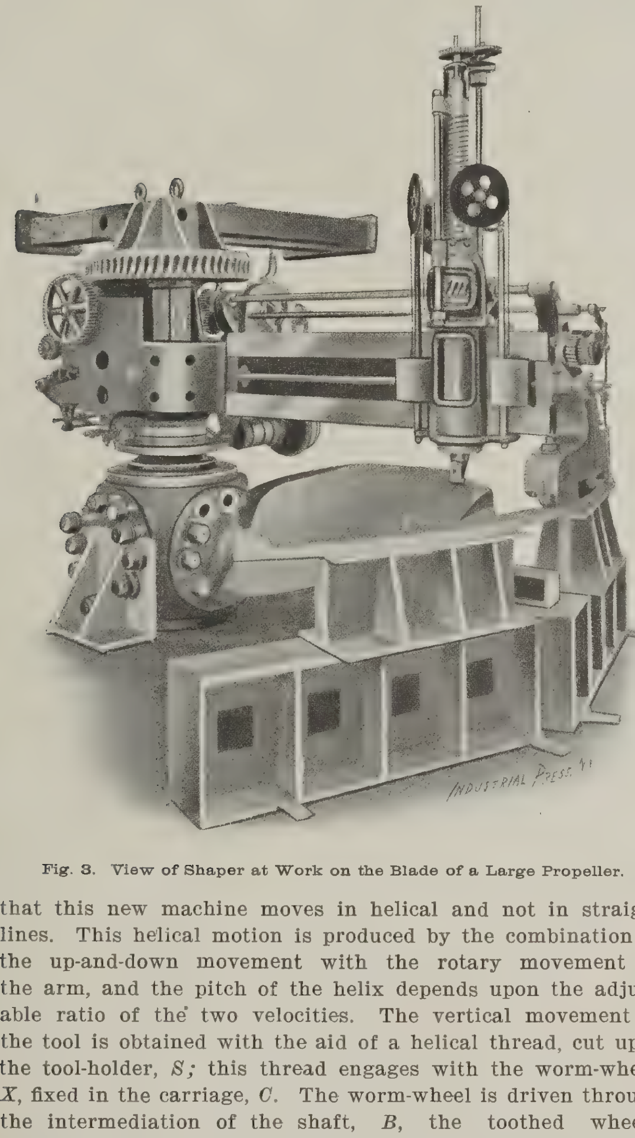


Fig. 3. View of Shaper at Work on the Blade of a Large Propeller.

The feed of the carriage, *C*, along the arm, *A*, is produced by a tappet attached to the guide-path; or what practically amounts to the same thing, the precise construction being a roller attached to the ratchet feed levers, which runs on a stop. For the simple form of propeller in which the generating line is at right angles to the axis, shown at *A*, Fig. 4, the requirements are satisfied by feeding the carriage radially along the arm, *A*, in whatever ratio as determined by the pitch of the propeller. But when the generating line is inclined to the axis as at *B*, Fig. 4, the conditions become slightly more complicated, because it is necessary to provide for axial movement of the tool to correspond to the inclination of the generating line. That is, the axial movement must equal the tangent of the angle made by the generating line with the line at right angles to the axis. In the case of the *Kaiser Wilhelm II.* the diameter of the propeller from tip to tip of the blades is 22 feet 8 inches and the radius is, of course, 11 feet 4 inches. The angle made by the generating line is such that the tips of the blades are separated from the right angle line nearly 26 inches, and it is to compensate for this departure of 26 inches in a radial distance of 11 feet 4 inches, or any other diameter, that the movement about to be described, is introduced.

As already mentioned, the tool is not directly mounted in its tool-holder, *S*, but in the sliding piece, *H*, which can be displaced within the tool-holder by the aid of a screw spindle. In order to ensure the desired inclination between axis and generating line, the proper ratio has to be maintained between the axial and the radial feed. In the case illustrated, the tool is, at the completion of each stroke, raised by the distance, s_1, and advanced outward by the distance, s_2, thus producing a blade surface in accordance with the generating line, *xy*. The spindles for imparting the radial and the axial feeds must be in positive connection, and special gearing is provided for this purpose. The tool itself is an ordinary cutter-bar, whose cutting edge is suitably inclined to the face upon which it works. Since, however, the surface slope diminishes as we approach the top of the blade, it might be thought that the tool would frequently have to be changed during the shaping of one blade. As a matter of fact, however, a blade may almost be completed with one tool, provided the cutting angle be suitably adapted to the average slope of the blade. The tool is, of course, pivoted as in a planing machine, so that it can be deflected during its return stroke, and glide over the blade without meeting any resistance.

The machine represented in the photographic view can deal with screw propellers up to 23 feet in diameter. The pivot, *Z*, about which the arm, *A*, turns, has a diameter of 15¾ inches, and the arm a length of about 13 feet, measured from center to center. When the machine has been mounted in the hub, the height from the upper edge of the bedplate to the upper edge of the worm-wheel is about 10 feet 9 inches; reckoned up to the highest point to which the change-wheels may reach, the height is about 16 feet 6 inches. Complete with bedplate and guides, the machine weighs 40 tons. With a feed of 1-25 inch the machine can, without difficulty, take a cut ¼ inch in thickness. A blade of the *Kaiser Wilhelm II.* was shaped in 150 hours, a roughing as well as a finishing cut being made in this time. The blade has a length of 8 feet 3 inches, and a surface of nearly 37 square feet. Only one man is required for attending to the machine. In setting up the work a blade is located by shifting it on the studs securing it to the hub, until the pitch is as nearly uniform as possible all over the face. Turning the blade to accommodate the conditions is permitted by the slotted holes for the studs, this being the usual practice to permit slight changes to be made in blade-pitch, if found desirable after the test runs have been made.

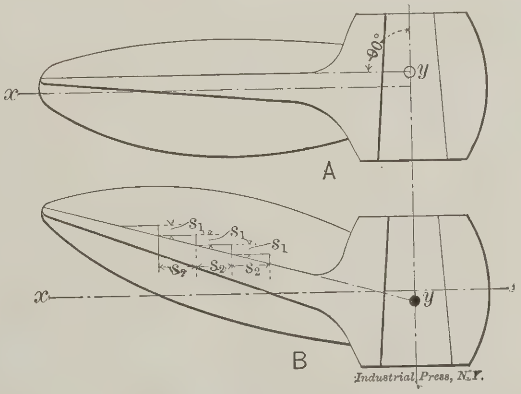

Fig. 4.

* * *

In one American shop that we know of, the metric system is used on special work without trouble by simply directing the workmen to measure "so many marks" on a metric scale without any attempt at converting distances into feet and inches.

SUDDEN DEATH OF ROBERT H. THURSTON.

As we go to press with the last form of this number, the announcement comes of the sudden death of Dr. Robert H. Thurston, Director of Sibley College of Engineering, Cornell University, on the evening of October 25th. Dr. Thurston was sixty-four years old on the day of his death, and had invited several members of the faculty of Cornell University to take dinner with him in honor of his birthday. He had just returned from a walk on the campus and was awaiting his guests in the drawing-room of his residence when suddenly he fell into a stupor, and died shortly after from heart disease.

Dr. Robert H. Thurston.

Robert Henry Thurston was born in Providence, R. I., in 1839, the son of Robert L. Thurston, one of the first builders of steam engines in this country. He was educated at Brown University, being graduated from there in 1859. He was employed in his father's shops until the beginning of the Civil War, when he joined the engineering corps of the United States navy. He served on several vessels during the war, and for gallantry and commendable service as an engineer was twice promoted, and toward the close of the war received his commission as first assistant engineer.

At the end of the war he was appointed a professor at Annapolis. He resigned his commission in the navy in 1872, having previously accepted an appointment to the chair of mechanical engineering in the Stevens Institute.

In 1871 Dr. Thurston became Professor of Engineering at Stevens Institute of Technology, Hoboken, N. J., and his fifteen years of service there showed him to have executive ability of a rare order, and profound technical knowledge. During his stay at Stevens he, in conjunction with President Morton, did much to advance the fame and standing of the Institute among mechanical engineers, both in this country and abroad. In 1885 he was called to Cornell University to take the directorship of the then newly organized Sibley College of Engineering, and his administration there has been phenomenally successful.

Dr. Thurston was the first president of the American Society of Mechanical Engineers, and has contributed a large number of papers to the proceedings of this society, probably more than any other author. He was highly talented both as a speaker and a writer, and was able to express himself with such ease and fluency that it was always a pleasure to listen to him or to read his writings. Nowhere was his remarkable grasp of affairs and his capabilities as a worker more evident than in these writings, which followed each other in rapid succession, and yet were in most cases of great merit. This was particularly so in some of his more recent papers in which he summarized the state of the art with respect to certain important engineering questions, like steam jackets, superheated steam, the steam turbine, etc.

The text books from the hand of Dr. Thurston were many, the best known being his volumes on the materials of construction, steam boilers and steam engines. Another book that has had a large sale was his "Friction and Lost Work in Machinery." As a text-book writer he often collected and summarized the conclusions of others rather than confining himself to his own personal investigations; and in this respect was frequently criticised. But his grasp of engineering subjects was so secure and his ability for drawing fair conclusions so good, that we consider it fortunate, rather than otherwise, that he saw fit to collect the great number of data that he did and place them where they may be conveniently referred to.

As a teacher Prof. Thurston was able to inspire his students with high ideals and always insisted that they should take up engineering on a broad gage plan. While he undoubtedly appreciated the necessity for careful attention to the details on the part of the engineer, he also knew that the engineer who has to achieve distinguished success must also be a man of affairs, and have a knowledge of men of affairs and of their ways. This spirit of broadmindedness, which he himself had, and attempted to inculcate into his students, was probably the distinguishing characteristic of Dr. Thurston.

* * *

THE GREAT CATHEDRAL COLUMNS OF NEW YORK.

The great columns for the Cathedral of St. John the Divine, New York City, are the largest monuments composed of one or a few pieces of stone ever built in this country. They are monuments because each one is a memorial, the expense of which was defrayed by some wealthy person. It was originally intended that these should be monoliths and over two years ago we published a description of the immense lathe that was designed for turning the great blocks of stone and converting them into cylindrical columns. The failure of the attempt to turn them in one piece has also been discussed in this journal. One or more of the columns broke before being finished, probably because no center rest was provided for supporting the stone midway between head and tailstocks, and it was decided finally to make the columns of two pieces each. The lower and larger piece in each case is 38 feet long and 6 feet diameter and weighs upward of 90 tons. Next in size in the way of a home product are the front columns of the New Hall of Records, New York; but these are only 36 feet long and 4 feet 2 inches diameter, weighing 40 tons, or less than half the weight of the largest stones in the columns of the Cathedral of St. John the Divine.

Comparisons with other large monuments of the world, show that Americans, with their advanced methods and improved machinery, are still far behind in stone working. Figures published by the *Philadelphia Record* show that the obelisk in Central Park, New York, is 69 feet high, 7 by 8 feet in cross section at the base, and weighs 220 tons. It was quarried more than 3,500 years ago, without the aid of any except the simplest mechanical devices. Largest of all the obelisks is the one at Rome, which is 108 feet tall, 8 feet square at the base and weighs 450 tons. At Karnak, Egypt, there is a great column which weighs 297 tons. It is 60 feet high and 11 feet in diameter. In Rome, again, is Trajan's Stone, a stupendous column 127 feet 6 inches high. It weighs 300 tons. Cleopatra's Needle, in London, a companion to our obelisk, is 71 feet high and has a base of 7 feet 7 inches. It weighs more than ours. In Alexandria is the famous Pompey's Pillar. It is 104 feet tall, and weighs 400 tons.

* * *

The theoretical water power of the world has been thus roughly computed by John Clarke Hawkshaw, of the British Institution of Civil Engineers: Assume a depth of 10 inches of rainfall to flow off each square inch of land surface, the mean height of which may be taken as 2,250 feet above sea level. Then the water from the whole surface falling through the mean height would give 10,340,000 000 horse power in perpetuity. Our present yearly output of 225,000.000 tons of coal would give that horse power for only a day under very economical conditions.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

For the past year or so, interesting experiments in high-speed electric traction have been conducted on the Berlin-Zossen military railway, which was specially constructed for high-speed work. Announcement was made by cable October 6 that the experimental car had attained a speed of 125.8 miles per hour without damaging the roadbed or machinery. The experiments made last year were unsatisfactory, as the roadbed was not equal to the stress imposed on it by high speed. The attempt will now be made to increase the speed to 140 miles per hour. The current is three-phase at a pressure of 13,000 to 14,000 volts and is reduced by transformers on the car to 450 volts. The car has four motors, giving an aggregate motive force of nearly 1,100 horse power. The results so far reached have led the engineers, it is said, to recommend a speed of 93 miles per hour for commercial purposes on the State Railway between Berlin and Hamburg.

The most persistent experimenter, as well as the most scientific investigator, in regard to aerial navigation in this country has been Prof. Langley, the secretary of the Smithsonian Institute, Washington. His many years of effort, however, have again resulted in failure the past month. His aerodrome, perfected as far as his knowledge would permit, was launched into midair from a high staging, hovered uncertainly for a moment, and then plunged downward into the Potomac. It is said that the total failure of this trial was due to a certain part of the mechanism catching when gliding along the launching ways. Prof. Langley has conducted his experiments in part under government aid, though we do not know on what grounds the appropriation for this purpose was made. While he may not live to see human flight a reality, or even a reasonable possibility, it is certain that his efforts will have contributed materially to our store of knowledge on the subject of flight, and his many attempts, even if failures, are but steps to be expected in dealing with a problem of almost infinite difficulty.

The power plant equipment for the New York terminal of the Pennsylvania Railroad for operating the trains in the projected tunnel under the North River is to consist of Westinghouse-Parsons steam turbines of the horizontal, short-barreled type. There are to be three turbines, each of approximately 7,400 electrical horse power, which will drive 5,500-kilowatt three-phase, alternating-current generators, operating in parallel. Their overload capacity will be over 11,000 horse power and each turbine will be provided with a by-pass automatically controlled by the governor to accommodate abnormal fluctuations in load. This will also permit operation at full load, non-condensing. The turbine equipment will operate under conditions favorable to the attainment of high economy, viz.: 200 pounds steam pressure at the throttle, 28 inches vacuum and 175 degrees F. superheat. The generator will be direct-connected to the turbine shaft through a flexible coupling, each section of the unit having two bearings of ample proportion, thus avoiding shaft stresses. The three-phase winding will deliver current directly to the distribution system at 11,000 volts, no step-up transformers being employed.

The introduction of blueprints into the United States was not such a rapid process as the present universal adoption of this method of copying tracings might indicate, says the *Engineering Record.* The first prints of this nature shown in the country were part of an exhibit in the Swiss section of the Centennial Exposition, and it was stated by one of the gentlemen in charge of that exhibit that the process had but recently been introduced into Switzerland from Germany. Mr. Rudolph Hering was requested to prepare an article for the proceedings of the American Society of Civil Engineers on the Swiss display, and came across these prints while engaged on this work. He obtained a copy of the formula for the solution, and after some trouble secured the ingredients and tried the process at his home. This was in 1876, and was probably the first case of blueprinting in the United States. He sought to interest the city engineer of Philadelphia in the process, but Mr. Smedley, who then held the office, refused because the operations would be too sloppy. Then he showed some of his prints to Dr. Coleman Sellers, but that eminent engineer refused to see anything good in them. Workmen, he said, were so accustomed to working from drawings in black ink on white or brown paper that the attempt to introduce drawings with white lines on a blue background would be the cause of serious trouble.

In a consular report reference is made to a type of oil engine developed abroad in which the oil is vaporized and ignited without the use of any external source of heat. The main drawback has been that the engine would not run indefinitely with light loads, owing to the explosions not occurring with sufficient frequency to keep the igniting portion at a sufficiently high temperature. A modification of this type of motor brought out by the Britannia Company, of Colchester, England, is claimed to be free from this drawback. The vaporizer is arranged, as usual, at the back of the cylinder. On the suction stroke a vapor valve is opened by the cam shaft, and through this valve air is drawn into the cylinder through the vaporizer, into which at the same time a little oil is sucked through an automatic valve. This mixture of air and oil is in itself too rich to be explosive and the main supply of air is drawn through a separate air valve into the cylinder. Two passages connect the vapor valve with the cylinder. One of these is large and straight, while the other is narrow and U-shaped. The lower portion of the U contains the igniter—a piece of metal having ribs, which enable it to absorb heat readily when the explosion takes place. This piece therefore becomes and remains red hot, while the rest of the vaporizer is only at a black heat. The vapor which is drawn through this igniter on the suction stroke is far too rich to burn, but on the compression stroke air is forced back into the igniting piece and provides the necessary oxygen for the vapor already there to ignite. None of the exhaust passes through the igniter, which is consequently not cooled down in the case of a missed explosion. The proportion of oil and gas used is regulated by throttling the air supply. As already stated, part of this air is drawn through the vaporizer and the rest through the air valve. If the admission to the latter is throttled a greater proportion of the air used will be taken through the vaporizer and will carry with it a proportionately greater amount of oil. The makers claim that, once started, the engine will run absolutely without attention for several hours.

SHOCKS FROM ELECTRIC LOCOMOTIVES.

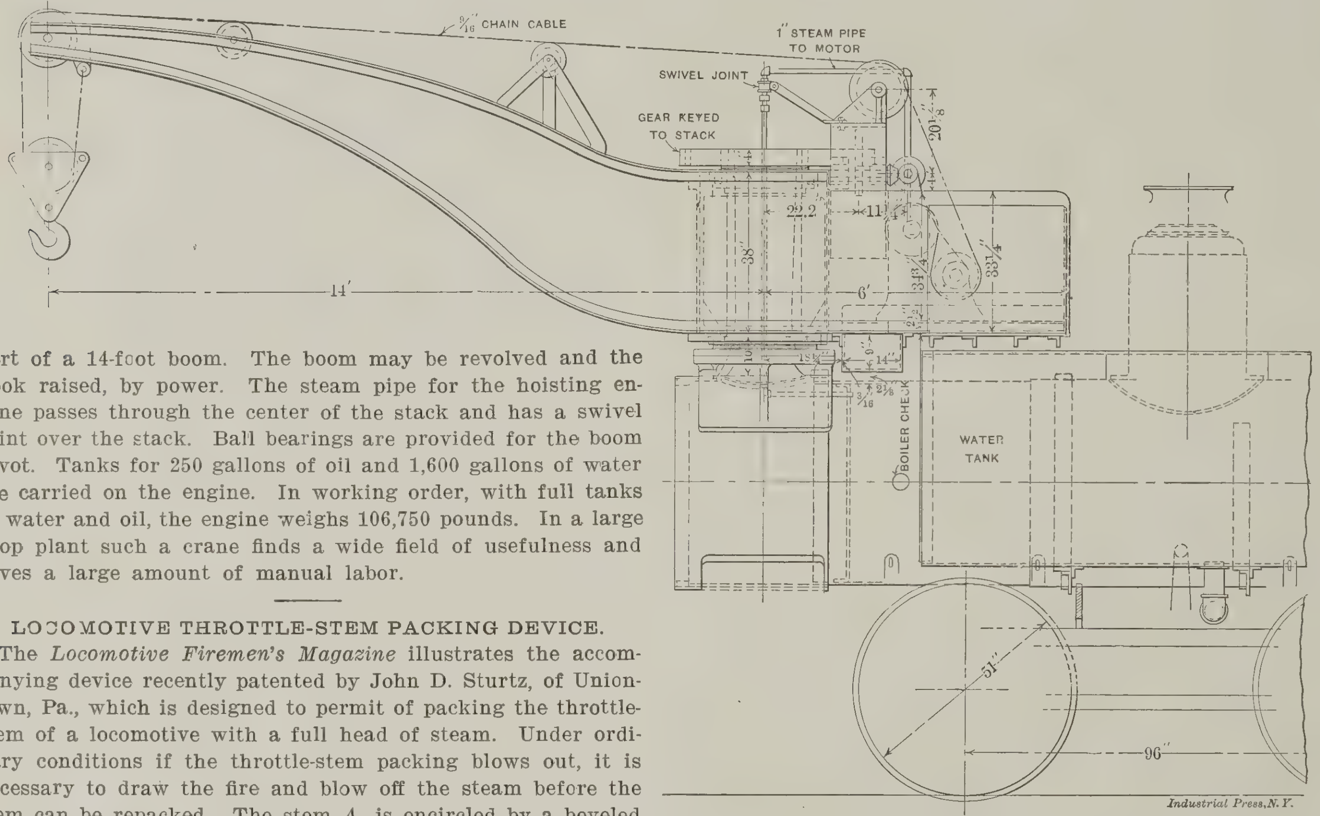
Street Railway Journal, August 22, 1903, p. 247.

Electric locomotives or cars having voltages more dangerous to life than the common 600-volt direct-current are few as yet, but with the introduction of alternating current their number will increase; and it is in order to call attention to one element of danger in their operation which cannot be too carefully guarded against. It is a danger for which prevention is easy, but is nevertheless a real one, and has already resulted in at least one serious accident in this country. We refer to the possibility that a locomotive may run onto a portion of track covered with sand or dirt, so that there is a partial insulation between the wheels and rails. In such a case, if the locomotive is running on a grounded circuit, using the rails as a return, there is an excellent chance for employees to receive serious shocks in attempting to board the locomotive, because there is likely to be a dangerous voltage between the locomotive frame and ground. Shocks from this cause have not been unknown in street railway practice, but the voltage is usually not dangerous to life on a street railway system, and there is considerable insulating wood in the make-up of a car. On an electric locomotive, using high-tension electric current, and having a steel frame, however, a shock of this kind is almost certain to be attended with disagreeable consequences. Although the possibilities of a shock from this cause are apparent, consideration is not usually given to the danger, so we feel justified in uttering this warning. One obvious remedy is to omit the sand boxes from such a locomotive's equipment, and furthermore, if the locomotive is ever to operate on dirty rails, it should be equipped with a set of brushes for brushing the rail in advance of the wheel.

SWITCH ENGINE EQUIPPED WITH CRANE.

American Engineer & R. R. Journal, October, 1903, p. 391.

A convenient locomotive crane of four tons lifting capacity has been fitted up at comparatively little expense at the Topeka shops of the Atchison, Topeka & Santa Fe and will be used about the locomotive shops and yards. An old four-wheel switch engine was equipped to burn oil (so that it may safely enter the buildings) and fitted with a substantial cast-iron stack, with a large base, forming the pivot and support of a 14-foot boom. The boom may be revolved and the hook raised, by power. The steam pipe for the hoisting engine passes through the center of the stack and has a swivel joint over the stack. Ball bearings are provided for the boom pivot. Tanks for 250 gallons of oil and 1,600 gallons of water are carried on the engine. In working order, with full tanks of water and oil, the engine weighs 106,750 pounds. In a large shop plant such a crane finds a wide field of usefulness and saves a large amount of manual labor.

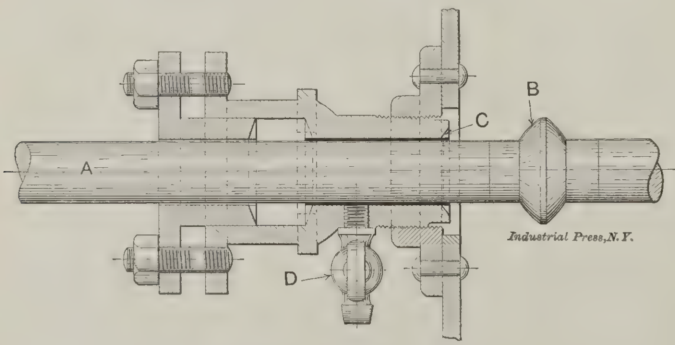


Industrial Press, N.Y.

Crane Attached to Switch Engine.

LOCOMOTIVE THROTTLE-STEM PACKING DEVICE.

The *Locomotive Firemen's Magazine* illustrates the accompanying device recently patented by John D. Sturtz, of Uniontown, Pa., which is designed to permit of packing the throttle-stem of a locomotive with a full head of steam. Under ordinary conditions if the throttle-stem packing blows out, it is necessary to draw the fire and blow off the steam before the stem can be repacked. The stem *A*, is encircled by a beveled ring *B*, preferably integral with the stem, which, when the throttle is opened to the full extent, bears upon the beveled seat *C*. and shuts off the flow of steam or water into the stuffing-box cavity. The stem is swiveled so that it can be rotated without disconnecting the lever, the object of this being to grind off any scale that may have settled on the seat *C*. To pack the throttle all that is necessary to do is to place the engine so that the cranks on one side are on a center, disconnect the slide valve-rod from the rocker, and cover the steam ports with the valve. The ports on the other side can be covered by placing the reverse lever in the middle notch of the quadrant. The throttle lever can then be pulled wide open without admitting steam to the cylinders. The pet-cock, *D*, is a telltale by which the engineer can determine whether the ring, *B*, is seated tightly enough to make it safe to loosen the nuts and remove the gland.



Industrial Press, N.Y.

Packing for Throttle Stem.

The principle of the device is identical with that of the Jenkins valves; these can be packed under full pressure when open by screwing the valve upward until it abuts against the under side of the stuffing-box, thus shutting any flow through the gland.

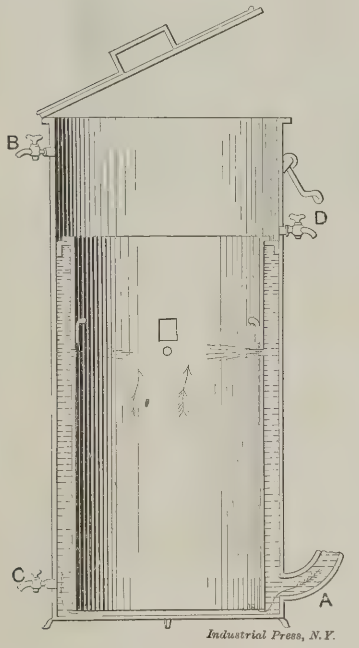
THE REASON FOR THE VERTICAL DESIGN OF THE CURTIS STEAM TURBINE.

Extract from Paper read by W. L. R. Emmet before the American Street Railway Association, Saratoga, N. Y.
September 2-4, 1903.

The question as to why the vertical shaft design was adopted for this unit (5,000 K. W. unit for Chicago station, 25 feet high, 14 feet in diameter and weighing 400,000 pounds) has often been raised and many doubts and criticisms concerning it have been expressed. It is not easy to explain all the reasons which led up to its adoption but it may be said that the compactness and simplicity of this unit, which are its most marked characteristics, are largely due to the merits of this design. With the vertical shaft arrangement all lateral strain is removed from the bearings which align the shaft and all deflection of the shaft is avoided with a minimum number and length of bearings. This matter of properly supporting a shaft and keeping it exactly central and in perfect alignment is an important one where small clearances are desirable with a large diameter in the revolving part. To carry such weights as are necessary in the revolving part of this large unit many very large bearings would be required if the shaft was in a horizontal position. An elaborate system of forced lubrication with artificial cooling would be necessary in connection with these bearings, and a failure of any of these bearings would occasion serious danger to the operation of the machine. If the machine were built in a horizontal position it would be very difficult to so support the wheels that their clearances would not be affected by sagging of shaft or looseness in bearings, and also, it might be difficult to place them with such a relation to each other that the clearance would not be affected by expansion of the shaft. In the vertical design the space between wheels is reduced to a minimum, the supporting structure is perfectly symmetrical and cannot be in any way distorted or put out of line either by mechanical or steam pressure strains or by the effects of expansion.

STEEL HARDENING APPARATUS.

Zeitschrift fur Werkzengmaschinen und Werkzenge, June 5, 1903, p. 371.



Hardening Tank.

After a number of trials and experiments, Louis Bahner, of Berlin, has brought out an apparatus for hardening steel that is said to overcome the well-known troubles and difficulties surrounding that class of work. The treatment depends upon the fact that the object is to subject the whole piece to a continuous stream of water forced into a tank, in such a way that an equal and uniform hardening is obtained. As the result of the contact of the red hot piece of metal with the surrounding liquid, it is well known that a steam envelope is formed about the former, which prevents the access of the water to the hot surface and thus checks the hardening process. Even by moving the piece about in the water this difficulty is not altogether obviated; for, if a closer contact of the hardening liquid is obtained on the side toward which the piece is moving, there is still the existing steam pressure on the other side.

The illustration shows one form of the apparatus referred to, as designed for large pieces. The water is delivered through the pipe *A* and enters the inner cylinder at four points, opposite where the piece to be hardened should be placed, and flows out at *B*. In smaller designs the water is admitted at the bottom only. The object is to cause a current of water of uniform temperature to flow evenly over all of the surfaces of the submerged piece and thus produce a constant rate of cooling at all points.—G. L. F.

ELECTRIC CONTROL OF COMPRESSED AIR BRAKES.

Annalen fur Gewerbe und Bauwesen, May 1, 1903.

The electro-pneumatic system of controlling air brakes, as exploited by the Siemens Company, permits a simultaneous action to be obtained at all points on a train. The brakes upon each car act automatically whenever the pressure in the train pipe is lowered below a fixed point. No change is made in pre-existing arrangements and the apparatus can be worked as before when the electric apparatus is cut out.

Valves are put into a pipe leading from the main train pipe to the brake cylinders. These valves are kept closed by the air pressure, but can be opened by the action of electro-magnets and thus cause an application of the brakes. The current is sent through the magnets by a switch attached to the handle of the engineer's valve, and similar switches and cocks are placed in each of the cars to be used in case of emergencies.

A switch operated by a piston which is subjected to main train pipe pressure upon one side and is balanced by a spring on the other, serves to close the circuit, if, for any reason the train-pipe pressure is lowered; so that the brakes are at once applied. A complementary arrangement serves to apply the brakes in case of any breakage of the wires or short-circuiting.

The following advantages are claimed for the system: The brakes are applied without shock to the train, regardless of their length or speed, or whether the application is made from the locomotive or a car; the efficiency of the braking is independent of the distribution of braked cars throughout the train, while the purely pneumatic system is dependent solely upon the unbroken succession of braked vehicles; the electric control at once utilizes the train-pipe pressure without permitting it to escape, thus reducing the consumption of compressed air; the conditions of brake application since it takes place in case of a break-in-two as the result of the action of either the pneumatic or electrical portion of the apparatus and the engineer can test the brakes without leaving his place or requiring assistance.

A battery of twenty cells supplies the current for the operation of the device.—G. L. F.

ELECTRIC SOLDERING.

Moniteur Industriel, September 12, 1903, p. 574.

This process of electric soldering is especially adapted for use in foundries and steel works and is giving excellent results in practice. It was developed and is in use by the Societe d'Electricité et d'Hydrauliques, at Charleroi, France. It consists of causing an arc to play between the piece to be soldered and a bar of soft iron. It effects a great saving over those methods of soldering where an oxyhydrogen flame is used or of those where molten metal is caused to flow over the part to be filled.

A complete installation for the work consists of a direct current generator; a switchboard, a secondary switchboard upon which the soldering apparatus is placed; a rheostat and the soldering apparatus. The dynamo is a direct-current machine with a capacity of 26 effective kilowatts and developing 400 amperes under a normal tension of 65 volts. The induction coils are so wound that they can sustain a considerable overload, the amperage rising suddenly from 0 to about 1,200 at the instant of production of the arc. The dynamo can also work without sparking from 0 to 1,200 amperes.

In the operation the workman holds a sheet of violet glass in one hand, both to protect himself from the effects of the arc and to enable him to adjust the soldering apparatus to exactly the right place. With the other hand he manipulates the apparatus proper, which consists, according to the weld that is to be made, of a bar of iron or carbon fastened to the end of a wooden handle that is fitted with a guard to protect the hand. The work consists of causing an arc to play between the piece to be soldered and the soldering bar, and can be done in one of two ways. Iron filings can be put into the hole to be filled and then melted by means of an arc made to play between it and the solid metal, more filings being added until the hole is filled. A carbon welding bar cannot be used when the parts are to be machined, as the results leave the metal harder than the original piece.

The second method is to cause the arc to play between the piece to be soldered and the soft iron bar. The latter is melted by this operation, lowers the temperature of the arc and furnishes the material needed for the soldering. This lowering of the temperature of the arc avoids overheating the metal.

These operations require the services of two men; one handles the soldering apparatus while the other changes the bars, adds the filings and hammers the metal when the arc is cut off. When the soldering is well done a perfect union of the metal that has flowed in with that of the main piece is obtained, for the two are united while in the liquid state—a condition that does not obtain with the ordinary methods of doing the work. The saving effected by this method is very great as compared with the use of the oxyhydrogen blow pipes or fused metal, while in many cases it makes it possible to effect repairs upon defective pieces that would otherwise have to be consigned to the scrap heap on account of the trouble and expense involved in doing the work.—G. L. F.

THE RATEAU STEAM TURBINE.

A. Rateau, in Engineering Magazine, Oct., 1903, p. 49.

The Rateau multi-cellular turbine, the result of an especial study of the subject by the writer, was briefly described in 1900, in a report presented by him upon the subject of steam turbines at the International Congress of Applied Mechanics at Paris in July, 1900. In designing this machine it was sought to satisfy the following conditions:

1. The attainment of a high mechanical efficiency, together with as low an angular velocity as possible.
2. The provision of a large, and at the same time non-injurious clearance between the fixed and the moving parts.
3. The attainment of the least possible weight of the whole machine, and especially of the rotating parts.

The revolving wheels are formed of disks of thin sheet steel, as shown in Fig. 3, carrying cylindrical buckets on the periphery, these buckets being riveted to a band of steel welded to the disk. This gives a very light and strong construction, maintaining its balance at all speeds. The guide buckets are fixed in circular diaphragms, secured at the periphery in grooves cut in the interior of the turbine case. There is thus left between the successive diaphragms a series of annular chambers in which the revolving wheels are placed, Fig. 2. The shaft passes through bushings fitted in the diaphragms, there being but little play or clearance. Between the fixed and revolving portions of the turbine, however, the clearance may readily be made as much as 5 or 6 millimetres, without injury. The main bearings of the shaft are generally outside of the casing, a special form of stuffing box being employed, assuring tightness against leakage. The external appearance of the machine is shown in Fig. 1.

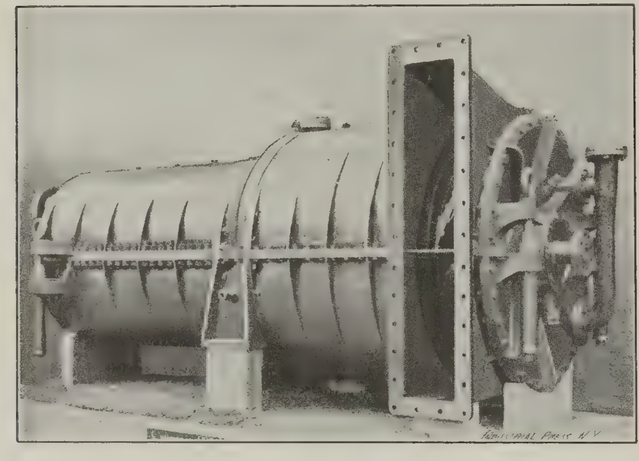


Fig. 1. Rateau Turbine.

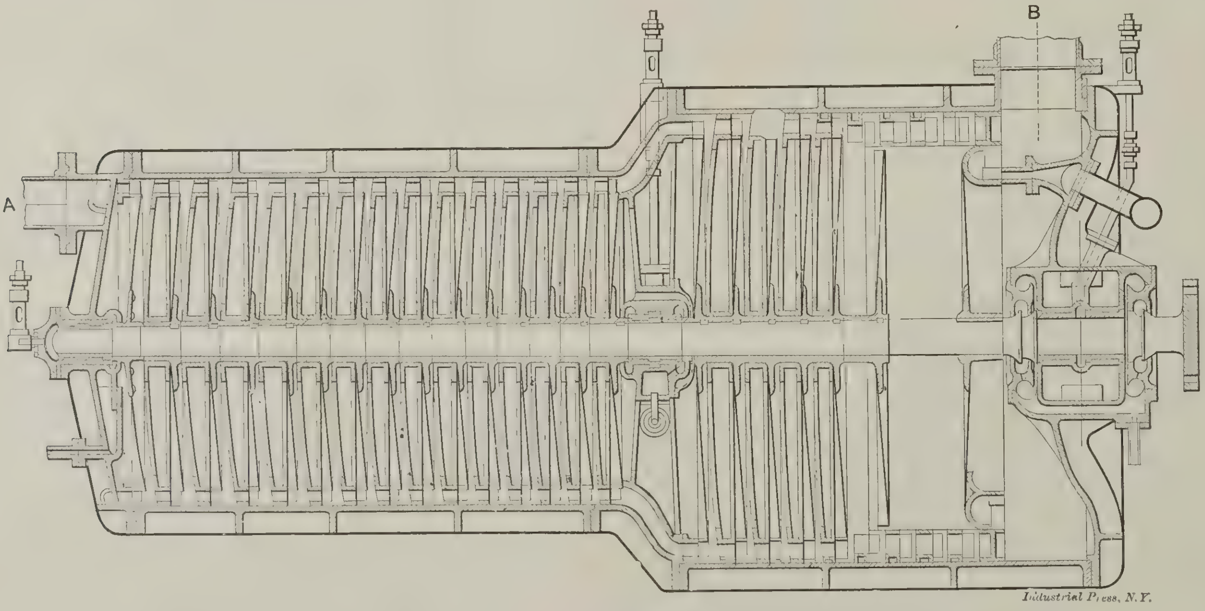

Fig. 2. Sectional Elevation of Rateau Turbine. Steam Enters at A and Exhausts at B.

An ordinary compensated centrifugal governor is used to regulate the speed, acting by varying the pressure of the steam delivered to the turbine. By means of a by-pass in the main steam pipe it is possible to deliver steam of full pressure both to the entrance of the turbine and to a point in the machine nearer to the condenser, this enabling a higher power than the normal amount to be produced by the machine, much in the same manner as a compound engine may be used with full pressure steam in both high and low pressure cylinders.

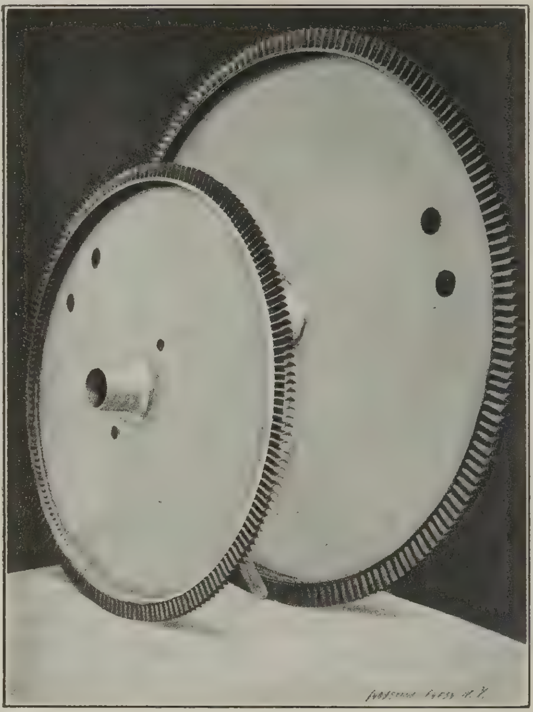

Fig. 3. Two of the Rotating Turbine Disks.

PLATING PROCESS.

Engineering News, August 27, 1903, p. 192.

A peculiar plating process is being employed in Germany to produce sheet-metal consisting of several layers of different metals. The process utilizes the adhesive qualities of aluminum at moderate heat. A typical product is a sheet of iron (soft steel) coated on both sides with copper, the completed sheet having about 15 per cent of copper. Such sheets can be used as a roof-covering, either plain or corrugated, in place of copper on wood, or in place of galvanized iron. The process of making such plates is as follows: A copper plate is cleaned and roughened by sand blast, and is then rubbed over with a piece of aluminum, which forms a thin partial coating of aluminum on the copper. A thin sheet of aluminum is then laid on the prepared copper plate, the two are heated to about 800° C., and then passed through the rolls and rolled out into a thin sheet of copper having an aluminum plating on one side. By laying two such sheets, aluminum side down, on the two sides of a clean iron plate, and heating to about 400° C. in a muffle furnace, the sheets may be rolled together and a partial adhesion secured. The combined sheet is then heated to a higher heat, about

800° C., and rolled out to the desired thickness, a perfect adhesion being thereby secured between the iron and the copper by virtue of the layer of aluminum between them. Other combinations than this one are produced in the same general way; examples are copper-aluminum sheets, copper-aluminum-copper, steel (soft steel) coated with aluminum on one or both sides, or an aluminum core coated with steel, combinations of copper and zinc, of aluminum and zinc, or of all three metals, etc. The process is the invention of Mr. H. Wachwitz, of Nürnberg, and is being exploited by the German Wachwitz-metal Co., of Hersbruck, Germany.

THE PHENOMENON OF LIGHTNING.

From Paper, "Safeguards Against Lightning," read by Alfred Hands before the Fire Prevention Congress in London, July 6, 1903.

At the best, lightning is too often regarded as an electric current overcoming the resistance of the air; but this resistance has nothing in common with that which is the subject of Ohm's law, and to consider it merely as a momentary current is apt, I think, to give a somewhat misleading view of the matter. I want you to regard it as a breakdown of the dielectric—not as something leaving the sky to come to earth, or as being hurled from the clouds to strike a building, but to consider it—as indeed it is—as a fracture or cracking both of the air and of any other resisting medium between the oppositely charged bodies, the clouds and the earth. As a mechanical analogue, one may liken the air under these conditions to a thick slab of glass subjected to an enormous pressure from above and below, and which will crack when the pressure is greater than the material will bear. A building may be considered as a weaker object firmly embedded in the glass. We may, in fact, regard ourselves as living between the inner and outer coatings of an enormous Leyden jar or other condenser. Now, when the stress to which the air is subjected has reached the breaking point, which is about half a gramme weight per square centimeter (about 1-9 ounce per square inch), the line of the fracture becomes visible by the intense heat making the air particles momentarily incandescent, and this we call "lightning." The building which, being in the line of the strain, gets damaged, forms only a part of the fracture; the air is equally damaged, but is a self-repairing medium. Unfortunately, our buildings, trees and bodies, which are less resisting than the air, are not self-repairing, and so we get the deplorable losses of life and property that occur every year. A building offers less resistance than the surrounding air, therefore the breakdown would tend to go through a building rather than pass it by and go through the air beside it, even if there were no metals in it to render it still more weak. Even allowing for the effects of induction, lightning can no more be attracted by a conductor than a crack across a sheet of glass can be attracted by any weak part which would cause it to take other than a straight course.

DROP FORGING.

Proceedings of Engineers' Society of Western Pennsylvania, June, 1903, *p.* 292.

In a paper on drop forging read before the May 19 meeting of the Engineers' Society of Western Pennsylvania Mr. Dwight Goddard outlined the process of making drop forgings. That portion of the paper describing the dies is given in the following:

A set of dies consists of forging dies, outside trimming dies and, if there are any holes in the forging, inside trimming dies. The forging dies are the most important item. A pair of dies usually consists of two blocks of tool steel in which have been cut the shape to be forged. There are often two or more impressions in the same die block. On one side is an impression for breaking down or blocking out the metal, then a roughing impression that distributes the metal and approximates the shape and a finishing impression that brings the forging to exact shape and dimensions.

The shape and sequence of these impressions must be carefully considered to provide for a natural flowage of metal under hammering and to be such that the desired shape will be surely, quickly and economically formed. There must be no place short of metal, no overlapping and consequent "cold shuts" and no unnecessary blows or waste of stock. A draft of 5 to 7 degrees from the perpendicular must be allowed to permit a free release of the forging from the die. This is especially necessary if the section is such that an unusually quick chilling of the stock would cause the forging in shrinking to grip the die.

It requires a specially trained machinist known as a "die sinker" to make these dies. He must have experience and knowledge as to the action of metal under hammering, must have good judgment and high skill to enable him to plan, lay out and make the impressions. He must have a ready use of tools, both hand and machine, to reduce to a minimum, the cost of the labor in making, which will be high at best. The hand tools which he uses consist of a wide range of dividers, gages, shrink-rules, protractors, micrometers, rifflers, chisels, files, and scrapers; the machine tools, die sinking machines, sensitive drills, milling machines, profilers, shapers, etc. In designing the dies, it is always best to procure, if possible, a model of the piece to be forged. Then a full sized drawing should be made showing the draft, the allowance for finish and any changes that seem necessary, to be submitted to the customer for his approval.

When the dies are about done, as far as shaping the impressions is concerned, they are clamped together and a lead cast made, as a proof of the shape. This is also sent to the customer for his approval. If satisfactory, the impressions are nicely finished to insure free release of the forging. The face of the die is cut away slightly for from ½ to 1 inch from the edges of the impression, to permit the free escape of the flash, or surplus metal. A groove is also made from one end of the impression to the outside to provide room for the sprue, which enables the forger to manipulate the forging by means of the bar from which the forgings are being made. Lastly the dies are carefully hardened and tempered that they may give the maximum service.

This is a very important operation and requires great skill in accomplishing. Even hardness of the face is essential, with no cracks or warping. By this time the dies represent great value, often hundreds of dollars. They should be capable of making from five to ten thousand forgings and the breaking of dies or the early wearing away of the edges may be a costly experience. The making of the dies is the expensive part of drop forging and forbids the making in small quantities.

The customer is usually charged only a part of the cost of making the dies, and while they are kept strictly for his use he is not permitted to remove them. In such a case the drop forger is expected to keep the dies and tools in good order and to make such repairs as are necessary and to replace them when worn out, at his own expense. The reasons for this custom are obvious. Each drop forging company has developed from this experience special methods for the designing and construction of dies, which they do not care to place at the disposal of competing companies. They are also seeking to accumulate an amount of dies that will provide them their principal business which is forging, not die making. If a customer insists on owning the dies outright he is charged the full cost of making with a reasonable charge for this engineering experience, and is expected to keep his own dies in repair.

THE DEPTHOMETER; A DEVICE FOR MEASURING THE DEPTH OF LIQUIDS IN TANKS, ETC.

Daily Consular Report, No. 1772.

United States Consul Waterman at Dublin, Ireland, describes a depthometer invented by Mr. Leonard Murphy and manufactured by Daniel Miller & Co., Dublin. It is an instrument designed to show the depth of liquids either in open vessels—such as water tanks, vats, ship's holds, wells, etc.—or of liquids inclosed in vessels under any degree of pressure, as in the case of petrol tanks in some motor cars and other vessels of this kind. It may be placed at a distance from, and at any level relative to the tanks—above, below, or on a level with them. Any number of tanks may be connected to one depthometer and the depth of each ascertained by indicating one at a time. The reading of the indicating column of the depthometer is absolute, marking to a fraction of an inch the depth of the liquid being indicated. The reading can, of course, be reduced proportionately by using mercury or other heavy liquid for the indicating column. No floats or moving parts are used in the vessels being indicated, a fixed pipe of small bore being all that is required. The diagram shows the depthometer attached to a tank containing liquid. The instrument, shown in section, is placed somewhat above the tank and registers the exact depth of liquid in the tank by means of the column of liquid seen in the gage glass. When wishing to ascertain the depth of liquid in the vessel connected, it is merely necessary to raise the lever marked "compressor lever" and bring it back again to its starting point. On doing this the exact depth being measured will be shown by the column in the gage glass of the depthometer.

TANK FOR PETROL, WATER, ETC., OPEN TO THE ATMOSPHERE, OR UNDER ANY DEGREE OF PRESSURE

Industrial Press, N.Y.

Device for measuring Depth of Liquid in a Tank.

The parts of the depthometer shown in the diagram are as follows: Two chambers, fixed one above the other, are connected by a gage glass tube, open at both ends, which reaches almost to the bottom of the lower chamber and only just enters the upper chamber from beneath. The top one is called the "upper chamber" and the lower chamber is called the "gage reservoir." The latter has attached to its top a flexible "air chamber" capable of being enlarged or reduced in volume by the compressor lever shown in the diagram. To the upper part of the air chamber a short tube and coupling, *A*, is attached, from which the line tube, No. 1, can be carried to the distant vessel, terminating in a dip pipe, *C*. If the vessel be under pressure a second line tube, No. 2, is necessary and is laid beside the first tube, reaching from the top of the tank to upper chamber, coupling at *B*, as shown in dotted lines on the diagram. This pipe is, however, not used if the vessel be open to the atmosphere, and in that case coupling *B* is left open to the air. The gage reservoir is next almost filled with the indicating fluid (petrol, water, etc.), and when at rest the liquid should just appear at the base of the visible portion of the gage glass. The instrument is then ready for use.

The method of working is as follows: Raise the compressor lever to its highest point, thus causing the air chamber to expand and take in a supply of air; the latter enters at coupling *B*, passes through the upper chamber, down the gage glass, through the liquid in the gage reservoir, and finally reaches the air chamber. On depressing the lever the air in this chamber becomes compressed and presses on the liquid in the gage reservoir. The air cannot, however, return through the gage glass, as the end of the latter is sealed by the indicating liquid. Some of the air, therefore, passes into the line tube No. 1, and on reaching the tank forces out any liquid which may have risen in the dip pipe, *C*, and ultimately the excess of air escapes from the open end of the dip pipe into the liquid in the tank. During this operation the liquid column in the gage glass of the depthometer will be seen to rise gradually to a certain point and then stand. The column ceases to rise further the moment the air commences to escape at the open end of the dip pipe in the tank, and the column thus shown will be equal in height to the depth of the liquid in the tank, as it will be seen that the air, having completely filled the line tube, has created an exact balance between the column of liquid in the tank and the indicating column of the depthometer.

CYLINDRICAL GRINDING.

Extract from paper read by Mr. C. H. Norton before the Cincinnati Metal Trades Association, October 8, 1903.

There is very little doubt that the first glimpses of cylindrical grinding came to all mechanics when using the lathe, and that these early dreams were tried here and there by mounting a small emery wheel on the tool-post of the lathe. Just where and when this was first done would be difficult to ascertain, but so far as we know the first really accurate grinding was done at Waltham, Mass., by the watch tool concerns about 1860. Mr. Webster, the father of the watch tool business, told me a few years before his death, the story of their earlier grinding. After using the lathe for some time with a small wheel in the toolpost they discovered that in order to grind tapers they should keep the centers in line; this they could not do with the lathe of that period, so they made what they called grinding lathes, that is, lathes with wheel carriage traveling on a slide that could be adjusted to an angle with the line of centers. This was some time about 1865. These were perhaps the first grinding machines with fixed centers and traversing wheel. They were rightly called "grinding lathes." They were small, the wheel being 4 inches diameter by ⅛ face on a spindle about ½ inch diameter. The swing of these lathes was about 6 inches and the largest work done did not exceed 1 inch diameter, while the greater amount was less than ½ inch diameter.

Some time about 1865, Mr. Brown, of J. R. Brown & Sharpe, at Providence, R. I., was grinding needle bars for sewing machines with what was called a "grinding lathe," arranged for the carriage to traverse and reverse automatically. This carried a wheel 6 inches diameter by ¼ inch face. The idea of constructing a machine designed especially for cylindrical grinding and to cut entirely loose from all traditions and features of the lathe, except, of course, the supporting center points, seems to have originated with Mr. Brown; for in the years following 1865 he gave the matter considerable study, and at his death in 1876 he had invented the "universal grinding machine," which was not a lathe but had a fixed wheel and traversing work.

When we realize that some 26 years ago cylindrical grinding machines were manufactured and sold by one of the best known concerns in the world, and that 40 years ago cylindrical grinding was done successfully in some of the best known shops of the day, we cannot but feel a little surprise that after all these years so important a factor in the economical production of good machinery should be strange to so large a proportion of machine builders, and that journeymen machinists, with exceptions so few that they are noticeable, have either neglected or refused to learn to use the grinding machine. At the same time there is no tool on our lists that is held in greater awe than the grinding machine.

Twenty years ago grinding was considered essential to really good work by concerns that now enjoy the best patronage of the entire world, and fifteen years ago they had reached the point where it was impossible to produce their work as cheaply without grinding as with it. The best grinding machines of to-day produce from four to six times more work than those of twelve years ago; and yet while large numbers of American machine builders are using modern grinding machines, there is a class who demand proofs in the way of tests, etc., before they can believe that grinding is practical for their work. The reason for this condition can be traced to the fact that while there are a large number of grinding machines in use, they are "universal grinders." In fact so familiar has the universal grinder become that it is very difficult for mechanics to understand that there are now in successful use cylindrical grinding machines that are not universal, and that they do not grind complicated or tool work. But they do grind all cylindrical work that is turned in lathes on two centers, and that, contrary to experience with universal grinders, they do remove considerable stock in an economical manner, saving many hours (on single pieces of work) that without their use would be expended in lathe work.

There is a common belief that it must consume more time to grind away stock than to turn it away. Therefore we find many insisting that to grind more than six or eight thousandths from the diameter of cylindrical work must be an expense, and in fact to grind at all must cost more than to turn to size in the lathe. This belief has been strengthened by the fact that grinding machines in the past have been made as producers of accurate work only, with no thought as to the possibilities of reducing diameters economically.

Within the last three years there have been great changes in the design of machines and in the methods of handling work, as well as great improvements in grinding wheels. So great have been these changes and so really wonderful have been the results, that no manager can afford to judge by any experience gained by the use of machines of the older designs in the hands of operators trained under the older methods using wheels of older selection.

SPEEDS AND FEEDS.

From paper read before Cincinnati Metal Trades Association, by Frederick Holz, President Cincinnati Milling Machine Co.

We may listen with wonder to-day to one of our friends who is running a surface cutting speed of 100 feet per minute, and feel that this is the limit, only to learn to-morrow that our neighbor applies a speed of 150 feet per minute, and thus the increase in speeds goes on. To-day the speed barometer stands at 250 feet in one of our Cincinnati shops.

It is also true that while we read a great deal of fast feeds and speeds we see very little of them when going through the country visiting shops, for these things are in a very experimental stage. Most of our present machine tools are not satisfactory for high-speed tool steel. Whenever we undertake to use the new steel, we meet with all sorts of breakdowns and other difficulties.

We have often noticed on forged spindles and similar work, evidence of very coarse feeds used on the rough turned part as they come from the forge shop, and Mr. Lodge and I went to Pittsburg to see the methods by which these are made. At one of the Carnegie shops near Homestead, we witnessed an axle lathe taking a heavy cut ¼ inch deep on a 5-inch diameter axle as it came from the forge. The carriage on this lathe traveled 3⅜ inches a minute. This was done with a single, tool, Crescent self-hardening.

Later we took a trip through some of the large shops in the Great Lakes district and in Milwaukee. We were told of a speed which broke all records we had ever heard of. Mr. Schoeltke, superintendent of the Nordberg Mfg. Co. told us that he turned a 5¼-inch diameter shaft, reducing it to 5 inches, 22 inches long, in one minute. Very much to our disappointment, we could not see the actual performance, but we were shown the data and records of the test.

Upon returning I had a 24-inch lathe rigged up with a 5 horse power motor, which we supposed would have ample power. We commenced our experiments on a 4¾-inch diameter machinery steel shaft, such as we use for overarms on our milling machines, and it worked well. We got carriage travel on this job of 17 inches in one minute, taking a cut ⅛ inch deep. We could see that this was not the limit, but had already consumed 10 horse power for this one lathe and that was all the motor could stand. We had two Novo tools—one in front and one in back—and used the leadscrew for feeding, and geared it up same as for cutting 5 threads to the inch. Since that time we have arranged for a 12 horse power motor. I only mention this experiment to point out what we may have to look for in the near future as to power. Of course, this 4¾-inch shaft had all the advantages in its favor. It was short in comparison with its diameter and quite stiff. Two tools were used to counterbalance the strain. The material was uniform. Records like these cannot be made in every-day practice, but experiments of this kind have a good effect, in that they help to make things "speed up" all around in the whole establishment.

We are not altogether through with this experiment yet. I feel that by the time we get to the end the same shafts will be turned at the rate of 24" a minute. On planer work we run light roughing cuts ⅛ inch deep, 70 and 80 feet per minute on cast iron, provided the material is fair. We use variable speed countershaft, which is absolutely necessary on planers, since finishing cuts are run at the rate of 18 to 20 feet per minute on the same planer.

In milling machine practice it is very seldom a cutter is injured by a feed unless it is abused. It is an old and mistaken idea that a cutter must be fed slowly in order to preserve it. If we analyze this subject we will find that the chip per tooth of a milling cutter is very small in comparison with the chip of a lathe or planer tool, and it is better for the cutter to give it a fast feed instead of a slow one. It is certainly better for any tool to cut into the surface instead of simply rubbing over it, and the more positive and steady this feed is, the better it is for the cutter. This argument especially holds good for roughing out work. For finishing, a high speed may be applied and a finer feed used, with finer teeth in the cutter. For roughing cuts, cutters with very coarse teeth to allow room for the chips, should be used. On ordinary class of work the medium coarse-tooth cutter answers for both the roughing and finishing.

Example 1.—Material, .90 carbon tool steel; width of surface, 5 inches; depth of cut, 1-32 to 3-64 inch; cutter, 3 inches diameter; 56 revolutions per minute; table feed, 2.8 inches per minute. This is a severe test, but the No. 2 plain miller does the work right along without chatter, with limit of accuracy of .001 inch.

Example 2.—Cast-iron bar, 1 inch thick, in which a slot is milled 22 inches long; Novo steel end mill, working at surface speed of 66 feet; table travel, 4 inches per minute.

Example 3.—Roughing the top of vise housings for a milling machine; Ingersoll type cutter used, 4½ inches diameter, at cutting speed of 40 feet per minute; feed, 8½ inches per minute; depth of cut, 3-32 to ⅛ inch.

[Several other illustrations were given, of pieces milled with formed cutters, or having several operations, with more than one cutter, which cannot well be summarized.—Editor.]

STEAM TURBINES COMPARED.

From paper by A. R. Dodge, read before N. E. Cotton Mfrs. Assoc. (Mr. Dodge represents the Curtis Turbine.)

One of the earliest efficient turbines of practical form was brought out by De Laval, and consists of a single combination of nozzles and a wheel attached to the shaft, carrying the vanes on its periphery.

The transformation of pressure into velocity in the nozzle is complex, but highly efficient. The steam at the area of smallest cross section, called the throat, always has a pressure about 58 per cent. of the initial and a velocity of 1,500 feet per second, unless reduced by a higher back pressure, at the discharge end of the nozzle. If a greater velocity is desired, the cross section at the throat is not changed, but the area of nozzle discharge is increased. We have, therefore, a means of obtaining any desired velocity entering the vanes by throttling the nozzle-end pressure, if less than 1,500 feet is desired, and by nozzle expansion if a greater velocity is essential. With this type a high velocity of the moving vanes is essential.

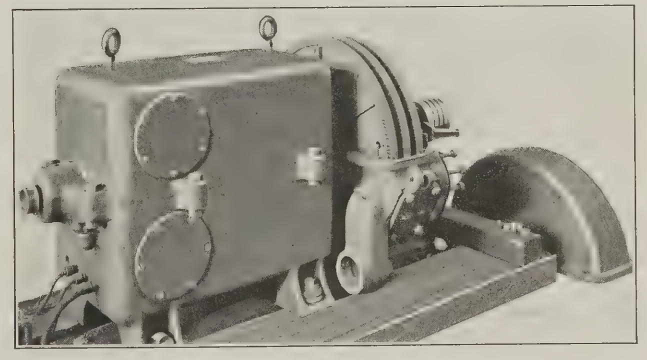

Fig. 1. Small Curtis Turbine and Generator for Train Lighting.

An initial pressure of 150 pounds will give a jet velocity of about 4,000 feet per second, if expanded to 28 inches vacuum. The vanes must therefore rotate at a speed of about 2,000 feet per second to abstract the maximum energy, a speed limited by the strength of material. About 1,200 feet per second is realized in practice, therefore this type is better adapted for a smaller range between initial and final pressures. A peripheral speed of 1,200 feet per second with this form of wheel necessitates the use of a flexible shaft and special gearing.

The Parsons machine was brought out shortly before the De Laval, and has much lower velocities of steam and vanes, and the process of transforming pressure into work must be repeated many times, entailing a large number of successive revolving rows of vanes with stationary rows of vanes between each. As there is considerable drop in steam pressure between the entering and discharging sides of the revolving vanes, owing to small clearances, an unbalanced pressure acts on the vanes. This results in a serious end thrust, which is reduced by making the drum carrying the vanes of small diameter, thereby increasing the revolutions per minute and the difficulties of generator design, as gearing is not used.

Many of the vanes must therefore rotate in steam of high density, and there is considerable brake action between vanes and outer shell due to water of condensation. Both of these losses are reduced by superheat. The large number of vanes, about 31,000 in a 300-kilowatt set, are inserted by hand, and the longer ones held at the outer end by supporting wires, to which the vanes are soldered.

The Rateau type is similar to the De Laval, except that the combination of nozzles and single wheel is repeated several times, with less expansion during each process than in the earlier turbines. A space is given for the steam discharged from the revolving vanes to utilize its energy in the form of velocity by evaporating part of the moisture, and start the process of fractional abstraction anew in the following nozzle. A single wheel per nozzle, or group of nozzles affords a minimum change in the direction of the steam jet at high velocity and shortens its opportunity to diverge, before a following nozzle again brings it into line.

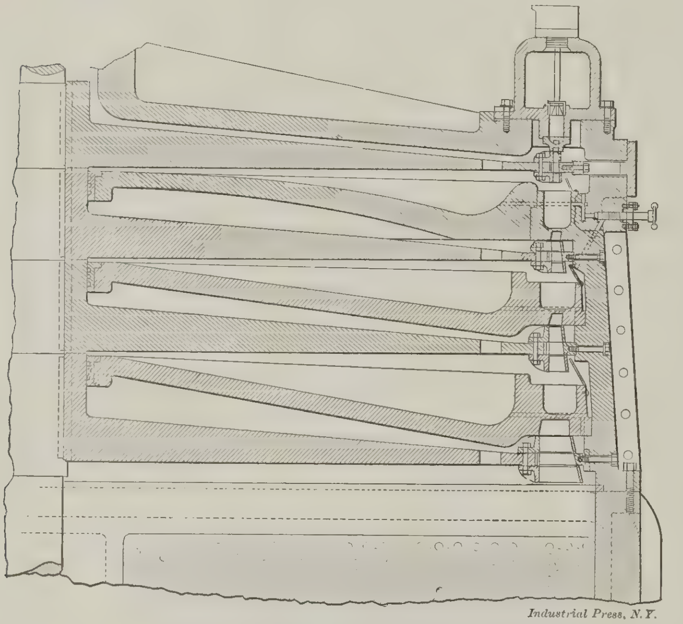

Fig. 2. Sectional Elevation of one-half of Curtis Turbine.

The outer clearance is small and the buckets have no outer band like the De Laval, but as steam is admitted only in sections of the periphery, end thrust is eliminated as the pressure on each side of the disk tends to equalize through the empty vanes.

The cylindrical clearance space between each intermediate nozzle and revolving element is near the shaft where the clearance can be made a minimum. This greatly increases the area of stationary nozzle surface near the revolving elements and adds to the loss through friction. As in the Parsons type, many of the wheels revolve in steam of high density and the friction caused by water of condensation is considerable. A print of this turbine, recently published, shows twenty-five wheels and twenty-five sets of directing nozzles. Proper adjustment of these twenty-five clearances with variable shaft temperatures, leaves much to be desired as to simplicity.

Still another type is that brought out in this country by Mr. Curtis, which in addition to nozzles delivering steam at high velocity to a single wheel has also stationary vanes which redirect the steam discharged at considerable velocity from the first wheel, due to the relatively low bucket speed, into the second wheel. The velocity of the jet leaving the nozzle is about 2,000 feet per second, about half the velocity of the De Laval under the same conditions of exhaust pressure, while the peripheral speed of the vanes in the Curtis is proportionally much less, about 400 feet per second, instead of 1,200 feet per second. By this process of fractional abstraction the speed of revolving vanes need not be excessive to secure maximum economy, in other words to bring the direction of the jet discharged from the last set of vanes parallel to the shaft. With this high-steam velocity comparatively few revolving vanes are necessary, and they rotate in steam which has a lower density, due to the considerable drop in pressure from one stage to the next. There is a large clearance between outer wall of revolving vanes and the shell, reducing friction due to water of condensation. End thrust is eliminated, as there is abundant opportunity for the pressure to equalize on each side of the revolving disks, and the entrance and discharge angles of the vanes are the same.

A still more recent type, the Stumpf turbine, has a single rotating element with buckets cut in the solid disk, which is made of nickel-steel, and operates with a rim velocity of 1,200 feet per second, and a low shaft speed, reduced by the large diameter of the disk. The centrifugal forces are very high, but a factor of safety of five is guaranteed.

The vanes are cut similar to those of the Pelton water wheel and the jet is directed against the wheel in much the same way. The wheel is sufficiently wide to allow two rows of vanes. Steam enters one of these sets of vanes, which abstracts a fraction of the velocity, flowing in the direction of the shaft to the edge of the wheel, and is then carried over to enter the vanes on the other side of the wheel by a stationary vane.

The following table embodying approximately the velocities of turbines of 300 kilowatts to 500 kilowatts capacity will aid in this comparison:

	Rows of Rotating Bucket Rings.	Steam Velocity feet per second.	R. P. M	Peripheral Speed	Buckets.
Parsons.......	35	400	3,600	200	inserted
Rateau........	25	800	2,400	400	inserted

Each type has its characteristics and the advantages of one over another will depend largely on the cost of construction, reliability, and improvement in efficiency.

* * *

A correspondent of the *Railroad Gazette* suggests a solution of the alleged vexing confusion in the use of the word "engineer" in this country. In England and on the Continent, the term "engineer" means a member of a learned profession; here it means both the learned gentleman and the greasy "gent" who pulls the throttle of a steam engine, which, of course, is supposed to materially detract from the dignity of the aforesaid gentleman. In England a locomotive "engineer" is a "driver" and a stationary throttle-puller is an "engineman" or "machinist." Mr. Szlapka would substitute the word "ingeneer" for "engineer" when it is applied to the professional man, thus: *Henry Szlapka, Consulting Ingeneer.*

* * *

The moving picture machine is now being used not only for the purpose of amusement, but for business as well. An instance is that of a new car fender that is being exploited by the aid of a portable mutoscope, which the salesman can carry about with him to capture the attention of the busy street railway manager, and at the same time make an impression that otherwise would be quite impossible. The views show a practical test of the fender on a living subject, the fender picking him up without injury when running at a speed of about 22 miles per hour. The views, taken in Brooklyn, show the car rapidly approaching the victim, the "accident," his position in the fender and final rescue uninjured. The scheme for selling the appliance is not less wonderful than the device itself.

CUTTING FRACTIONAL SCREW THREADS.

FRED H. COLVIN.

Thread cutting is always an interesting problem and the question of change gears is one that comes up every day in the shop. The gear tables show what to use for a regular thread but when it comes to fractional threads many are all at sea. Then they want a book or a table that will show just what they wish to know without any figuring. But they forget that there is almost no uniformity of practice among lathe builders and that leadscrews vary, as well as the "jumps" between change gears; some go by 4 teeth, some by 5, etc. Then, too, there are ways of "doubling up" in the head, by putting in a compound or back gear out of sight in the headstock.

The first thing to do in any case is to find out the exact ratio between the spindle and the leadscrew, which might be called the "constant" for the lathe. This could be defined as the ratio between the gears required to move the carriage one inch for every revolution of the spindle. It might be suggested that this could be the ratio between the gears which would cut the same thread as the leadscrew, but for fractional threads the former is the better and will cause less confusion. If there are no multiplying gears (which would be equivalent to putting the first gear on the lathe spindle) the teeth in the spindle or first gear will be as many times those of the leadscrew gear as the leadscrew has threads per inch. Thus, with a 6-pitch leadscrew the screw must turn 6 times to move the carriage an inch. But as is often the case, it may be found that with even, or similar gears, the lathe would cut a 3-pitch, or only require 3 turns of the leadscrew to move the carriage an inch. This shows there is a multiplying gear in the head, such as a 48 on the spindle, driving a 24 on the stud which takes the first change gear.

For practical use, find the equivalent pitch of leadscrew by putting even gears on both stud and screw, and find what thread would be cut. It may be that a 48 gear on spindle drives a 32 on the stud, when the screw will be equivalent to a 4 instead of a 6. Then to cut a 12-pitch thread multiply both 4 and 12 by any number that will give gears upon the gear list. Multiplying by 5 gives 20 and 60. If these gears are not at hand, try multiplying by 4½, which gives 18 and 54. To cut 11½, multiply by 8, giving 32 and 92. Probably there will not be any 92 gear so a 46 may be used on the screw and a 2 to 1 multiplying gear put on the compound stud. If these gears cannot be had, try some multiplier which will give gears that are in stock. 4 times 4 = 16 and 4 × 11½ = 46, so that a 16 will do, but it is smaller than is usually found. Six gives 24 and 69 and the latter is an odd gear but may be supplied for cutting this thread.

For cutting threads expressed in pitch to the inch this is the easiest way, but for pitches expressed in inches it is apt to be confusing, and for this reason it is better to consider the leadscrew in inches rather than threads per inch. A 4 pitch leadscrew would then be ¼ — a 2 pitch ½ etc., always remembering that the leadscrew is considered at its equivalent pitch, or the distance it moves the carriage for one revolution of the lathe spindle. Taking the leadscrew as ¼ inch pitch and having to cut a screw which measures ¾ inch from thread to thread we readily see that the leadscrew must make 3 turns to one of the spindle. Consequently the gear on the stud must have 3 times as many teeth as the gear on the screw. Putting this in example form we say: ¼ is to ¾, as the gears that we are to use. The ¼ is the leadscrew gear and ¾ the stud gear. As they both have the same figure below the line (denominator) we only consider the figures above, which are 1 and 3. Multiplying both by 20 we have 20 and 60; or by 24, we get 24 and 72. Either of these gears paired as shown will cut the thread.

Still keeping the ¼-inch pitch leadscrew—and we will keep this during all the calculations—we have a piece of work requiring a thread with a 13-16-inch pitch, or ¾ and 1-16 as some say. Now, while this looks like a puzzler, it is easy if we keep cool and do a little thinking. As the pitch desired is in 16ths of an inch, reduce the leadscrew pitch to same terms and ¼ = 4-16. Then we can neglect the denominators and only consider 13 and 4. As the desired pitch is faster than the leadscrew, the leadscrew must be turned faster than the spindle, so the large gear goes on the stud. Multiply 13 and 4 by any number that will give gears that are in stock. Multiplying by 4 gives 52 and 16, by 5 gives 65 and 20, and by 6 gives 78 and 24, any of which will answer the purpose.

Another puzzle is when the foreman calls for a thread making one turn in an inch and seven-sixteenths, or 1 7-16 pitch. As we usually think of a thread as being less than an inch pitch this might easily puzzle one who isn't used to it. But we simply reduce the fraction to 16 + 7 = 23-16 and the leadscrew to 4-16 and then forget the 16s entirely, so this is 23 and 4. Multiplying by 6 gives 138 and 24. But 138 is larger than most lathes possess, so we must compound. A 2 to 1 compound would give 69 for the large gear. Many lathes would not have this gear, so if we can compound 3 to 1, divide 138 by 3 and get 46 for the large gear.

Still another way to get stuck is to have the pitch given as ¾ of a turn to the inch. This isn't ¾-inch pitch but a pitch faster than one per inch. As there must be 4-4 to the thread and only 3 of these take place in one inch it is clear that ¼ of the pitch must take 1-3 of an inch so that the whole pitch must be 1 1-3 or 4-3 inch. With the same leadscrew of ¼-inch pitch we must reduce the fractions to the common denominator which will be 12. Then 4-3 = 16-12 and ¼ = 3-12 so we have a ratio of 16 to 3. Multiplying by 6 gives 96 and 18 as gears that will cut this. One more example of this kind may help. Call this 7-16 of a turn to the inch. As there are 9-16 more to the thread it must move 1 2-7 inches for the balance. This makes the pitch 2 2-7 inches or 16-7. Then with leadscrew ¼ we must reduce them to same fraction. The lowest common denominator is 28 and this gives 64-28 and 7-24 or 64 to 7, a large ratio. Multiplying by 4 gives 256 and 28 which will probably require compounding at 4 to 1 if it can be done. This would give 64 to 28 as the right gears.

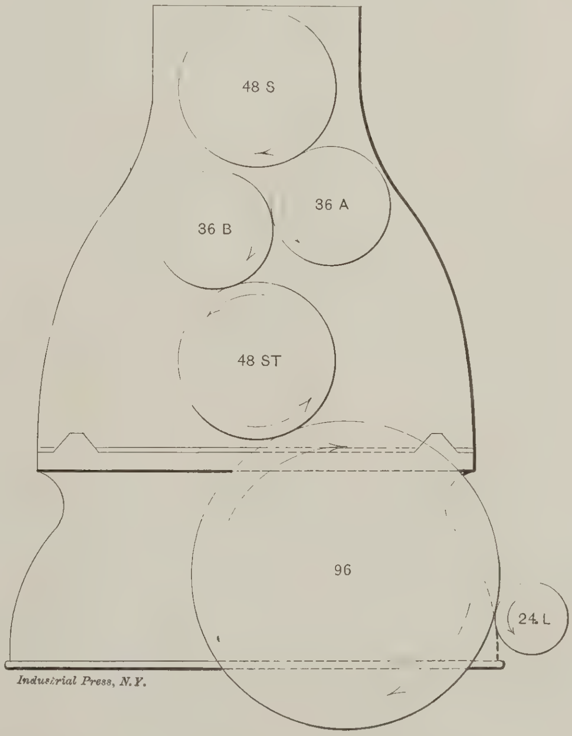

Diagram of End of Lathe, showing Gearing.

Fractional pitches are not nearly as hard as they look if one goes at them slowly and follows directions. To make this more complete and satisfy those who want tables, the writer has calculated the two tables which follow. But before giving them it is necessary, or at least desirable to go to the root of thread cutting, so that they will not be wrongly used and then blamed for mistakes which may be made. To help make this clearer the end of the lathe with its gears is shown in outline. This is only one of many arrangements but it will serve the purpose. The lathe spindle has a 48 toothed gear which drives one of the two smaller gears shown. The arrows show direction. The 48 toothed gear below carries the stud on which the change gears are placed, but to avoid confusion, the large intermediate gear is shown driven directly by the 48 tooth gear. The leadscrew carries a 24 tooth gear, as shown.

This is a good place to emphasize the fact that the only gears that need be counted in a simple train are the driver and the driven, or the first and the last. The intermediate gears do not count *unless compounded*, but this will be explained later.

First consider the lathe head only or the gears from the spindle to the stud, including both. The spindle carries a 48 gear. In one revolution this will drive the next gear 48 teeth. No matter about revolutions now—these don't count till we come to the driven gear—the last of the train. Each gear moves 48 teeth every time the driver makes one revolution and as the gear on the stud—the last of this train—has 48 teeth it moves 1 revolution. In other words, they are "geared even." The intermediate gears marked 36A and 36B are merely for reversing the direction of the leadscrew or for cutting it out altogether. The gears move so that both *A* and *B* can be out of mesh with the spindle or that *B* drives. In this case gear *A* simply runs idle. If the gear driving the stud *ST* had 96 teeth it would turn half as fast as the spindle and make it necessary to consider the leadscrew half the actual pitch. This is the "true" or "equivalent" pitch considered in the tables. This is sometimes done in building lathes and, as will be seen, confuses anyone who attempts to figure gears with an iron-clad rule and doesn't look at the ratios of the spindle, stud and leadscrew. Returning to the cut and calling the stud 48, we realize that this will drive the large gear 48 teeth (no matter what part of a revolution) and in turn drives the last gear the same number of teeth. As this last gear has 24 teeth, it will make two revolutions, and cut a thread double that of the leadscrew.

EQUIVALENT OR TRUE PITCH OF LEADSCREW.

Table No. 1.

If now, instead of running the large gear in mesh with the 48 *ST* gear, we put a 24 gear beside it, and drive the large gear from that, we have compounded the gears. While *ST* moves 48 teeth, the large gear is only driven 24 and the leadscrew makes one revolution. If on the other hand, we put a 96 on beside the *ST* gear, we will compound the other way and drive the leadscrew four revolutions to one of the spindle.

It is sometimes difficult to see the gears in the head but it is easy to put "even" gears on both stud and leadscrew and see what thread is cut. This is the true leadscrew pitch and should be used in all calculations rather than the actual pitch. In the tables that follow, gears have been used that are usually found on lathes, although in some cases it has not been possible to do so. Two combinations are given in most cases, one using gears which vary by 2 or 4 teeth and the other by 5 teeth. Where very large gears are called for, it will usually be found necessary to compound between the stud and leadscrew. Take, for example, the pitch of 11-16 inch with a 4 pitch leadscrew. The gears are 136-32. If now we compound so as to double the speed of the leadscrew, it becomes equivalent to a 2 pitch and a 68 gear on the stud does the same work. The tables are accurate if used as intended—but care must be taken to avoid mistakes.

EQUIVALENT OR TRUE PITCH OF LEADSCREW.

Threads to inch.	2	3	4	5	6
	S. L S	S L S.	S. L S.	S L. S.	S. L. S.

	20 — 25	30 — 25	40 — 25	50 — 25	60 — 25
1½	32 — 24	48 — 24	64 — 24	80 — 24	96 — 24
	40 — 30	60 — 30	80 — 30	100 — 30	100 — 25

Table No. 2.

The tables do not by any means show *all* the gear combinations that will cut given threads, only two of the combinations most likely to be found. No gear below 20 is used. As an example of what might be done take 7-16 inch pitch and leadscrew of 2 pitch. This reduced to inches gives 7-16 and ½ inch or 7-16 and 8-16 or a ratio of 7 to 8, the 7 for the stud and 8 for the leadscrew. Multiply both of these by any number and get any gears that can be used, such as:

S.	L. S.	S.	L. S.
21	24	49	56
28	32	56	64
35	40	63	72
42	48	70	80

And by compounding, a much larger variety may be obtained.

Just remember that the whole question is simply the number of revolutions of the leadscrew as compared with the spindle, or the distance the carriage will be moved by one turn of the spindle, and no trouble will be experienced.

* * *

MOLDING WITHOUT PATTERNS.

An interesting article by Mr. Henry Hess on floor molding without patterns, appeared in the October issue of the *Foundry*, which is based on the writer's experience while connected with the German Niles Tool Works at Berlin, Germany. The article illustrates how floorplates, lathe beds, large faceplates, etc., were molded without the use of patterns. Of course dry sand cores play a leading part in such work, units being joined together to form the complete mold in much the same manner as has been practiced for several years in the country in the casting of medium heavy flywheels. Molding flywheels in this fashion as practised by Jones & Laughlins, Pittsburg, Pa.; Struthers, Wells & Co., Warren, Pa.; Geo. V. Cresson Co., Philadelphia, Pa., and others, requires a pattern of one section only, by which is meant one spoke and such a portion of the arc of the hub and rim as is expressed by 360 degrees divided by the number of spokes. Dry sand "cores" are made from the pattern, and when assembled, of course, inclose a cavity of its shape. If there are eight spokes in the wheel, the complete mold will consist of eight of these cores arranged in a circle, thus forming a complete hub and rim. Jones & Laughlins have a large flywheel cast in one piece by this process, which has been running for a number of years at a peripheral speed of nearly two miles a minute.

* * *

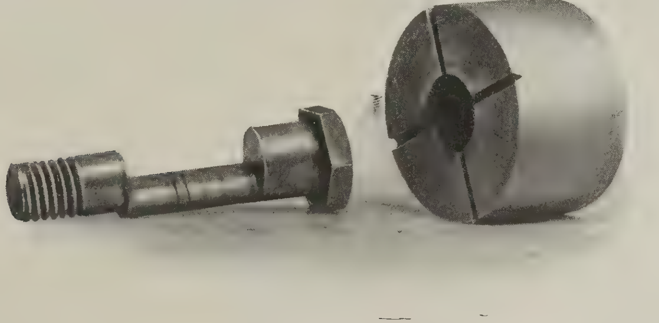
A subscriber is building a special machine in which it is necessary to have certain iron parts covered with canvas and wishes the receipt for a cement which will stick the canvas securely to the iron. If any readers have had experience with such a cement we should be glad to receive directions for making it.

LETTERS UPON PRACTICAL SUBJECTS.

A SLIGHTLY (?) WORN ROLLER PIN.

Editor Machinery:

The accompanying cut shows a cam roller and pin as they were recently removed from a machine in which they had been in use for about eight months. They had been causing trouble for some time and an examination by the master mechanic revealed the condition of affairs here shown. It was found that the rollers had been made from tool steel and hardened, while the pins were of machinery steel which was not hardened. As will be seen in the photograph, a series of grooves have been cut by the workman in each end of the roller for the purpose of admitting oil to the pin. This had the effect of causing the roller to act as a milling cutter and the pin was cut smooth and true on each side of the portion that was worn down. As the chips had no way of escape, the roller being held in a forked lever, they were carried in with the oil and helped to grind the pin down, thus throwing the machine out of order.



Cam Roller and Worn Pin.

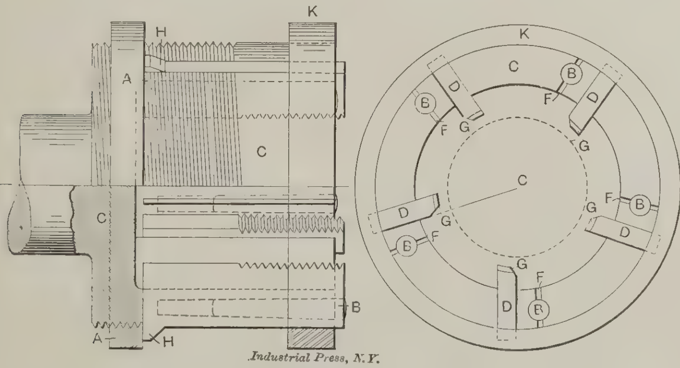
Two lessons may be learned from this experience: First, to follow the specifications given on the drawing, which in this case called for both pieces to be made of tool steel and hardened; second, not to cut oil grooves in the ends of a roller.

Port Chester, N. Y. A. D. Finley.

A LARGE DIE FOR CAST IRON.

Editor Machinery:

The accompanying sketch shows a die, made by the writer, which has been used with considerable success for threading large cast-iron work. *C* is a collet which holds the dies *DD*. A short distance in front of the slots in which the dies fit, are a series of smaller slots, *FF*, in the center of which are placed taper pins, *BB*. When the dies have been put in place these pins are driven in firmly and, expanding the slot, they cause the die to be held tightly in position. A ring, *K*, is placed around the outside of the collet to prevent the dies from spreading out. On the back end of the collet is screwed a ring, *A*, and the ends of the dies, terminating in the shoulders, *H*, bear against this ring. As the die becomes dull the ring is screwed further on and the blades are thereby pushed forward so that their front ends may be ground off until a sharp thread is reached. In this way the blades can be used for almost their entire length and, when completely worn out, it is a comparatively simple matter to supply the holder with a new set of cutters.



Die for Large Cast Iron Work.

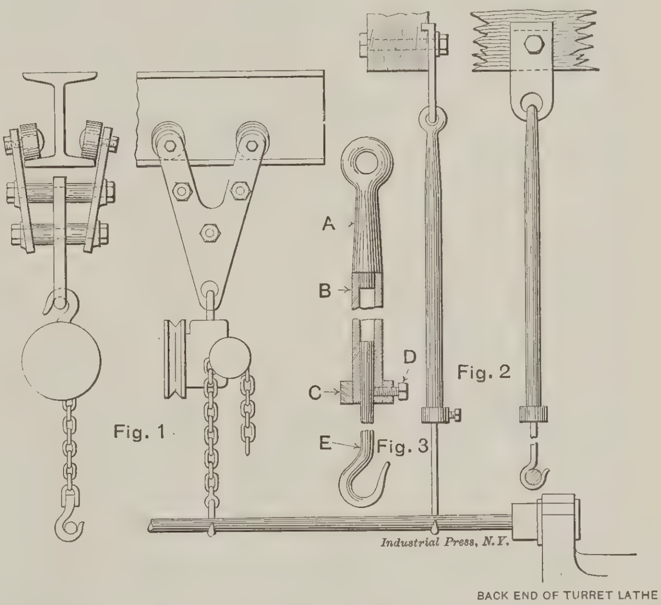
It will be seen in the sketch that the front side of the die is in line with the center of *C*. When the dies were first made they would not work at all, but when the corners had been ground off, as at *G*, they worked very well except on some castings which seemed to be of unusually difficult iron to cut. I would like the opinion of some of the readers of Machinery as to whether I have followed the right course in constructing the die in this way, or should the cutters have been set forward of the center? Dies of this class may be profitably employed quite frequently, and if any one can suggest an improvement, or point out any error in regard to the position of the cutters, the information will, without doubt, be of interest to others as well as to the writer.

Cedar Rapids, Iowa. M. E. Sanders.

ADJUSTABLE HANGERS AND SUPPORTS FOR USE WITH TURRET LATHES.

Editor Machinery:

Almost any one who has had much to do with the handling of bar stock on the screw machine or the turret lathe, is familiar with the troubles common to the forked support or rest generally used, and cannot fail to realize the heavy strain imposed upon a man when using large stock; to say nothing of the noise and rattle that accompany the revolution of a 2-inch iron or steel bar, 16 feet long, when the rest is a little too high or too low. Additional strain is also put upon the man when he is, every now and then, required to move the heavy standard to accommodate the length of the bar.



Stock Supports and Hangers.

Figs. 1 and 2 show two types of stock carriers that will be found to greatly lessen this trouble and incidentally save considerable time owing to the ease and quickness with which stock can be handled with their aid. Fig. 1 shows a chain hoist attached to a small traveling carriage which moves upon the lower flange of an I-beam that is fastened to the floor timbers above the machine. Fig. 2 shows an adjustable support that is fastened to a beam just above the end of the lathe. This same style of support may also be attached to the traveling carriage in place of the chain hoist. With a traveling support of this kind, one man alone can readily take a bar of the largest stock from the rack, run it up to the machine, slip one end through the fixed support and place the bar in the machine. The chain hoist, however, will be found most convenient as it enables the operator to easily lift the stock from the floor.

The construction of the adjustable hanger is shown in Fig. 3. On the end of eye, *A*, is forged a piece of wrought iron pipe, *B*, of any length required to suit the height of the beam above the machine. A collar, *C*, is shrunk onto the lower end of this pipe and through it is passed the setscrew, *D*, which holds the hook at any desired height. The hook, *E*, slips up inside of the pipe and if marks be made upon it where it enters the pipe, it can be readily adjusted in height to suit any size of stock.

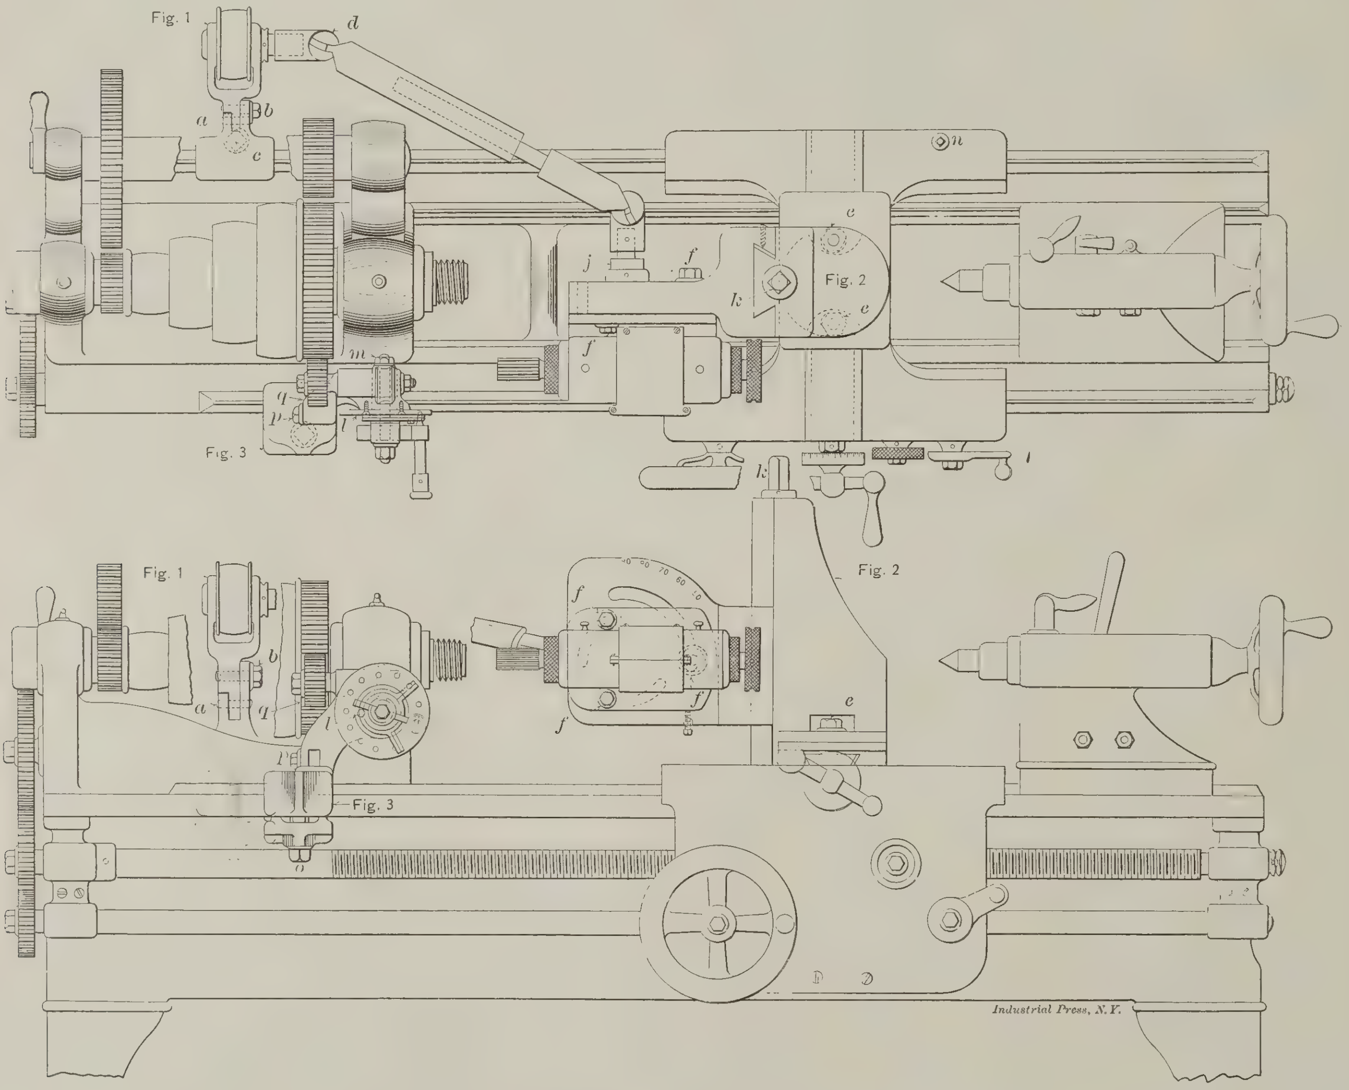
A convenient arrangement, where stock is to be supplied to several machines, is to furnish each machine with one stationary, adjustable support and one adjustable support on a traveling carriage, then one carriage with chain hoist can be used to bring stock up to any of the machines desired, and as soon as it has been placed in the supports belonging to that particular machine, the hoist may be removed and used elsewhere.

C. NEIL.

A MILLING ATTACHMENT FOR THE LATHE.

Editor MACHINERY:

It frequently happens that it is desired to take a milling cut on a piece of work while it is still held upon the faceplate of the lathe upon which it has been turned. In order to do this the attachment illustrated in the drawing herewith will be found very convenient. While the arrangement here shown may be still further improved, this one has already proved very satisfactory for any kind of work that has been attempted upon it. With the three attachments in position as shown, all that is necessary for the operator to do is to attend to the indexing of the work around to its lines of measurements. These attachments are especially useful for milling circles, circular slots, etc., in plain or irregular pieces. When in use they are bolted securely to the lathe and can be adjusted to any desired position. One point of advantage that will be noticed in connection with these attachments is that it is unnecessary to change the construction of the lathe in any respect, as they require no holes or other alterations that would in any way impair the efficiency of the lathe. They are quickly attached and easily adjusted, and as they are driven from the lathe itself no extra countershaft is required.



Industrial Press, N.Y.

A Milling Attachment Applied to the Lathe.

The milling spindle is driven through bevel gears which are connected by telescopic rod and universal joints to the driving attachment shown at Fig. 1. The driving attachment is operated by a belt which runs over any step of the lathe cone that is calculated to give the required cutting speed to the milling cutter. When the milling attachment is being used the cone locking bolt is thrown out so that the cone runs free on the lathe spindle, and as the cone may be driven on any step and the driving attachment may be driven from any other step the range of milling speeds is consequently very wide.

The driving attachment consists of a pulley which is held in a forked bearing. This fork is hinged to a base *c* in such a manner that it may be set at any angle and when so set is firmly clamped by the bolt *b*. The base itself may be clamped at any position along the bed of the lathe by means of the clamping bolt *c*. The fork is hinged about the pin *a*, while the bolt *b* moves through a slot which allows a movement of the pulley of 5 inches, so that the different lengths of belt caused by employing different steps of the cone, may be kept at proper tension. The universal joint *d*, by which the driving attachment is connected with the milling attachment, is capable of working to an angle of 70 degrees.

The milling attachment proper is fastened to the cross slide of the lathe by the two screws *ee* and in no way interferes with the use of the lathe for ordinary purposes. The cutter head is pivoted so that it can be set at any angle from horizontal to vertical and graduations are provided for indicating the angle. It is clamped in position by the three bolts *fff*. In addition to this movement the cutter head has a movement of 7 inches up and down on the face of the column upon which it is mounted, being operated by the screw *k*. These combined movements allow the operator to bring the cutter to bear upon the work in the most advantageous positions. The spindle is very large and formed to receive collets, drill chucks, milling cutters, etc.

The fixture shown at Fig. 3 is for the purpose of indexing the work on the spindle of the lathe. The base of this indexing attachment is clamped to the bed of the lathe by the screw *o* and is provided with a swivel joint similar to that used on the driving attachment, so that the gear *q* can be meshed with the spindle gear or thrown back out of mesh without disturbing the arrangement in any way. Mounted upon the swinging arm is the shaft bearing the gear *q* and having at its opposite end a worm wheel which meshes with a worm mounted on the indexing shaft. The indexing shaft passes through the plate *l* and terminates with an index pin. By the use of this attachment any desired divisions of the circle may be made upon the work as in the regular milling machines.

New Haven, Conn. A. L. Monrad.

ECONOMICAL BOILER SETTINGS.

Editor MACHINERY:

I noted the criticism of "J. A. P." in the letters of the August issue, and as this is an interesting subject, further discussion of it seems to be in order. He says that the pit in rear of the bridge wall should be filled up in order that the gases may be more thoroughly burned, but his conclusion is not logical. We are told that a large, high furnace is necessary to secure combustion of the fuel, also that we must have a large chamber at the rear for the combustion of gases—all of which seems proper. Then why must we have a small passage behind the bridge wall to secure the same result?

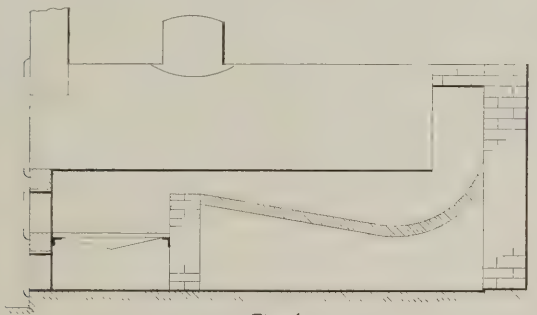


Fig. 1

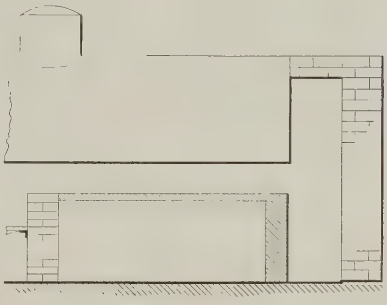

Fig. 2

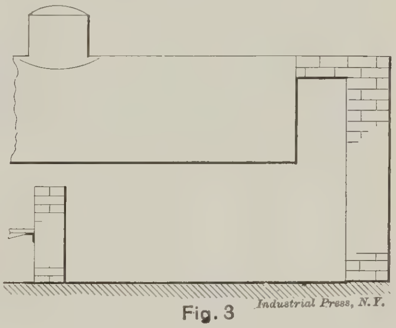


Industrial Press, N.Y.

Fig. 3

He mentions a battery of three boilers, two of which gave good results, but the third was less efficient. After a while the third did better work because the space back of the bridge wall filled with ashes, making what he calls a better combustion chamber. I should like to know what method was adopted to determine the efficiency of the third boiler. If the steam was discharged into a main common to all of them, was not the increased efficiency due to the imagination of the engineer in charge, or was a careful test made to determine it? How long was this boiler run before its efficiency increased? Under ordinary conditions it would take about three years for the space to fill with ashes, so as to equal the ordinary method of filling in this space; therefore if the efficiency was really increased within a few months, it was due to some other cause.

A certain engineer had charge of a battery of 10 small tubular boilers. Three of them were taken out and replaced by two larger ones. He had the bridge walls built in the form of an inverted arch, only 4 inches distant from the shells. As the products of combustion were forced through this narrow space the heat was intense at this point, doing the shells no good to say the least, but he always claimed that this plan saved much coal. As the whole battery of 9 boilers discharged their steam into one main it was impossible to tell which boiler was the most efficient, so far as I could judge, and he never could give a reason for his belief; therefore it was an open question, in my opinion, and the same reasoning applies to the third boiler mentioned by "J. A. P."

He mentions another "set of boilers," but does not state the number, in which a saving of 500 pounds of coal was made in 24 hours, by filling in behind the bridge walls. If there were 5 of them it means 100 pounds each, or 40 pounds for an ordinary run of 10 hours. This amount is so small that it would take a long time to pay for the brick work, etc., required, especially when the extra cost of more frequently removing the ashes is considered. Were any other changes made at the same time? What measures were taken to know exactly the amount of water actually evaporated both before and after the change?

If these boilers were of 100 horse power each, and 9 pounds of water were evaporated by each pound of coal, the saving mentioned amounts to but 36 pounds of water per hour for each boiler, and if tests were so carefully made that it is known beyond dispute that this small saving was due to the change mentioned, said tests were of a very superior order, as there are many other things to be considered, any one of which would make more difference than he reports.

While investigating this matter I compared the results of several tests made on boilers that are practically alike, except a difference in the setting. I found reports of five tests made on boilers set as shown in Fig. 1. The average of these is 9.73 pounds of water evaporated per pound of combustible, from and at 212 degrees, which is a proper standard for comparison. Four tests were made on boiler set as in Fig. 2, the average of which was 10.97 pounds. Five tests were made with the setting illustrated in Fig. 3, and the average was 11.28 pounds of water. In one case the pit behind the bridge wall was 7 feet deep. These figures, which were taken in an impartial manner, show results in favor of a large combustion chamber behind the bridge wall, and this seems logical in view of the large space required in the furnace, and at the rear end of boiler.

Many years' experience with this type of boiler satisfies me that it is better to have the space at this point so large that it will not get half full of ashes in a year, than to have it small, making it necessary to clean it out every three months, especially if the rear end of boiler setting is within a yard of a nice engine room door, as in the case of my present plant. We can stand one such job each year, but do not want it every quarter. The lower half of a boiler shell can be inspected and repaired much easier and better, where there is room to do it, than where the space is but a few inches deep, and our boilers are not accessible enough at present, therefore all useless incumbrances should be dispensed with. W. H. Wakeman

New Haven, Conn.

[In reply to the above letter we have received the following communication from "J. A. P.," in which he answers the questions raised by Mr. Wakeman.—Editor.]

Editor MACHINERY:

Relative to the remarks by Mr. Wakeman, concerning the suggestions on boiler settings which were offered by me in the August number of MACHINERY, I would say that they were the evidence of practical experience rather than a comparison of efficiency tests, and the conclusions drawn were not entirely original but followed out the idea of a number of able engineers of broad experience in the designing of boilers. It will be readily admitted that we need a large and roomy furnace, but it would be possible to make a furnace too large, and the same reasoning applies to the combustion chamber. Let us consult a few statements of leading engineers relative to the design of a furnace of the most economical type.

Mr. J. W. Shepard, in a paper before the Western Railway Club, makes the following statements, among others, on the subject of combustion: "Let it be said that coal, as such, does not burn. Before any burning can occur the coal must be broken down. The gases evolved are almost all hydrocarbons; these hydrocarbons must also be broken into their component parts, hydrogen and carbon. The real process of burning is the uniting of oxygen, a gas, with the fuel to be burned."

Now since all of the above statements are true, we have placed a limit upon the size of the furnace. As far as the breaking down of the coal is concerned it might be of almost any size, but when it comes to the gases we are limited, because when one atom of carbon unites with two of oxygen we get the best condition for burning, or for uniting the oxygen with the fuel. Since the air contains the oxygen used, we must have our furnace of such a size as will furnish as nearly as possible the required amount of air to supply the oxygen; a furnace abnormally large will contain more air than is necessary and will prove detrimental. Now since the combustion chamber does a large part of the work of decomposing or breaking down of the hydrocarbons into their component parts, and since this latter is a process of burning, we can get too large a combustion chamber as well as too large a furnace. The igniting temperature of hydrocarbons is from 940 degrees to 1,230 degrees, and we should have our combustion chamber up to at least this heat and keep it there. It is quite evident that a built-up combustion chamber is much warmer than a large open space back of the bridge wall. We are told that the ideal furnace is one in which the coal is burned separately from the boiler, only the heated gases being allowed to pass under the shell, and in the path of these gases we may erect pieces which, becoming highly heated, tend to increase the efficiency of the furnace. Now this is the idea of the built-up chamber; its bed is intended to be at the height of the lower strata of gases, or nearly so, and this becoming heated increases the efficiency of the furnace.

Mr. E. P. Parker, in writing upon the subject of smoke abolition, advocates a bridge wall three feet thick, making a combustion chamber of the bridge wall, in a sense. I find also in a design presented by him the built-up combustion chamber in addition to the thick wall.

Mr. G. B. N. Tower, formerly U. S. supervising inspector of steam vessels, presents the following suggestions upon boiler settings: "As gases are generated during the process of burning coal, suitable provision must be made to supply them with air necessary for their combustion. Now this air cannot be supplied through the grate bars, but must be supplied in the furnace above the fuel, and also *at and behind the bridge wall.*" Since air is to be supplied at the bridge wall, is it not far better to so design our combustion chamber that the air which enters shall be compelled to mix with the gases as much as possible, by limiting to some extent its permissible range of movement? This is the office of the built-up chamber.

The three boiler battery which was mentioned in my former article was not under a test, the facts of the case being as follows: When the installation was first made the whole battery was run for some time, then one boiler was dropped out and remained so for about six months. After this time it became necessary to run the third boiler again, and upon starting it up it was found that the first two boilers steamed faster than the third. The feed pipes were removed and cleaned and, as this was the only condition which could make an unequal feed, it was clear that the evaporative efficiency of the boilers which had been run regularly was greater for the reason before mentioned.

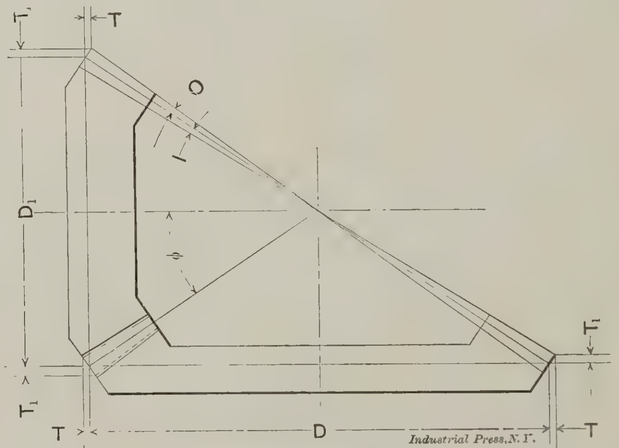
In regard to the other set of boilers mentioned it may be stated that there were two, not five. No efficiency test was made at the time, but they simply did the same amount of work after building in as before, and they used 500 pounds of coal less in twenty-four hours. Mr. Wakeman's water saving statement seems to be rather abstract in connection with this subject, as it was a saving of coal for which we were working, not water. We saved no water at all since the same amount of steam was used both before and after the change; we simply evaporated the same amount of water with less coal. Under a carefully-conducted calorimetric test these boilers showed an evaporation of 10.5 pounds of water per pound of coal. In connection with this test it may be well to say that the firing was not of the best, the fireman being somewhat inexperienced. In view of the fact that a run of these boilers before putting in the built-up chamber showed very poor steaming qualities it seems that the change was a decided improvement. With a properly designed combustion chamber there will be ample room for cleaning and inspecting the shell as well as for making repairs. The expense of a combustion chamber built in this way is very small since it requires only a double brick wall, about 5 feet long and 3 feet high, filled in with sand and covered over with brick. J. A. P.

BEVEL GEAR FORMULAS.

Editor MACHINERY:

It is doubtful if there is any other mechanism of equal simplicity that has called forth as many or as elaborate formulas as has the ordinary bevel gear. This fact appears more strange when we contemplate the simplicity of the essential calculations, and one is led to think that the matter has been slightly overdone. Instead of clearing up matters, this mass of formulas seems to have had a tendency to make the beginner regard the subject with more or less suspicion and dread. Then there is often the man of inquiring mind who would fain acquaint himself with the method of calculating bevel gears, but stands aghast when he finds that between him and the required goal there are a lot of trigonometrical expressions. He is willing to grapple with a few algebraic expressions but when it comes to trigonometry, he draws the line. That these expressions are not anywhere nearly as difficult as a great many are prone to imagine, goes without saying; but, on the other hand, are not these expressions injected into mathematical expressions unnecessarily?

For example: To find the maximum outside diameter of a bevel gear by the ordinary method, we take the ratio of the diameters, or numbers of teeth, and thus ascertain the corresponding center angle from a table of tangents. We then look up the sine and cosine of this angle and from these values and the pitch we obtain the required amounts to add to the pitch diameters of the gear and pinion respectively. This moreover is not as direct as it may seem, since the ordinary trigonometrical tables give only the function of angles varying by 10 minutes so that in most cases interpolation becomes necessary.



Industrial Press, N.Y.

Diagram of Bevel Gears.

In order to avoid all this inconvenience and the consequent liability to err the writer uses formulas (1) and (2) to determine the tooth increments to add to the pitch diameter in order to obtain the outside diameters.

For the pinion, $$T_1 = \frac{D}{P\sqrt{D^2 + D_1^2}} \qquad (1)$$

For the gear, $$T = \frac{D_1}{P\sqrt{D^2 + D_1^2}} \qquad (2)$$

In which

D_1 = diameter of pinion.

D = diameter of gear.

P = diametral pitch.

The calculation made in this way is much simpler than by trigonometry since it necessitates the use of no tables and consequently no interpolation; also it will be noticed that the denominator is the same for both equations.

To find the center angle ϕ we have of necessity to resort to our table to find the angle whose tangent corresponds to the ratio of the gears; that is:

$$\phi = \tan^{-1} \frac{D_1}{D} \qquad (3)$$

Similarly, we have for the inside and outside tooth angles I and O (where the whole depth of the tooth equals 2.157 divided by the diametral pitch).

$$O = \tan^{-1} \frac{2}{P \sqrt{D^2 + D_1^2}} \qquad (4)$$

$$I = \tan^{-1} \frac{2.314}{P \sqrt{D^2 + D_1^2}} \qquad (5)$$

These two values may, however, be determined without trigonometry by an approximate method, giving a result near enough for practical purposes, particularly for a set of gears with a large number of teeth, and by making a slight correction we may obtain as close, or closer, results than by (4) and (5) unless the decimal points are carried well out and values carefully interpolated. The approximation consists in assuming that the depth of the tooth, above or below the pitch line, corresponds to a circular arc with center at intersection of the axes of the gears. The fraction that this angle is of 360 degrees is taken as the fraction that the depth of the tooth, above or below the pitch line as the case may be, is of the whole circumference of this circle. Then

$$O = \frac{360}{P \pi \sqrt{D^2 + D_1^2}} = \frac{114.59}{P \sqrt{D^2 + D_1^2}} \qquad (6)$$

$$I = \frac{416.52}{P \pi \sqrt{D^2 + D_1^2}} = \frac{132.53}{P \sqrt{D^2 + D_1^2}} \qquad (7)$$

The maximum discrepancy would occur with a 12-tooth miter gear where the outside angle is 6° 43′ and figured by formula (6) is 6° 45′. As the results are always large, and increase as the angle, it is a simple matter to make the correction. The table herewith gives the amount in minutes to be deducted from the results obtained from (6) and (7), for various tooth angles.

Tooth Angles in Degrees.	Deduction in Minutes.
1°	.02′
2°	.05′
3°	.17′
4°	.40′
5°	.65′
6°	1.38′
7°	2.08′

To find the number of teeth for which to select the cutter we have:

$$\text{For the pinion,} \qquad \frac{P D_1 \sqrt{D + D_1^2}}{D} \qquad (8)$$

$$\text{For the gear,} \qquad \frac{P D \sqrt{D + D_1^2}}{D_1} \qquad (9)$$

The objection to the general expressions for these values, such as the number of teeth divided by the cosine or sine of the center angle, is that before the values can be obtained it is necessary to consult the table and interpolate, whereas, with (8) and (9) the results may be obtained directly.

When one is about to lay out a pair of bevel gears, the diameters and pitch are determined from a consideration of the space available, power to be transmitted, speed, etc. These having been obtained the above formulas enable one to obtain all of the data generally required to construct the ordinary pair of bevel gears, viz., outside diameter, backing, turning and cutting angles, and number of cutter to be used.

A GERMAN SPIRAL GEAR CUTTER.

Editor Machinery:

In reference to the subject of spiral gears, upon which you have published several articles, it may be of some interest to your readers to state that we are building a special machine for making very accurate gears with helically-formed teeth in a very cheap and quick way. The sale of this machine is growing rapidly in this country (Germany) and people experienced in gear cutting are surprised at its simplicity and the accuracy of its working.

Our cutting tool is a spiral worm cutter and the great feature of the machine is that all spur wheels with straight or spiral teeth, and with any number of teeth, provided they are of the same diametral pitch, can be cut by means of a single cutter. The faults in the completed gear are therefore limited by the errors existing in the single cutting tool, which it is possible to make very perfect, and the work of cutting the teeth is rendered independent of the care and intelligence of the operator.

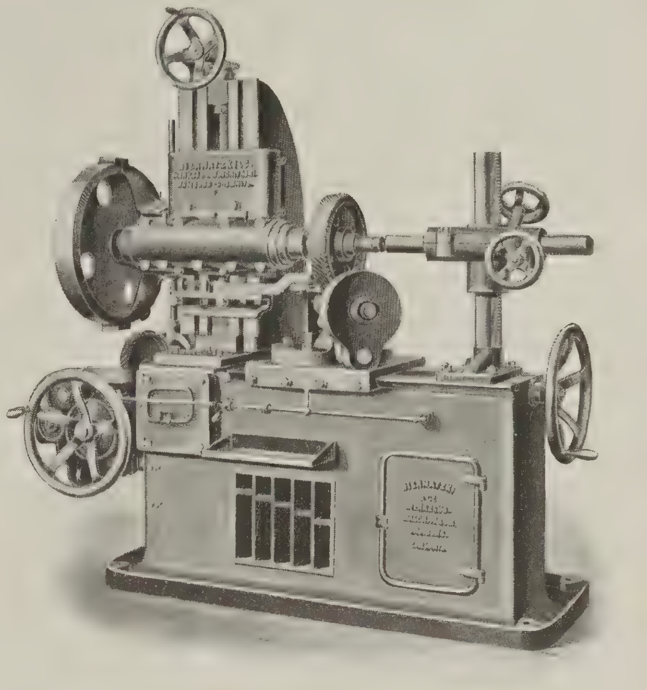

Fig. 1. Spiral Gear Cutter.

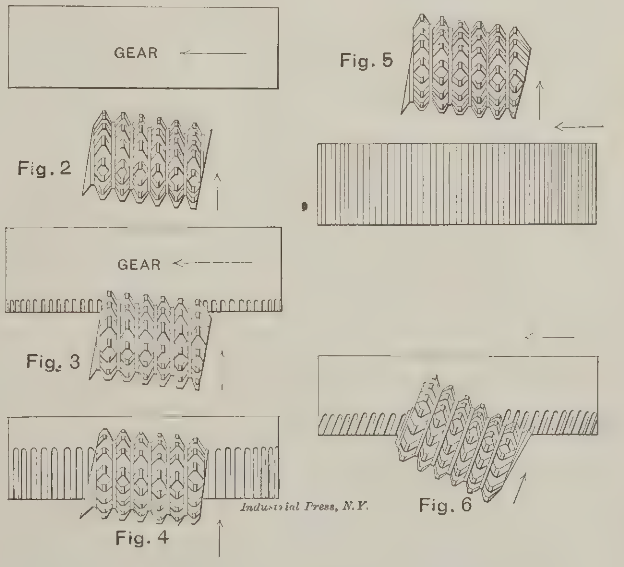
In explanation of our system, we will first describe the usual way for cutting an ordinary spur wheel with straight teeth by means of a single-thread spiral cutter. The cutter is supported on a swivel carriage and is set with its axis at an angle with the plane of the wheel to be cut, this angle being such that the plane of the gear will be normal to the spiral of the cutter. Both the cutter and blank are given a rotary motion, the cutter making as many revolutions for each rotation of the spur wheel blank as there are teeth to be cut in the latter. The cutter is now fed into the blank in a direction parallel to the axis of the latter, whereupon it begins to cut some of the teeth. As the blank rotates, all of the teeth are finally started and by degrees the cutter passes across the face of the blank and gradually cuts the teeth across the full width of its face. This action is illustrated in the diagrams, Figs. 2 to 5, inclusive, in which Fig. 2 shows the angular position of the spiral cutter before



Figs. 2-6. Illustrating the Principle of the Spiral Gear Cutter.

commencing work; Fig. 3 its position after the wheel blank has completed one revolution; Fig. 4 its position after about one-half the width of the teeth has been cut, by a corresponding number of revolutions of the wheel blank; and Fig. 5 shows the finished spur wheel, with the cutter moved beyond it.

Our method for cutting spiral wheels differs from that above mainly in that the number of revolutions of the spiral cutter, necessary for cutting a straight-toothed wheel as above described, has to be increased, say, by one revolution, while the number of revolutions of the wheel blank remains the same as before. This one additional revolution of the cutter, taken in connection with its advancing motion, gives as resultant the helical direction required for the teeth of the spiral wheel. This action is indicated at Fig. 6. It will be evident, however, that any other proportional increase of the number of revolutions can be employed such, for instance, as two, three or more additional revolutions or a fraction of a revolution, according as a greater or smaller pitch of the spiral teeth may be required. The number of revolutions of the cutter could also be reduced by one or more revolutions or fractions thereof, as above stated, instead of being increased, producing helical teeth of the opposite pitch having an opposite inclination of the axis of the spiral cutter.

In a like manner spiral wheels having an angle of spiral varying from zero to 180 degrees can be cut by one and the same spiral cutter, according as the cutter has one or more additional, or one or more less revolutions imparted to it.

These machines are patented in the United States and manufactured in our factory in Germany. The following is a summary of the advantages of the system:

1. The machine is simple in construction and easy to handle.
2. Only one cutter is required for different wheels containing different numbers of teeth, provided they are of the same pitch.
3. This greatly reduces the cost of cutters, it being only about one-half as compared with other machines with which it is necessary to use a set of 8 or 14 cutters for each pitch.
4. The form of tooth is absolutely and theoretically correct for wheels with any number of teeth and not correct by intervals only, as is the case when a set of cutters has to be used for each pitch.
5. Being formed by the same cutter, the teeth of all wheels of the same pitch, though containing different numbers of teeth, are of equal thickness at corresponding heights, consequently gears cut by this machine work smoothly and without backlash.
6. No previous nicking or preparation of the solid blank on a dividing machine is required, the machine doing its own dividing automatically during the process of cutting.
7. As several teeth of the cutter are working at once, the capacity as compared with the ordinary spur wheel cutter is much greater.

Biernatzki & Co.
Hamburg, Germany.

[This type of gear cutter is not unknown in this country, but, for some reason, no manufacturer here has made one operating on this principle a commercial success. We do not know why this is the case, for we learn from other sources, as well as from the above communication, that machines of this type are thought well of abroad and will do very rapid work. One possible reason for its non-development here is that there must necessarily be more or less elasticity in the train of gearing connecting the cutter and wheel being cut, and this may have been believed fatal to the proper performance of the work. Stiff and rigid construction, however, have evidently overcome this defect.

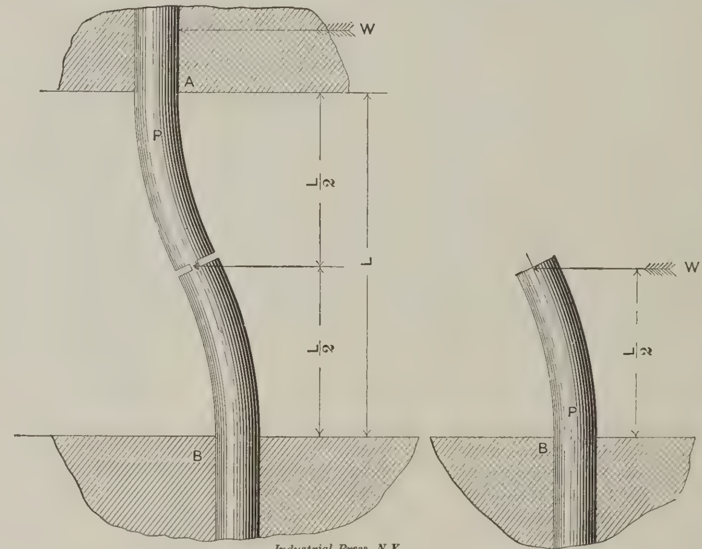
It will be observed that a gear cutter on this principle is but an extension of the principle of the worm-wheel hobbing machine manufactured by several firms in this country. What was probably the first of these machines was invented by Sir Joseph Whitworth in 1835, and since then many other patents have been issued, here and abroad, both on machines for hobbing worm-wheels and for cutting spur and spiral gears with spiral cutters. In 1889 Geo. B. Grant took out a patent on what he called a "Conjugator," a machine operating on substantially the same principle as the machine described above, though of not so good mechanical construction. Following upon Mr. Grant's invention William Sellers & Co., Philadelphia, did some experimental work in this direction, but for some reason did not see fit to develop the machine sufficiently to put it on the market. If it should happen that this letter of Biernatzki & Co. should bring out any further information upon this method of gear cutting, we should be glad to lay the facts before our readers.—Editor.]

* * *

THE STRENGTH OF FIXED BEND COLUMNS UNDER LATERAL THRUST.

Editor Machinery:

Every once in a while a person comes across something in engineering which he must think out for himself, as one is unable to find any information in the text books on the subject. One of these cases is shown in Fig. 1. The column, *P*, has one end fixed in a permanent structure, *B*, while the other end of the bar is also fixed in another structure, *A*. The latter has a lateral thrust, *W*, acting upon it. As the diameter of *P* was to be kept as small as possible, it became necessary to know what bending moment was exerted by the thrust *W*.



Industrial Press, N.Y.

Fig. 1 Fig. 2

Illustrating Strength of Columns under Lateral Thrust.

When the force was acting upon the beam, it would assume a reverse curve, as shown in Fig. 1, *A* being so arranged that it had to move parallel to *B*. The inflection point of the curve would be midway between *A* and *B*, and as the curve changes at this point, from plus to minus, the outer fibers of the beam would neither be in tension nor compression, and, therefore, if we should saw out the metal on each side, as shown, and suppose that a single fiber was strong enough to take care of the shear at this point, we would not have altered the curve or bending moment.

If the thrust *W* were now transferred to the center, and the remaining fiber removed, as shown in Fig. 2, the bending moment of the support would be unaltered. This bending moment is seen to be $\frac{WL}{2}$ which is ½ that of a simple beam of the length, *L*, with a load on the end. This beam, therefore, need only be made one-half as strong as a beam which would not be fixed at *A*. The maximum bending moment would be at the fixed ends and would be $\frac{WL}{2}$.

Frank B. Kleinhans.

PATTERNS AND PATTERN ROOM.

Editor Machinery:

Since patterns form a valuable asset in any business they should have the best of care and a careful and complete record should be kept of them. Many concerns who own patterns recognize this fact and have a system that is in keeping with the valuable and important part which these patterns have in the conduct of business. There is no reason why costly patterns should be in general disorder most of the time and usually covered with dust and dirt. There is no reason why they cannot be kept as clean as the books in the office or papers on the desk, and there is every reason for keeping them in the best of order and condition.

A little daily care and attention to the pattern room will be well repaid by the improved condition of the patterns and the general appearance of the room. There are times when one desires to show business friends around the plant, and how much satisfaction there is in a well-kept, clean and light pattern room. It is, indeed, strange how some men of good business acumen will look at the condition of some parts of their plant without a pang, and it is especially strange that they should take so little interest in the care and condition of patterns which have taken much valuable time to produce.

When a pattern is needed it is often needed in a hurry, and some scheme should be devised to locate it quickly and with facility. It is decidedly unpleasant, and irritating in the last degree, to experience trouble in locating a pattern when there is a rush order for castings from it, and no accurate record to show where it is or who had it last. The value of systems is brought out over and over again in the daily operation of the pattern shop and in no place can a system be utilized to greater advantage. Many shops have systems for keeping run of their patterns that are as good, or perhaps better, than the one that is here described, but to those that have no system the following outline may prove of benefit.

The pattern room should be in charge of one man, and he alone should have the entire oversight and be responsible for the condition of the room and patterns, and of the records connected therewith. It is always a good policy to concentrate responsibility as much as possible and, when it is practical to do so, to place one man in charge of certain departments of work, making him directly responsible for the conduct and general condition of that department. Of course there is the human element of fallibility, but the danger of mistakes can be reduced to a minimum by this one-man responsibility, leaving no opportunity for shifting the burden on others. A man having charge of the pattern room must of necessity know something about the business and about patterns in general. In some shops it is practical to turn the room over to the pattern maker and make him responsible for its condition, records, etc. This, however, cannot be done in large shops where the entire time of the pattern makers must be employed in the making of patterns, and so a man should be selected who can devote as much of his time as may be necessary to the care of this room.

It is, of course, difficult to determine just how much room should be set aside for the storage of patterns, but it should be borne in mind that conservatism in this matter is not economy, nor is it good judgment. If there is any branch of the business that increases rapidly it is the pattern department, and this fact should be taken into consideration when making plans for the pattern room. It is a still more difficult problem to arrange the shelving for the patterns, but the common shelf has proved the most satisfactory in the long run, and to this end a set of shelves should be arranged around the room on all four sides. These may be from two to three feet deep, and a trolley ladder should be employed to reach the top shelves quickly and easily. The center of the room may be utilized for the erection of another set of shelves which will be open at both sides. Very large patterns that will not go on the shelves may be arranged around the room on the floor. As the shelves are erected they should be divided off into compartments of about two feet each, so that when all of the space in a compartment has been utilized a small board tag may be suspended from the top shelf showing just what numbers are in that compartment. This will greatly facilitate the location of the patterns. When the patterns are placed in the room, insist that they be dusted every day and the room swept and cleaned as thoroughly as an office. In this way it will not be hard work to keep rooms and patterns in first-class order.

There are many different ways of designating patterns, but, in the opinion of the writer, the simple method of numbering them consecutively as they are made is the best and the least liable to confusion. In the matter of record the versatile card index is called into play. Give each pattern a card rather larger than the standard size, say 6 inches by 5 inches, and on this put the number and name of the part or piece for which the pattern is made. It will also be found desirable to keep on the record the date when the pattern was made, the cost in detail, and the weight in iron, steel, or whatever metal is used for the casting. On the reverse side a record should be kept showing the movement of the pattern, whether at home or away, and it should be impressed with special emphasis that this record must be complete and accurate. This will prevent many of the disputes and disagreements that often occur owing to inaccurate records of the whereabouts of patterns, and much trouble and delay will be avoided if the record is kept as it should be.

This system can be used by foundries doing a jobbing business by a little change in the matter of record shown on the card. In this case the record should show to whom the pattern belongs, when received, weight in metal, cost of casting and the number and name of the pattern. W. G. STEBBINS.

New London, Conn.

PEAT AS FUEL.

Since the coal famine of a year ago various sources of fuel other than the coal fields and forests of the country have been proposed—among them the peat bogs, found in many localities. The mud from these bogs consists partially of carbonized vegetable matter, caused by the decomposition of water plants, moss, grass, etc., intermingled with fibrous roots, and when dried out makes an efficient fuel. Another kind of peat, which may be designated as turf peat, consists of the mud which is found under the turf that grows in marshy places, the carbonized vegetable matter in this case consisting of decayed grasses or turf.

While it is generally known that peat will serve as a fuel, and that it is so used in some countries very extensively, it is only recently that authentic information as to its calorific power and characteristics appears to have been available. A bulletin of the Insurance Engineering Experiment Station, Boston, Mass., is devoted to the subject of "mud-fuel, coke and gas," showing that peat may be considered an emergency fuel, if nothing more.

The report refers to the Ziegler process—a German invention—for converting peat into coke and gaseous products, showing very low cost of production, based on the German scale of wages, which would have to be offset in this country by improved mechanical processes, should the manufacture of coke and by-products from peat be undertaken on a commercial scale. The report also contains the results of tests by Prof. Norton of the Massachusetts Institute of Technology, Boston, showing that the calorific power of air-dried peat, when "bone-dry," is from 9,600 to 14,000 B. T. U. per pound, or about 65 per cent. that of the best American coal. Prof. Norton makes comments on the use of peat and draws several interesting deductions. Samples of peat when wet weigh 100 to 125 pounds per cubic foot, and after drying in the air the weight reduces to about 55 pounds, when the mud becomes hard and tough, difficult to saw but easy to split with an axe. In the process of coking the tendency is for the mud to crumble; but if it is first dried thoroughly it produces a firm, dense coke, very much like the coke from soft coal. With 43,560 feet to the acre and depth, say, of 20 feet, there would be 860,000 cubic feet of mud per acre, which would yield 20,000 tons of air-dried mud, equal in heating power to 12,000 tons of good coal. If convenience in handling and diminished bulk should justify the coking process, 10,000 tons of good coke would be produced, and as there is almost, if not quite, enough gas distilled from the coke to make one pound of mud furnish the gas to coke the next, the process once started would require no extra fuel.

The success or failure of peat as a fuel here in America would seem to rest entirely upon the cost of excavating and drying it, compared with the cost of mining coal, taking into account the interest charges on the equipment. As long as anthracite coal is to be had, even at a high price, it will be preferred, because of its cleanliness, and high heating power; but in the case of fuel emergency here in the East, where people in general are accustomed to soft coal, it would seem as though peat might serve as a very efficient emergency fuel.

THE CARD INDEX IN THE DRAFTING ROOM.

REGARDING ITS USE BY THE DRAFTSMAN FOR HIS INDIVIDUAL RECORDS.

During the past few years the use of books for the keeping of records has been giving place to the more modern method of record keeping—the card index system. Introduced first in mercantile business, its use has extended, until now it is found in almost every branch of work in which the keeping of any kind of records is involved. In the up-to-date drafting room the card index found early acceptance for keeping records of drawings and similar purposes. There is, however, a place in the drafting room for the card index where it has yet to be more generally adopted, and that is as an individual adjunct to each draftsman's outfit. Years ago Nystrom said: "Every engineer should make his own pocketbook, as he proceeds in study and practice, to suit his particular business," and there is no better way of compiling a pocketbook than by the use of the card index. Outfits for this purpose may be purchased in all styles and prices, from the trial outfit of 3 x 5 cards, in a pasteboard case and costing about 75 cents, up to the most elaborate cases and trays for the 5 x 8 cards. As the individual index is of value primarily only to the draftsman using it, it may be difficult to persuade the "Company" to provide such outfits, so that as a beginning it may be necessary for the draftsman who is desirous of starting his own collection of data to provide himself with an outfit composed of materials that can usually be found at hand.

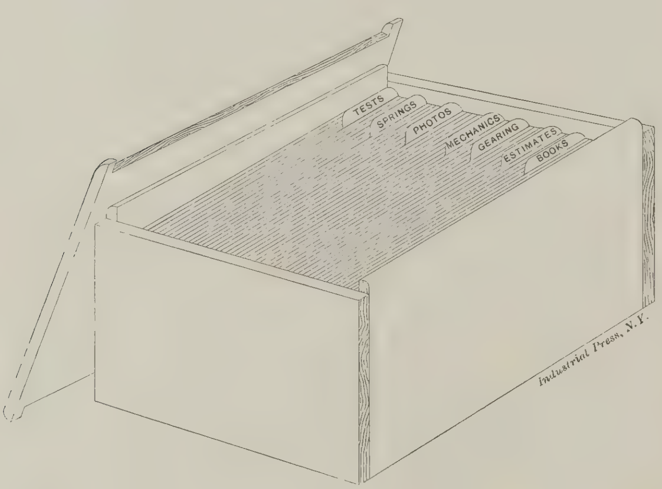

Fig. 1. A "Shop-made" Card Index Box.

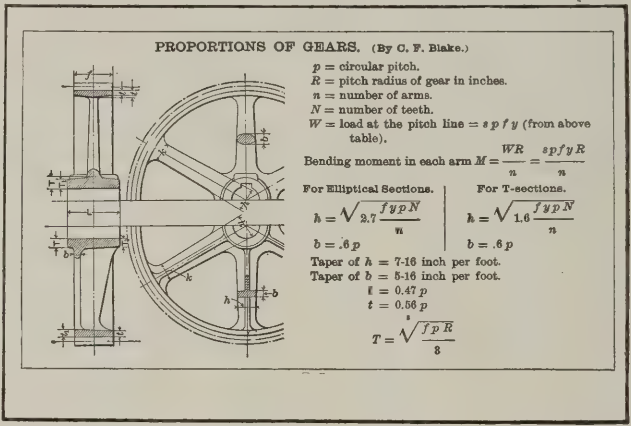
Fig. 1 is a sketch of a very cheap and serviceable index box that can be readily put together in the pattern shop and is in some ways better suited to this particular purpose than those purchased of the regular dealers in such goods. Being made of ½-inch pine, planed down to about ⅜ inch, it is very light and much more easily handled than the regular cases, which are usually made of oak. Another point in its favor is that it can be made much shorter than any of the regular trays which come in lengths of from 12 to 14 inches, and are, therefore, of a size that would prove unhandy upon a draftsman's board. A package containing 100 index cards of medium weight measures a little less than an inch in thickness, so that a box 4 or 5 inches deep will hold a sufficient number of cards to cover a long period of the average draftsman's experience. The object should be to compress the entire outfit into a size and weight which shall not greatly exceed that of an ordinary reference book.

Cards for these outfits are provided mainly in 3 x 5, 4 x 6, and 5 x 8 inch sizes, but if the index is to be put to all of the uses which are mentioned later, the cards should not be less than the 4 x 6-inch size. Either of the two larger sizes, if used in a short, light tray, will be found fully as convenient to handle as the ordinary tray for the smaller cards when it is of the usual length and constructed of oak. The cards chosen should be of sufficient size to allow of fairly lengthy computations, and for mounting complete tables and similar data clipped from periodicals. If home-made cards are to be used they can be easily cut from Manila or stiff white drawing paper, and will answer the purpose very satisfactorily. Guide cards are cut from the same material and labeled to suit the matter to be indexed. In the case illustrated no provision whatever is made for locking the cards in as none is considered necessary. When it is desired to refer constantly to a certain card or cards they may be easily slipped out and placed on the drawing board for the time being and any device which makes it necessary to lock and unlock in order to do this, or to remove and add cards, will, after a short trial, be found to be more of an objection than an advantage.

The uses to which the index can be put will suggest themselves to each draftsman as the requirements of his work present them. In the first place there are certain tables to which every draftsman has constantly to refer, and these should form a foundation of the index system. Such data as decimal equivalents, squares and cubes, trigonometrical functions, etc., furnish the most natural beginning. These are to be found in the handbooks in common use, such as Kent and Nystrom, but when only one table is needed for a particular use the convenience of drawing out a single card over the necessity of handling the whole book, will at once be apparent. Often several tables are used at the same time, and then the pages of the book must be turned back and forth, or, perhaps, two or more books must be referred to. With the index system any number of cards may be placed side by side where the draftsman may refer to them without trouble. Having started with the tables most commonly used the index will grow with considerable rapidity. If any unfamiliar table or data is to be consulted, much time may be lost in searching for it through the different handbooks, but if, when found, it is copied on to an index card, it is then ready for immediate use if again needed. Clippings from periodicals have before been referred to, and the value of a year's subscription to any good technical publication will be wonderfully increased if all of the data that is published pertaining to one's particular line of work is placed upon the cards. Fig. 2 is an illustration of a data card upon which is mounted one of the tables taken from a MACHINERY data sheet.



PROPORTIONS OF GEARS. (By C. F. Blake.)

p = circular pitch.
R = pitch radius of gear in inches.
n = number of arms.
N = number of teeth.
W = load at the pitch line = $s\,p\,f\,y$ (from above table).

Bending moment in each arm $M = \frac{WR}{n} = \frac{spfyR}{n}$

For Elliptical Sections.	For T-sections.
$h = \sqrt{2.7\frac{fypN}{n}}$	$h = \sqrt{1.6\frac{fypN}{n}}$
$b = .6p$	$b = .6p$

Taper of h = 7-16 inch per foot.
Taper of b = 5-16 inch per foot.
$l = 0.47\,p$
$t = 0.56\,p$

$$T = \sqrt[3]{\frac{fpR}{8}}$$

TEST OF SPIRAL RECOIL SPRINGS

14"
1¼"
1¾"
4¾"
Eight Coils

Load Applied	Compression
12 Tons	2"
14 Tons	2½"

Compression for each coil ¼" and 5/16" respectively

Beqtrup's formula for compression

$$F = 8\frac{L(D-d)^3}{Ed^4} \quad E = 8\frac{L(D-d)^3}{Fd^4}$$

D = outside dia of coil
d = diameter of wire
F = compression of one coil
E = torsional modulus of elasticity
L = load applied

Substituting values from Test.

$$E = 8\frac{24000(4\frac{3}{4}-1\frac{1}{4})^3}{.25\times(1\frac{1}{4})^4} = 13,500,000$$

$$E = 8\frac{28000(4\frac{3}{4}-1\frac{1}{4})^3}{.3125\times(1\frac{1}{4})^4} = 12,640,000$$

For future calculations use E = 13,000,000

INDUSTRIAL PRESS, NY

Fig. 3. The Card Index used for Record of Tests.

Reviews of all technical books that the owner reads should find a place upon these cards. To thoroughly digest any book there is no better plan than to make notes and extracts as the reader proceeds, and if these are afterward placed in his index, they will often prove of the greatest value.

In many drawing rooms the draftsman is provided with a note book in which to record all calculations, estimates, and other computations that may arise in connection with his work. After one of these books has been in use for several months, and a mass of calculations has accumulated therein, it is a most tedious job to search them over for the figures applying to the matter in hand. If, however, the calculations are made upon index cards and filed under appropriate headings, they may be found at a minute's notice.

A draftsman is often called upon to design certain pieces of mechanism in which the strength of the material must be taken from general data and may vary considerably from the strength of the material actually used. In such a case it may be practical to make subsequent tests and from these to obtain definite data. The card shown in Fig. 3 is taken from the writer's index and serves to illustrate the way in which the results of such tests can be recorded. The problem in this case was to design a spring that should stand a load of about 25,000 pounds and to determine its deflection when loaded. The spring was designed and the compression figured by Begtrup's formulas, in which the modulus of elasticity is given as from 10,000,000 to 14,000,000, and the exact modulus to be used is left to the judgment of the designer. After these springs were made they were tested, with the results shown on the card, and substituting the actual deflection for given loads we are able to determine a modulus of elasticity, in this case about 13,000,000, which can be regarded as comparatively exact data for use in designing springs that are to be made of the same material and to perform similar duty. If similar comparisons be made of castings and forgings of various kinds we soon accumulate a quantity of very reliable information that applies more closely to our particular cases than any published data which must, at best, be only general in its nature.

ITEMS OF MECHANICAL INTEREST.

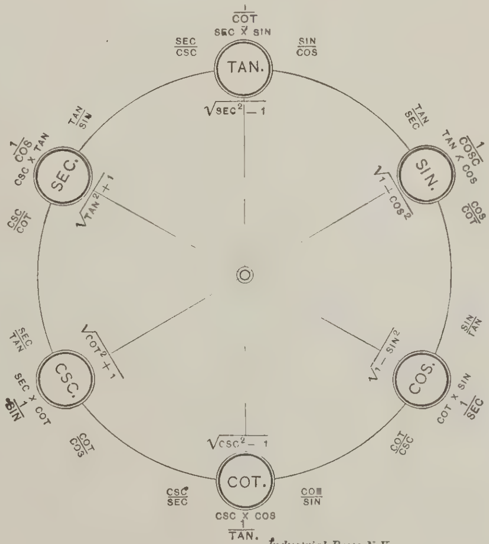
RELATION OF TRIGONOMETRICAL FUNCTIONS—SURFACE PLATE FOR LONG LEVERS—THE INVENTION OF BABBITT METAL—THE PRODUCTION AND USE OF CARBORUNDUM.

From investigations made in Germany it appears that wood which has been floated in rafts, or has in any way been for a long time immersed in flowing water, is better fitted for reliable joinery and building purposes. The water dissolves the sap, albuminous and salty substances in the pores and makes the wood less hygroscopic, that is, less likely to absorb dampness. Kiln-dried lumber containing large quantities of sap, may shrink, split or warp under certain conditions, but the liability of doing so is much lessened in the case of floated timber. The same condition can be obtained artificially. In a German process for drying wood described by Consul-General Hugue of Coburg, Germany, the boards or planks are piled up in a long iron box, with narrow spaces between; the lid is then tightly screwed down, so that neither water nor steam can escape. Steam is then turned into the box at a continuous pressure (3 to 5 pounds per square inch), and this process is continued for from sixty to seventy-two hours, the exact length of time being determined by the hardness and density of the wood. The steam opens up the wood and kills the protoplasm which is still alive in the cells. After having been thus prepared, the wood goes into a water bath, where it is kept for about a fortnight. The drying process then follows.

To shoot, yet not to shoot, is the problem solved by a Swedish inventor, for the protection of those in the vicinity of young army greenhorns who are learning to become marksmen, as well as to save ammunition now wasted in practice. The apparatus comprises a dummy gun mounted on a universally mounted support so that the gun may be pointed in any direction. A pointer, whose position is controlled by the position of the gun, indicates the slightest movements of the latter, and at the moment the trigger is pulled the pointer is automatically locked in the position at which it was at that instant. Graduations near the pointer show the direction the gun was pointing when the shot was supposed to have been fired and register the deviation from the bullseye that would have occurred had a real rifle been aimed at the same angle as the dummy gun fired by the pull of the trigger.

THE RELATION OF TRIGONOMETRICAL FUNCTIONS.

Prof. W. H. Wilson has prepared a diagram that illustrates in a very concise manner the symmetry of the relations of the trigonometrical functions. A careful study of this diagram, which is here reproduced, will prove of great aid in memorizing the relations which these functions bear to one another. Referring to the cut it will be seen that:



Industrial Press. N. Y.

Fig. 1. Showing Relation of Trigonometrical Functions.

Each function is the reciprocal of its diametrical opposite.

Each function is equal to the ratio of the first and the second in either direction.

Each function is equal to the product of its two adjacents.

Each function is equal to an expression involving the square of an adjacent, a radial and unity.

DIE WORK ON A LARGE SCALE.

In this country some of the heaviest die work has been the rather unpleasant but exceedingly interesting process of manufacturing coffins of metal sheets by means of a heavy press and dies. *Page's Magazine*, London, however, describes the process of the Heslop Seamless Steel Boat Works, an English concern, which affords an illustration of die forging or pressing on an immense scale. It is not found practicable to press a boat from one sheet of steel, due to the puckering of the sheet, so all boats are pressed in halves, and afterward jointed along the keel. There is an advantage, however, in this, namely, that it permits of the insertion of a stiff keel of I section, bent to the required curves, to which the thin flanged edges of the halves are riveted. With the exception of this, all the boat fittings are of timber. The advantage of the steel hull is that it does not shrink as timber does, in hot climates, and that a blow will only bruise, without fracture occurring. The firm turns out some three hundred boats a year. The dies used are so massive that they are built up and bolted together in sections. The cost of the entire stock of dies for boats of different sizes up to 35 feet and 40 feet in length, must have been enormous. The dies are arranged in line with the heating furnace, out of which the sheet to be pressed (of ⅛ inch steel) is drawn. It is located in place on one edge of the lower die by means of cotters driven by men stationed in a row. The lower die is then lifted hydraulically, and the sheet pressed to shape at once.

SURFACE PLATE WITH V-GROOVE FOR LAYING OUT WORK.

In the construction of the linotype machine a number of long light levers have to be mounted on comparatively slender shafts at right angles to same and certain holes have to be located in the levers in accurate relation to one another. In the shop of the Ott. Mergenthaler Co., Baltimore, Md.—who were the original builders of the linotype machine—a surface plate was used for this work and is still used for similar work. In fact the scheme is one that can be profitably employed in many shops as a time-saver and promoter of accurate work. In the plate a V-groove is planed across one end exactly at right angles to the side *A*. Holes are tapped along the side of the groove for clamps. A shaft with its lever is shown in position for laying out holes in the lever. The shaft *D* is clamped in the V-groove so that the arm *B* stands along the side *A*. With calipers the right angularity can be tested. Holes can be laid out in any desired relation by means of a surface gage, etc.

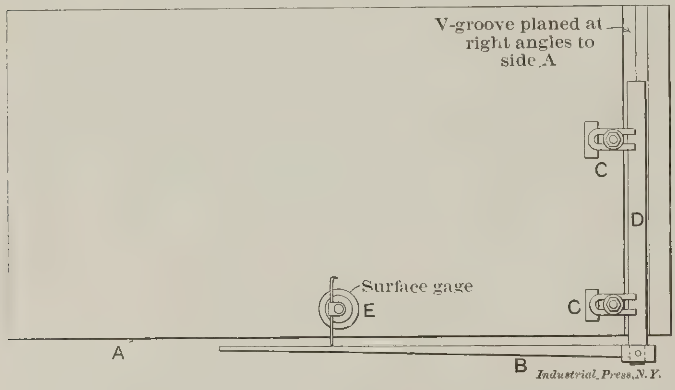


Fig. 2. Surface Plate for Laying Out Long Levers.

REGARDING THE INVENTION OF BABBITT METAL.

Although "babbitt" metal is one of the most common antifriction metals in use at the present time, but few users of this metal are aware that Isaac Babbitt, whose name it bears, was the inventor and patentee of the method of lining boxes with soft metal rather than of any particular alloy of the metal itself. The *Metal Industry* recently published a copy of the original patent, No. 1,252, which was granted to Isaac Babbitt, of Boston, Mass., July 17, 1839. In this he claims to have invented a new and improved mode of making boxes in which gudgeons or journals are to run. To quote from that part of his patent relating to the metal used, he says: "I prepare boxes which are to be received into housings or plummer blocks in the ordinary way of forming such boxes; making them of any kind of metal or metallic compound which has sufficient strength and which is capable of being lined. The inner parts of these boxes are to be lined with any of the harder kinds of composition known under the names of britannia metal or pewter, of which block tin is the basis. An excellent compound for this I have prepared by taking 50 parts of tin, 5 of antimony, and 1 of copper. But I do not intend to confine myself to this particular composition."

No claim whatever is made for the composition and, in fact, that specified is somewhat softer than what is now known as "Genuine Babbitt," which is commonly composed of 96 parts of tin, 8 parts antimony, and 4 parts copper.

Although Babbitt's name is somewhat erroneously applied to the metal yet, as he was the first to exploit the use of soft metals in the manner in which they are now so commonly employed, it seems but just that his memory should be perpetuated in this way. After devoting some time to the production of metals he engaged in the manufacture of soap and his name is now as well known in the household as in the shop.

CUTTING LEFT-HAND THREAD WITH RIGHT-HAND TOOLS.

A correspondent of the *American Electrician* shows a slight variation of the old scheme of cutting a left-hand thread on a rod by means of a right-hand tap, inasmuch as he shows how to do it with a die-stock, whereas the ordinary plan is to use a vise in combination with a tap and a V-block. The accompanying sketch shows the arrangement. The dies are opened sufficiently to admit a right-hand tap of the desired lead, and the rod to be threaded. The rod is backed up by a piece of annealed copper into which the threads may imbed themselves without injury. The die should be of the same lead as the tap, which permits the tap being accurately meshed with its thread. With this combination it is claimed that a fair left-hand thread may be cut with the ordinary right-hand equipment. It now remains for some ingenious reader to show us how a left-hand nut can be cut with extemporized tools.

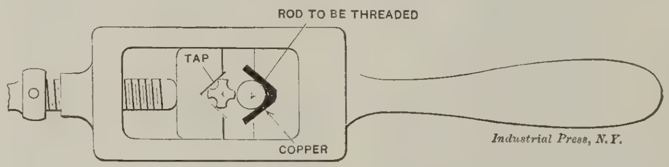

Fig. 3. Cutting Left-hand Thread with Right-hand Tap.

WHY ALUMINUM IS NOT EASILY SOLDERED OR PLATED.

The ever-present, invisible film on an aluminum surface, has a great influence on the success of various operations, especially soldering. The film is supposed to have considerable strength and continuity, and if it is broken or removed by mechanical means the aluminum immediately forms a new one. In soldering aluminum the principal difficulty seems to be due to the failure of the alloy used as a solder to adhere to the aluminum, a condition attributable to the protective film, which must be eliminated before the metals can unite. A successful solder consists of about 21 per cent. of zinc, 76 per cent. of tin and 3 per cent. of aluminum; it may be applied directly to a cleaned aluminum surface without the use of a flux, and at a temperature but little above that which is necessary for soldering copper or iron. There are certain advantages in the apparent complication which the use of a flux involves; a suitable solvent for the oxide film increases the rapidity of the soldering process, increases the certainty of adhesion and enables cheaper soldering mixtures to be used. The requirement for such a flux is that it should dissolve the coating and leave a clean surface for the solder to unite with, upon application of heat; it seems that water cannot be a component of a suitable flux. A material which, for certain solders, forms an admirable flux, is stearic acid; by applying it to a freshly scraped aluminum surface and then applying a tin-lead-zinc alloy, the matter of soldering aluminum presents scarcely greater difficulties than does the soldering of other metals. This almost ever-present coating upon aluminum is also the source of difficulty in the deposition of a permanent coating of other metals upon aluminum surfaces; while it is very easy to deposit a layer of metal upon aluminum from almost any plating solution, in the great majority of operations the resulting coating can readily be removed, sometimes in remarkably thin and continuous layers. The prime requisite in successful depositions on aluminum is the complete removal of the protection film, so that the electro-deposited metal may be applied over the complete surface of and in intimate contact with the aluminum; if this condition is fulfilled, and the coating is non-porous, it will be durable. The converse of this operation, *i. e.*, the electro-deposition of aluminum upon other metals, appears to be impossible from aqueous solution.—*Electrochemical Industries.*

AN EQUATING MICROMETER.

A very ingenious micrometer and recording gage, of English design, is illustrated in Fig. 4. The micrometer portion of this instrument follows the usual lines of construction except that the barrel, which is usually knurled, is in this case formed into a multiple threaded worm which operates a disk mounted below and carrying a series of figures representing various equivalents of the measurement made by the jaws of the micrometer. A bracket is fastened to the bow of the micrometer for carrying this worm disk and there is also a fixed disk which stands in front of the revolving one and has a series of holes through which the numbers on the revolving disk become visible as the worm is rotated.

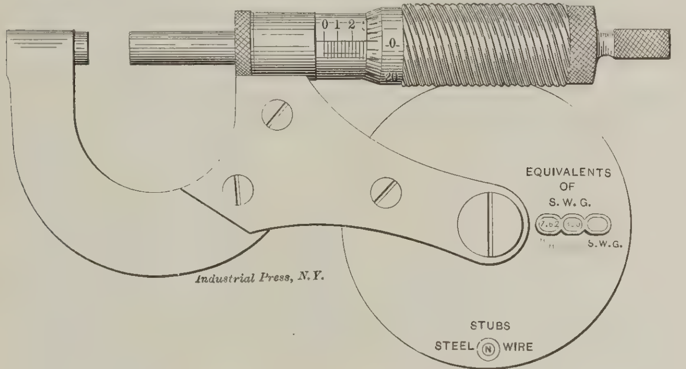

Fig. 4. English Equating Micrometer.

As shown in the cut, the jaws of the micrometer are set at .3 inch and on the dial may be read its metric equivalent 7.62 mm; also 300, denoting the number of thousandths; and 1, over S. W. G. indicating that .3 is the equivalent of No. 1 Stubs wire gage. At the bottom of the disk is another dial for Stubs steel wire in which the size *N* is indicated. This, however, is slightly misleading, as the letter will not occupy the exact center of the opening until the jaws of the micrometer have been moved .002 inch more, giving an opening of .302. A line on the worm disk corresponding with a similar line on the beveled edge of the hole in the outer disk indicates when the exact opening is reached. It is, of course, perfectly practical to apply this arrangement to any kinds of measurements for which the micrometer may be used, and in place of the equivalents here indicated we might have fractions of an inch, sheet metal gages, screw sizes or any other equivalents that might be desired by the user. This instrument is manufactured by Grimshaw & Baxter, London, England.

THE PRODUCTION AND USE OF CARBORUNDUM.

From the new catalogue just issued by the Carborundum Company, Niagara Falls, N. Y., we extract the following interesting information in regard to the production and use of carborundum, which they are producing in large quantities by the aid of electric power furnished by the Niagara Falls Power Co.

The crude materials which are used in the production of carborundum are sand, coke, sawdust and salt, and the first step taken is to reduce the coke to kernels of suitable size to be used as core, and ground to a fine powder to be used in making the mixture or charge for the furnace. To effect this the coke is first passed through a grinder which breaks it up into small pieces. It is then conveyed to the top of the building where it is passed successively through two cylindrical screens, the first of which removes all particles of coke which are too small to form the core, while the second allows kernels of requisite size to pass through its meshes and fall into a core bin, conveniently situated as regards the other constituents of the mixture. Below this bin are scales on which the sand, coke, sawdust and salt are weighed out in proper portions and then conveyed by an elevator to the mechanical mixer, from which the mixture, ready for use, is emptied into a bin.

In the furnace room are fifteen furnaces, built of brick in the form of oblong boxes, the internal dimensions of which are 16 feet in length, 5 feet in depth and 5 feet in width. In the center of the ends are the electric terminals consisting of carbon rods. The side walls of the furnace are first built up to a height of about four feet. The mixture is then thrown into the furnace until it is rather more than half full. A semicircular trench is now formed, the bottom of the trench being a little above the level of the bottom row of carbons, and into this trench is introduced the core. The top is rounded off neatly by hand, so that when finished a solid cylinder 21 inches diameter by about 14 feet long is produced, composed of small pieces of coke, and extending from either end of the furnace. The walls are now built up to a height of about 5 feet and the mixture thrown in and heaped up to a height of about 8 feet.

The electric current by which the furnace is operated is received from the Niagara Falls Power Co. at a pressure of 2.200 volts and must be transformed to lower voltage before passing through the furnace. One of the largest transformers in the world is used to reduce this current to 185 volts, but it may, by means of a regulator, be raised to 250 volts or reduced to 100 volts. The current is at first raised so as to overcome the resistance of the core, which is always greatest when new, but after about an hour the resistance decreases to normal when but little regulation is required, and the volume of the current has increased to a point where 746 kilowatts is expended in heating the furnace. This is continued for a period of about 36 hours after which a few hours more are allowed for the furnace to cool. Then the side walls are taken down and the unchanged mixture raked off from the top until the outer crust of amorphous carborundum is reached. This crust is cut through with steel bars and can then be easily removed from the inner crust of amorphous carborundum. The inner crust is then removed with a spade and the crystalline carborundum exposed, radiating from the core in beautifully colored crystals to a distance of ten or twelve inches. A single furnace yields about 7,000 pounds of crystalline carborundum.

After the carborundum has been removed from the furnace it is taken to a crusher where it is passed under rolls that break the mass of crystals apart. From here it is taken to wooden tanks where it is treated for several days with dilute sulphuric acid to remove all impurities. Then it is thoroughly washed and graded. There are twenty grades of crystals, from No. 8 to No. 220, the numbers indicating the meshes to the linear inch of the screen through which the crystals have passed. The washings pass through a series of tanks which serve to collect the fine powders, and from these are made the so-called "flours" and hand-washed powders.

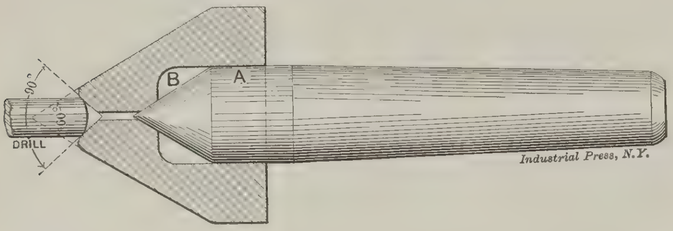
Carborundum is apparently infusible and is quite insoluble in water or any acid. Its hardness lies somewhere between nine and ten degrees, probably very close to ten degrees, which is the hardness of the diamond. Its specific gravity is 3.123, which is less than that of emery, one and one-quarter pounds of the latter being equal in volume to one pound of the former. It is used mainly for grinding wheels of all kinds and also in the shape of sticks, knife sharpeners, hones, scythe stones, cloth, paper, etc.

In the manufacture of the wheels, the carborundum is mixed in certain proportions with kaolin and feldspar, and the mixture is then placed in a mold and pressed in a hydraulic press. The wheel, when removed from the mold, is placed on a support called a "bat," which is made of baked clay. The vitrification of the wheels is carried on in kilns similar to those used in making porcelain. The "bats" upon which the wheels rest are placed on clay in "saggers" and are then built up in columns until they reach the roof of the kiln. When the kiln is filled it is closed and fired, an operation occupying about seven days, and is then allowed to cool slowly. When the wheels are removed they are placed in lathes and trued up with a dresser or diamond.

CONTRIBUTED NOTES AND SHOP KINKS.

AN IMPROVED FORM OF PIPE CENTER.

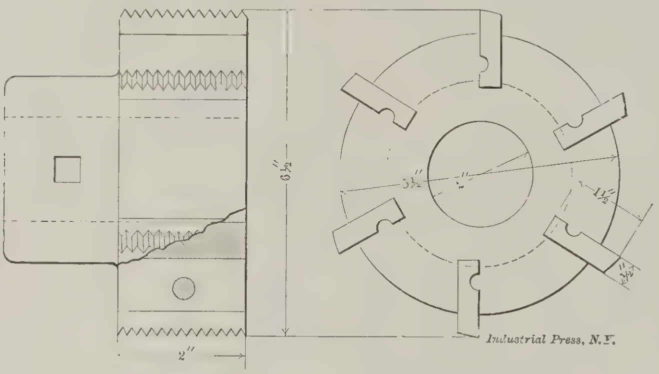
A. Putnam sends a sketch of a combination pipe and female center which, when carefully made and hardened, will be found very useful for a much wider range of work than is reached by the ordinary form of pipe center. It is turned at an angle of 60 degrees on the outside, for pipe use, while the point has a 90-degree female center for use with drills, as illustrated. It should be a good fit at *A* and is cut away at *B* so that the bearing surface and consequently the friction on the tail center is reduced. A small hole is drilled completely through the end of the center to allow the air in the space *B* to escape when the fit at *A* is very snug.



Industrial Press, N.Y.

A LARGE TAP WITH CAST-IRON BODY.

A. B. G. sends a sketch of a large tap which was made by casting tool steel blades into a cast-iron body. The blades, of which six were used, were grooved and drilled so that the iron could fasten to them more securely. They were finished all over and then passed through melted metal in order to warm them up before casting. When the castings were finished as required, they were heated all over, dipped, and the temper drawn. One of these taps served for tapping over 200 valves and it could then be annealed, recut and hardened for further use. The taps were used in a lathe on a boring bar to which they were fastened by a square key passed through the shank of the tap. A few dimensions are given on the sketch to show the size of the cutters and the general proportions of the tap.



Industrial Press, N.Y.

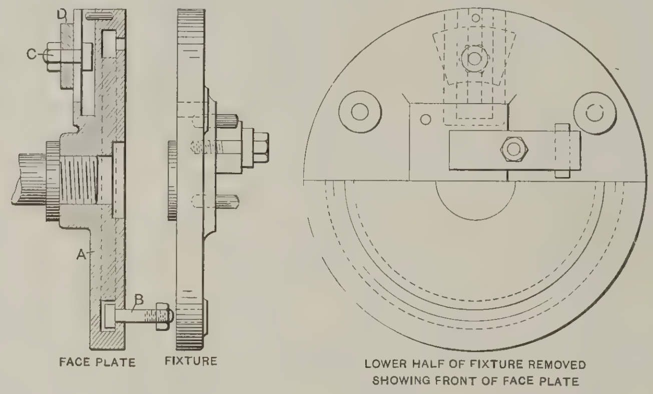
REMOVING SHAFTS FROM BABBITTED BOXES.

Regarding this subject N. G. B. writes: I have noticed in several repair shops the methods used when babbitting solid boxes and in most cases I note that trouble is experienced in removing the shaft, as it often sticks very tight. Machinists hold various opinions as to the best remedy for this trouble; some advise wrapping a piece of oiled writing paper around the shaft, others advocate the use of oil, and still others believe that the shaft should be smoked.

It happened the other day that we had several pulleys to babbitt on a 1¼-inch shaft. On one of these we tried the oiled paper and it was necessary to use a hammer to remove the shaft. On the second the shaft was simply oiled and still it stuck. The third shaft was smoked and this likewise stuck. We also had two boxes to be babbitted and on the shafts for these we used white lead. These shafts almost fell out from the box. While this "kink" may not be new to all of the readers of MACHINERY, there are doubtless many who will find the use of white lead of considerable assistance when they have work of this kind to do.

A FACEPLATE FOR USE WITH CHUCKING FIXTURES.

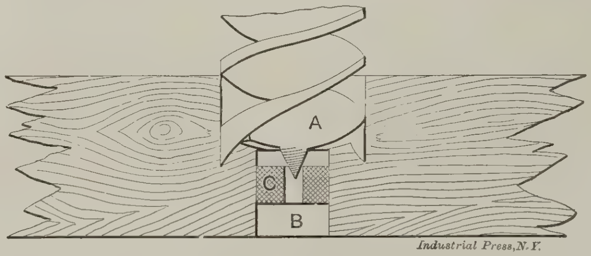
The accompanying sketch, sent us by R. E. F., illustrates a means for centering chucking fixtures accurately, and balancing them to prevent the vibration which results when large, lopsided masses of iron are revolved rapidly. The faceplate, *A*, is screwed onto the spindle in the usual manner and the fixtures are all made with a uniform base, and have three holes for the clamp bolts, *B*, and an accurately turned boss which enters a corresponding counterbore in the faceplate. On the back of the faceplate is a radial T-slot which holds the square headed bolt, *C*, and secures in place a counterweight, *D*. At the end of the slot is placed a stop-pin to guard against an accidental discharge of the counterweight by centrifugal force. The clamping bolts, *B*, are held in the faceplate by a circular slot so that the fixture may be revolved in relation to the faceplate and, with the provision shown for adjusting the counterweight, the whole rig, with work in place, may be balanced to run without perceptible vibration. Several sizes of counterweights are provided so that pieces of widely varying weights may be counterbalanced.



Industrial Press, N.Y.

COUNTERBORING HOLES FOR PATTERN WORK.

"Patternmaker" writes that the following "kink" often comes very handy to him when he finds it necessary to counterbore a hole in a pattern. Under ordinary circumstances the large hole *A* would naturally be bored first and then in the bottom of this would be drilled the smaller hole *B*. It is not, however, always practical to do the work in this order, so if the small hole *B* has been drilled first, and it is then necessary to counterbore the hole *A*, it is accomplished with the assistance of the small lead disk shown at *C*. A liberal assortment of different sizes of these disks is kept in the tool chest and even if one of the exact size is not at hand the softness of the metal readily permits one of a larger size to be shaved down with little trouble. This disk fills the small hole and affords a center for the screw of the drill which is thus led concentric with the hole first drilled. This is a much more satisfactory as well as quicker way of doing this work than the ordinary method of driving a temporary plug in the small hole.



Industrial Press, N.Y.

* * *

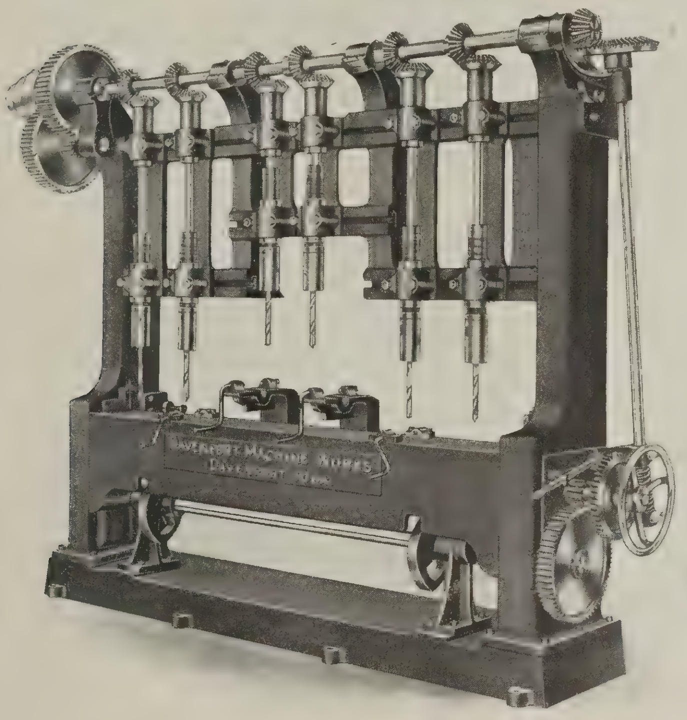
Working on the principle that if a power hack-saw having one saw is a good thing, a machine having two oppositely disposed saws will be twice as good, a British firm has brought out a power hack-saw for sawing I-beams in which two saw frames stand in a vertical position and attack the beam from opposite sides at the same time. It is said that the machine will cut through a 12 x 5 inch steel girder in 20 minutes, and that the opposite saw cuts will not deviate more than 1-32 inch at the meeting point.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

A NEW ARCH-BAR DRILL.

The Davenport Machine Works, Davenport, Iowa, have just brought out the new arch-bar drill which is illustrated in the photograph herewith. This machine, as shown, carries six spindles but it may be arranged for carrying eight if required. The crown of the arch-bar being drilled is held in a double support while the ends rest directly upon the table of the machine. The spindles have lateral adjustment for change of centers, and each spindle can be adjusted vertically to allow the use of drills of different lengths. The table, with the work, is fed up to the drills by means of two cams, one under each end of the table, which are driven by worm and spur gearing from the driving shaft. The table, which is counterbalanced, may also be raised or lowered by hand.



Davenport Arch-bar Drill.

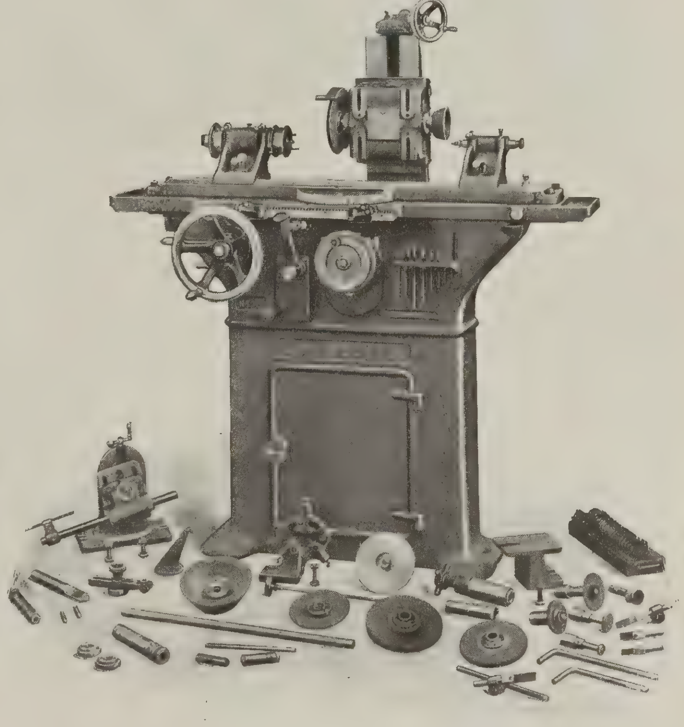
The drills are driven from a main shaft which is strongly back-geared to a three-step cone pulley carrying a four-inch belt. An automatic stop and quick return for the table also are provided. The width of the machine between housings is 7 feet and 4 inches, and it has a capacity for operating, at one time, six 1 15-16-inch drills with a feed of 1-64 inch per revolution of the drill. The weight complete with countershaft is about 12,500 pounds.

NEW UNIVERSAL AND TOOL GRINDING MACHINE.

The accompanying photographs illustrate a new grinding machine that has just been placed upon the market by the Brown & Sharpe Mfg. Co., Providence, R. I. As the name implies, this machine partakes in its nature, both of the universal grinder and the tool grinder, being designed to meet the requirements of the tool room for grinding milling cutters, formed cutters, beveled cutters of any angle, straight and taper reamers, etc., and also adapted to cylindrical grinding, either straight or taper. It is especially adapted to the needs of shops where the volume of work does not warrant the installation of different grinding machines to accommodate the variety of work that can be ground upon this machine. The arrangement of the various parts of the machine has been made with a view to facility of manipulation, simplicity and ease of access.

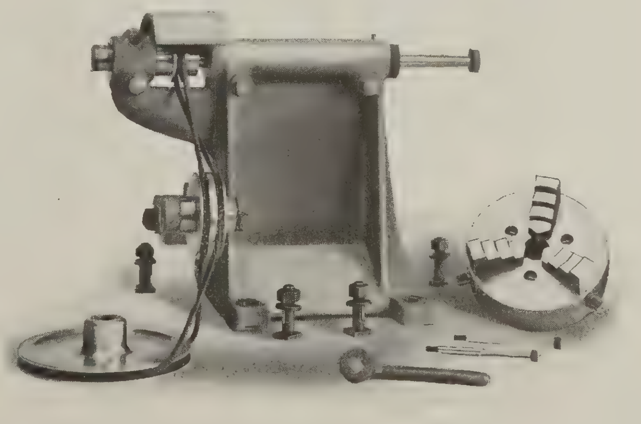
The grinder is provided with a swivel table which turns on a central stud and can be set to 45 degrees either side of the center line. Fine movement of this table is obtained by means of a thumbscrew adjustment. The table has an automatic longitudinal feed of 17 inches which is regulated by dogs that are provided with screws for fine adjustment. There are four changes of table feed, ranging from 6.7 to 40 inches per minute. A hand wheel is also provided for hand feed of the table, coarse or fine feed being obtained by a movement of the lever which controls both hand and power feeds.

The headstock and footstock have No. 3 taper holes and permit carrying work between the centers up to 8 inches in diameter by 24½ inches in length. The head spindle has both tight and loose driving pulleys and the front end is threaded to receive a chuck or faceplate. The footstock spindle can be adjusted longitudinally and has a fine adjustment by means of thumbscrews.



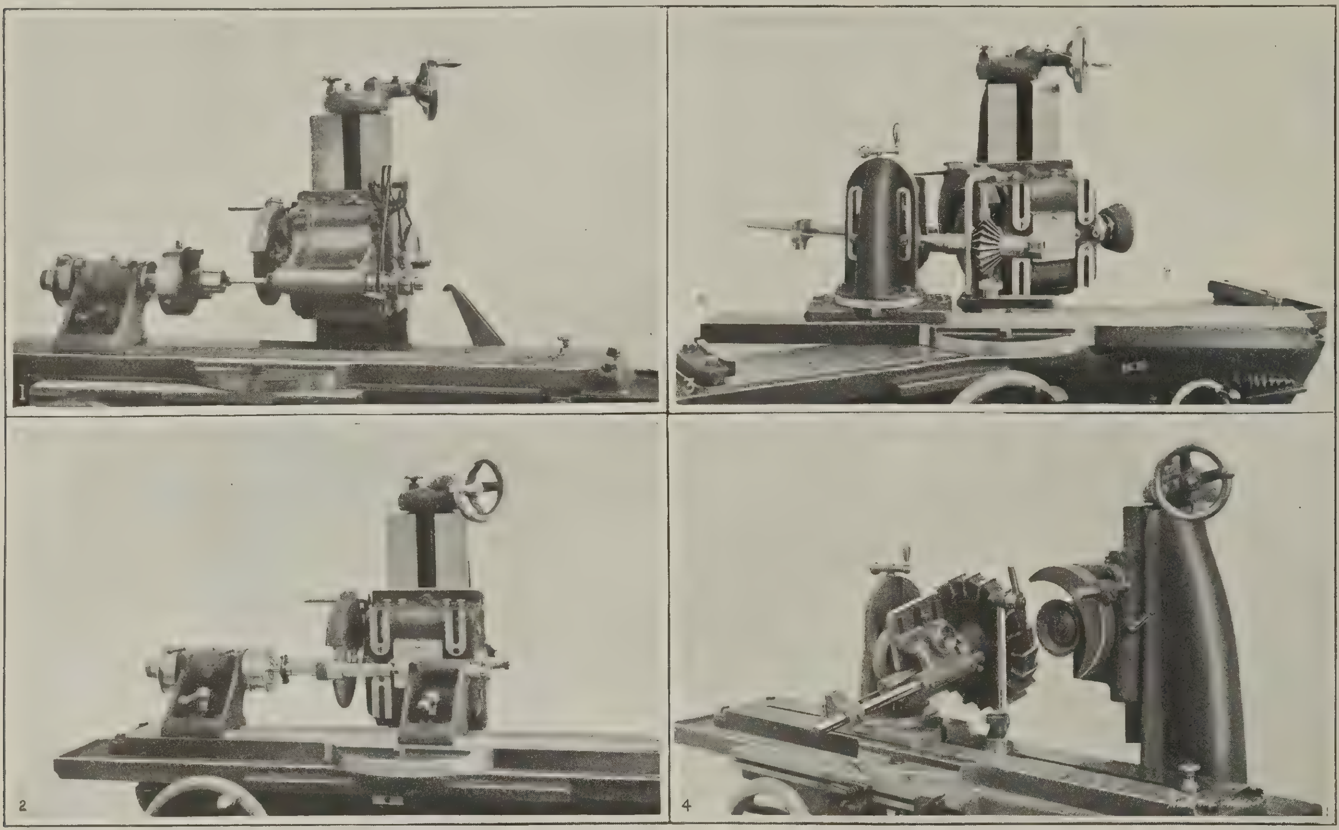
Brown & Sharpe Universal and Tool Grinding Machine.

The headstock and footstock may be replaced by the universal head, shown on the floor at the left of the machine, for holding all forms of milling cutters directly by the shank or arbors, also for holding cutter bars to receive work mounted on sliding shells. The headstock sleeve and pulley can be removed and placed in the universal head, for grinding work that is larger in diameter than can be swung on the centers. The base is graduated to degrees around its circumference and the tool head swivels to 90 degrees either side of zero. The tool head has a vertical hand adjustment of 4 inches and at its extreme height will swing 16 inches in diameter over the table.



Internal Grinding Attachment.

The cross feed is operated by a hand wheel graduated to read in thousandths of an inch on the diameter of the work. Both ends of the spindle are tapered to receive wheel sleeves upon which the wheels are mounted. The spindle is carried in a slide which has a vertical adjustment upon the slide upright, the movement being made by a handwheel that is graduated in thousandths of an inch. The upright has a transverse movement of 10½ inches and is operated by the cross feed hand wheel above referred to. It swivels on its base which is graduated to read to 90 degrees on either side of the center line.



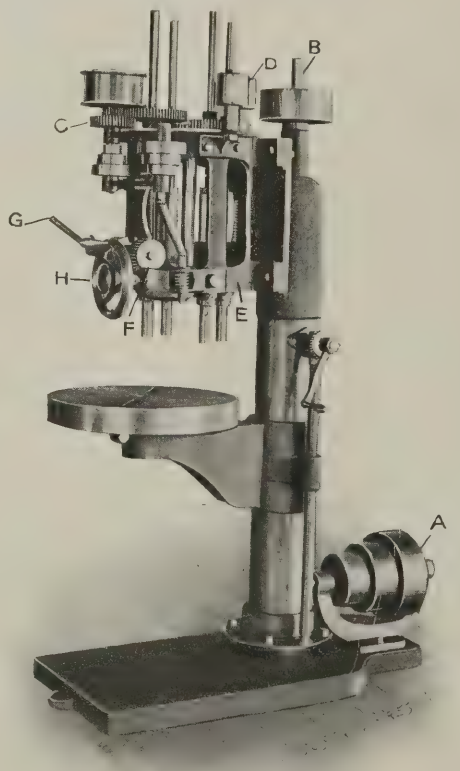
Some of the Applications of the Brown & Sharpe Universal and Tool Grinding Machine.

Numerous attachments are provided for increasing the scope of the work that this machine can accomplish. The internal grinding attachment on preceding page is made for grinding holes, either straight or tapering, from ¼ inch in diameter upward, and to 2¾ inches in depth. When in use this attachment is clamped to the front of the wheel slide by four bolts fitting in T-slots. The spindle is driven by means of a round belt running on a grooved wheel, that is placed on the right hand end of the main spindle. A circular grinding attachment is provided for grinding concave or convex cutters and work of a similar character, and a surface grinding attachment affords a means for grinding flat surfaces. This latter attachment comprises a wheel spindle extension, table plate and vise.

The group of photographs illustrates a few of the uses to which this grinder may be applied. Fig. 1 shows the internal grinding attachment employed for grinding a hole in a bushing. The bushing is held in a universal chuck mounted on the headstock spindle and revolved by the live center pulley. Fig. 2 shows the method employed for grinding the exterior surface of the same bushing, which in this case is held on an arbor revolving on dead centers. Fig. 3 illustrates the grinding of a double angle cutter, which is mounted on an arbor supported in the tool rest of the universal head. By swiveling the table, both angles can be ground without resetting the cutter. In Fig. 4 is shown a face milling cutter, held in the universal head, the teeth being ground on the sides by using a dish wheel. It will be noted that the tool holder is tipped at an angle to give proper clearance, and that the spindle slide upright has been turned through an angle of 90 degrees so as to present the end of the spindle to the work.

A MULTIPLE SPINDLE TURRET DRILL.

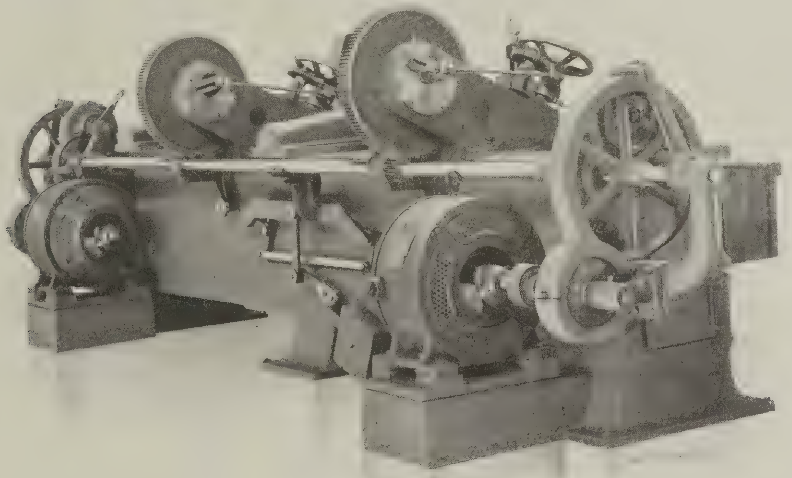
The accompanying half-tone illustrates a new turret drill, designed by Mr. S. A. Baker, and recently placed upon the market by the National Separator and Machine Co., Manchester, N. H. This machine is for drilling, tapping, reaming, etc., on duplicate parts without the necessity of changing the tool or the work. It is shown in the photograph as carrying four spindles but can be furnished, by the builders, with three, four, five, or six spindles, as desired, and with either power or lever feed. It is driven, from the countershaft, by the three-step cone *A* which operates the shaft *B*



Four-spindle Turret Drill.

by bevel gears. This shaft connects with the driving gear *C* by means of a belt which passes around the idler pulleys *D*. The turret carrying the spindle revolves in the casing *E* and is arranged so that when the desired spindle is turned to the front, the driving gear connects with that on the spindle and causes it to revolve while the other spindles are left back out of the way until they are to be used, when the turret is revolved to each spindle in its turn. It will be seen in the photograph that the same size gear is placed on all of the spindles but one and this is geared down to a slow speed for tapping and counterboring.

The spindle is fed down to the work by the worm and worm-wheel *F* and is arranged so that it can be moved down directly and quickly by the lever *G*, also by the handwheel in front, and by power by simply tightening the knob *H*. The spindles can all be set to stops and are counterbalanced. All of the tools work to the same point on the table and only one spindle, the working one, is revolving at a time. The locking pin is directly beside the spindle that is in use, and the moment power is applied the strain passes to the frame of the machine, the turret acting simply as a guide to the spindle.



Cincinnati Traverse Shaper with Electric Drive

ELECTRICALLY - DRIVEN DOUBLE HEAD TRAVERSE SHAPER.

The double head traverse shaper shown herewith has recently been supplied to the Locomotive & Machine Co., Montreal, Canada, by the Cincinnati Shaper Co., Cincinnati, Ohio. This machine is operated by two Westinghouse motors, which are arranged for the 2-voltage, 3-wire system and rated at 3 and 6 horse power at 115 and 230 volts respectively. The variation of speed of the machine is obtained through the variation of the motor, and also by back gearing on the machine, as may be seen through the large gear wheel on one of the two splined shafts at the back. This large gear wheel is driven by a pinion mounted on the motor shaft.

The two heads are driven independently, one from each end of the machine and as they are arranged to work at any point along the bed it is necessary that they travel past the center of the bed. Owing to the length of the splined driving shafts by which the heads are driven it has been thought best to provide a support at the center of the bed and the photograph shows the arrangement that has been made for automatically depressing this support when one or the other of the heads is passing the center of the bed. As stated, each head is driven independently by a full length driving shaft and the feeds to each saddle are also operated by independent full length screws. The travel of each saddle is 118 inches, the maximum distance between the tools 144 inches, and the minimum 26 inches. The total weight of the machine is about 14,000 pounds.

VARIABLE SPEED MOTOR DRIVE FOR PLANERS.

The half-tones, Figs. 1 and 2, illustrate a new motor-driven planer, built by the Cincinnati Planer Co., Cincinnati, Ohio, which is designed to give a variable speed to the cutting stroke and a constant return stroke at all times. It is adapted to the use of a standard constant speed motor which is mounted upon the top of the housings and from which the power is transmitted to the rear, or constant speed shaft, by a pair of spur gears, one of which is of rawhide to obviate any noise. This first or constant speed shaft carries the return shaft and consequently always gives the table the same speed for the return stroke. Upon this shaft is also mounted a heavy flywheel, to relieve the strain on the motor at the reverse.

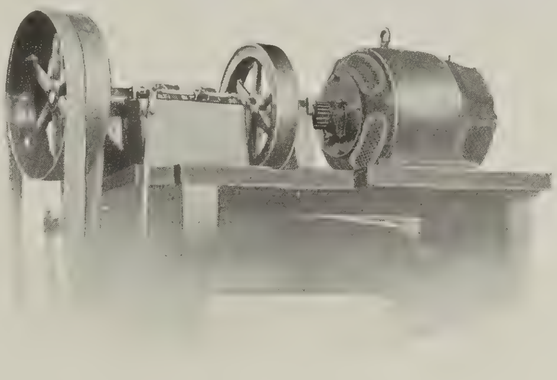


Fig. 1. Rear View of Variable Speed Planer Drive.

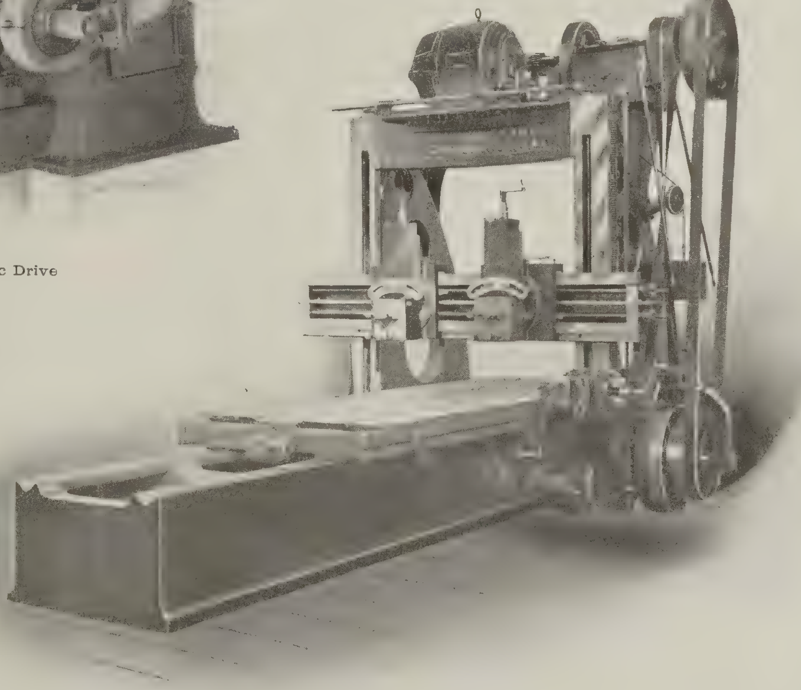

Fig. 2. Cincinnati Planer with Variable Speed Motor Drive.

The pulley for the cutting stroke is placed on a separate, or forward shaft, as shown in the front view, Fig. 2, and to it power is transmitted from the constant speed shaft by two trains of gearing, each giving two speeds, which consequently makes four cutting speeds available for driving the platen. The changes in speed are obtained by simply moving one or both of the levers shown on the side of the planer, and they may be made either while the machine is in operation or while it is standing idle.

The cuts illustrate this drive as applied to a 48 x 48-inch planer, but the builders state that the same style of drive has been applied to all the other sizes of planers which they manufacture. The speeds used on this machine were arranged for cutting at 20, 25, 30 and 36 feet per minute, with a constant return speed of 72 feet per minute.

HORIZONTAL BORING, DRILLING AND MILLING MACHINE

The Fosdick Machine Tool Company, Cincinnati, Ohio, have just placed upon the market the machine illustrated in Figs. 1 and 2, which is designed for both light and heavy boring, drilling, tapping, reaming, facing and milling, all of which operations are performed upon the work which is fastened to the table. The accompanying half-tone gives a view of the machine as seen from the operating side, while the line-drawing, Fig. 2, shows an end view and illustrates many of the details of construction.

The machine is driven by a splined shaft, which traverses the driving cone on the rear of the bed. The column, carrying the spindle head, has a horizontal movement on the bed, by hand or power, and a quick forward and return motion by power which is operated by a handwheel on the front of the bed. The spindle head is counterbalanced and provided with a safety chain. It has a movement on the column by hand or power, and for quick adjustment is operated through a rack and pinion by means of a pilot wheel on the front of the spindle head. The spindle runs in adjustable box bearings, and has a thread cut on its front part to receive chucks, large milling cutters, facing heads, etc. It is made to revolve in a right or left hand direction by the operation of a reversing lever. This is very convenient for facing, tapping or milling operations.

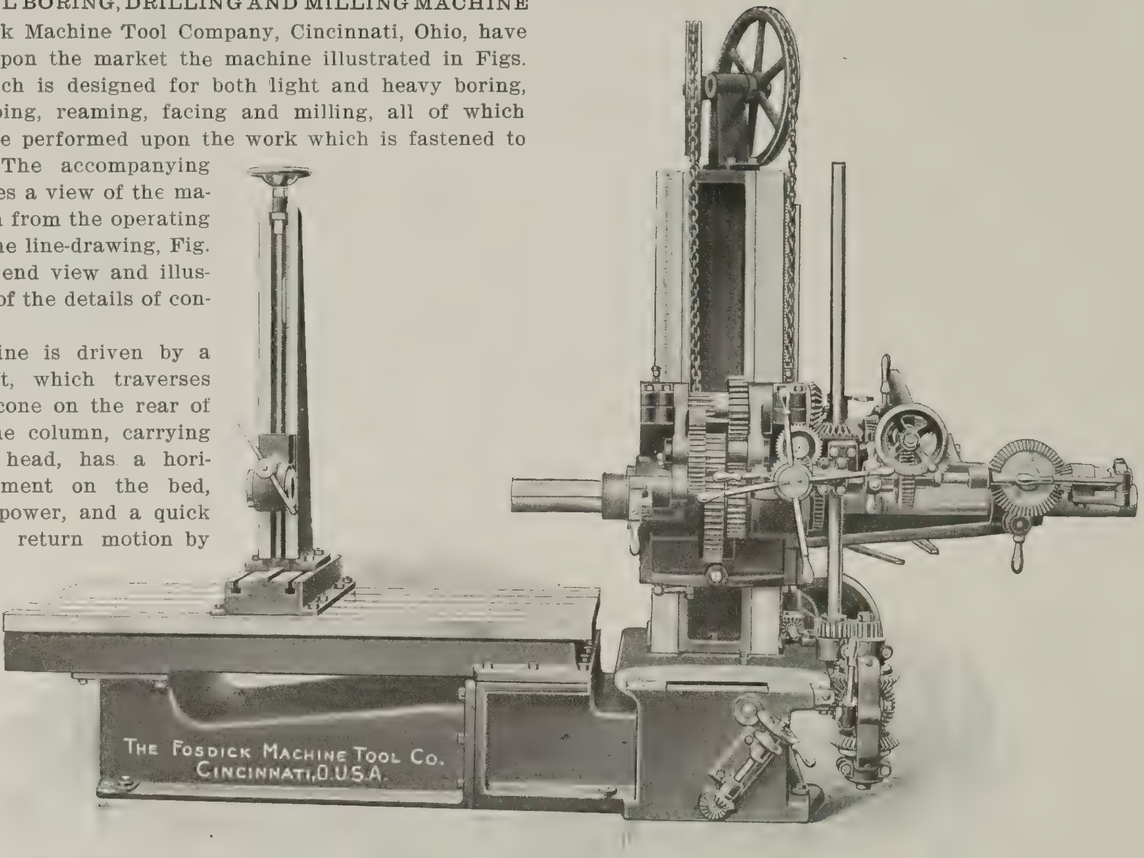

Fig. 1. Fosdick Horizontal Boring, Drilling and Milling Machine.

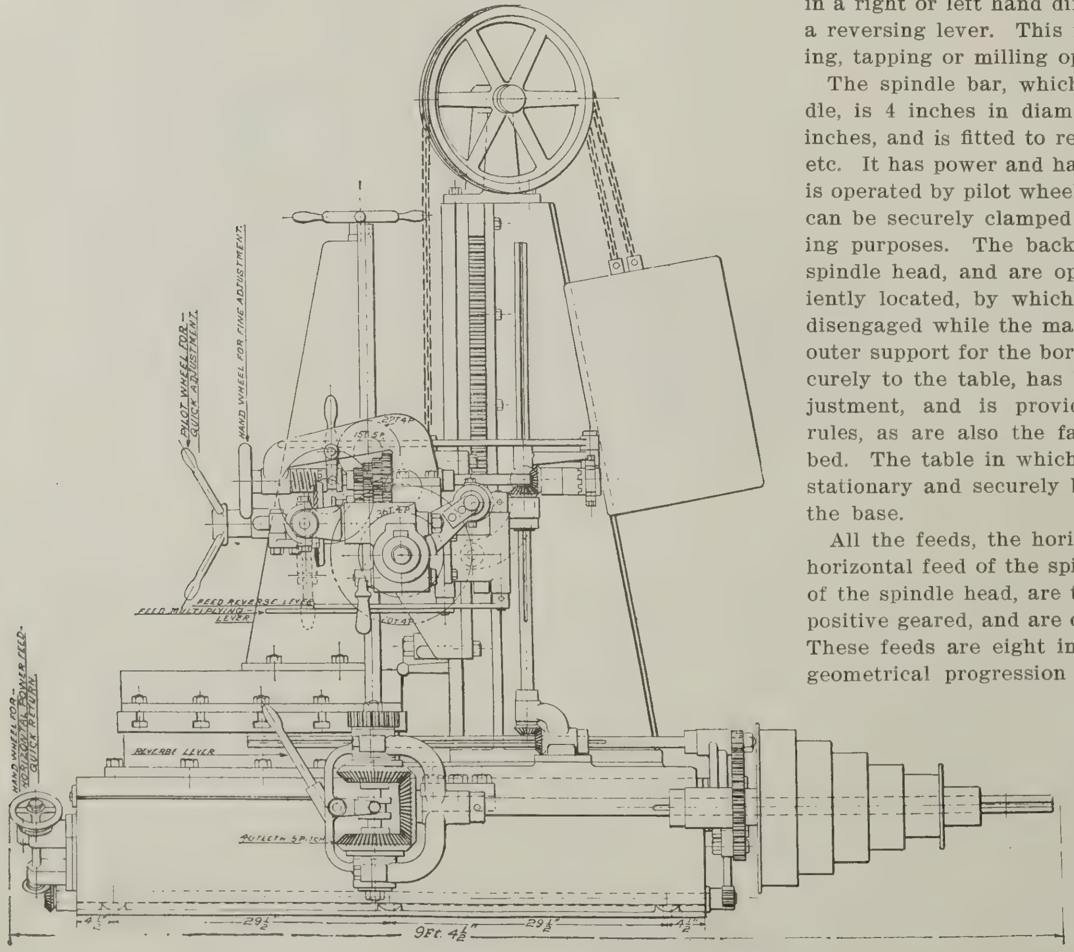

Fig. 2. End View of Horizontal Boring, Drilling and Milling Machine.

The spindle bar, which passes through the spindle, is 4 inches in diameter, has a traverse of 22 inches, and is fitted to receive drills, taps, reamers, etc. It has power and hand feed in both directions, is operated by pilot wheel for quick adjustment, and can be securely clamped when in use for face-milling purposes. The back gears are located on the spindle head, and are operated by a lever conveniently located, by which they may be engaged or disengaged while the machine is in operation. The outer support for the boring bar can be clamped securely to the table, has horizontal and vertical adjustment, and is provided with graduated steel rules, as are also the face of the column and the bed. The table in which the T-slots are planed, is stationary and securely bolted to both the bed and the base.

All the feeds, the horizontal feed of the column, horizontal feed of the spindle bar, and vertical feed of the spindle head, are taken from the spindle, are positive geared, and are operated by hand or power. These feeds are eight in number, and arranged in geometrical progression from .007 to ¼ inch per revolution of spindle; they are all reversible. The spindle speeds are ten in number, arranged in geometrical progression from 4 to 260 revolutions per minute. The total height of this machine is 8 feet and the length, over all, 10 feet 6 inches. The net weight is 12,000 pounds.

THE "QUEEN CITY" SHAPER.

The 16-inch crank shaper illustrated in Fig. 1 is especially designed for use with the high-grade tool steels and is furnished by the builders either with or without back gearing. The back gearing, when employed, is wholly enclosed within the column and is operated by a lever at the back. Fig. 2 shows a line drawing of this mechanism, and also shows the different trains of gears that are used for driving the bull wheel. The ram is of special construction, so designed as to lose none of its rigidity throughout the stroke. The connection of the rocker arm to the ram is of the link type, giving a straight pull on the cutting stroke and a quick return. The arm is provided with an adjustment to compensate for wear of the crank shoe.

The rail has unusually wide bearings on both top and bottom, and the adjusting gibs between the ram and the rail are firmly held by screws fitted with nuts flush with the casting. The head may be swiveled, over a graduated disk, to any required angle, and the down-feed screw is provided with a graduated collar indicating thousandths of an inch. The horizontal traverse screw is also provided with a similar collar. The table is of box form, having T-slots on top and side, and a *V* for holding shafts or similar work vertically. It can be readily detached from the apron. The vise has a graduated circular base, allowing it to be set at any angle, and it may be attached to the top or side of the table. An opening is provided under the ram so that shafts or pieces of any length similar may be passed through for key-seating. The length of the stroke can be quickly changed and locked from the working side without stopping the machine. The shaper is the product of the Queen City Machine Tool Company, Cincinnati, Ohio.

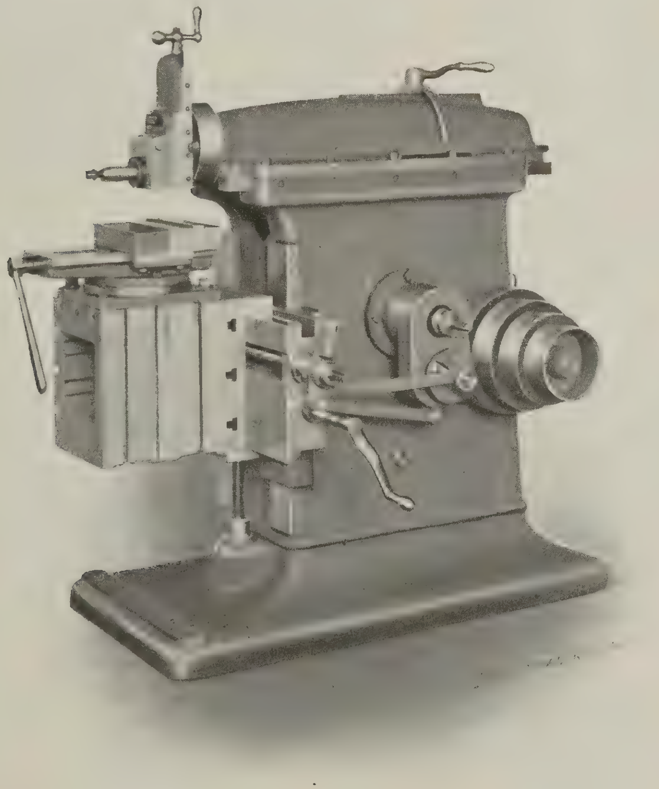

Fig. 1. "Queen City" Crank Shaper.

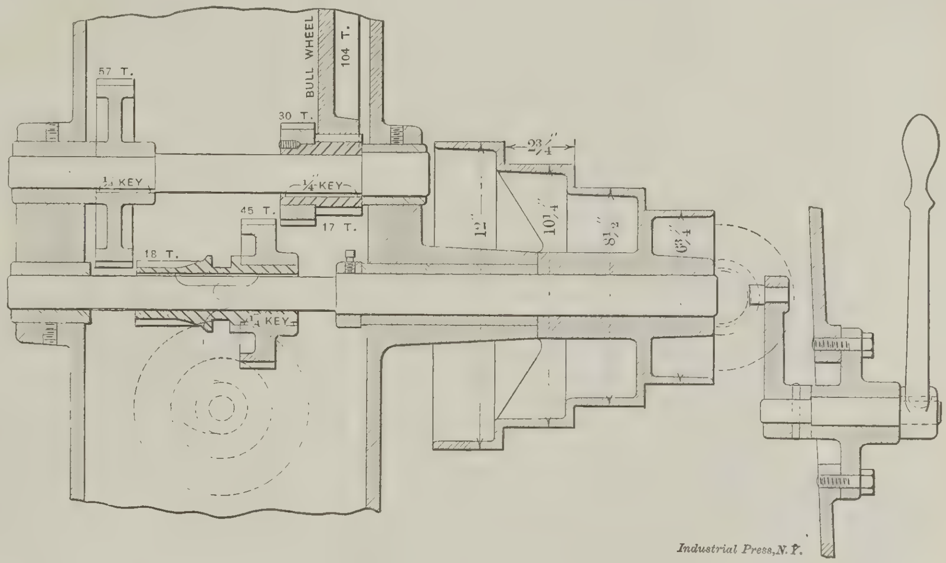

Industrial Press, N. Y.

Fig. 2. Back Gear Arrangement of "Queen City" Shaper.

NEW LATHE WITH ALL-GEARED HEADSTOCK.

The American Tool Works Company, Cincinnati, Ohio, have just brought out a new lathe, with all-geared headstock forming a unit to which any type of electric motor may be readily connected. The motor may be placed on the top or at the rear of the gear-casing. The changes of speed are produced by an arrangement of six gears, oppositely disposed on the spindle and driving shaft, which are engaged by means of levers placed in front of the speed box. In connection with a variable speed motor, on a 20-inch lathe, this mechanism provides for sixty spindle speeds, ranging from 5 to 322 revolutions per minute. The lever for the control of the motor is placed on the right-hand side of the carriage.

This same speed-changing mechanism is also adapted for belt drive, and will permit of a machine thus installed being converted into a motor-driven tool at any future time. In addition to the speed variator, the lathe is equipped with a rapid-change gear mechanism providing a wide range of changes for feeding and screw cutting, each change being available while the machine is in operation and without the removal of a single gear. The leadscrew is placed on the inside of the bed so that the pull on the carriage is directly under the cutting tool, and the half-nuts by which the screw is engaged and released are operated by a lever at the front of the carriage.

A NEW BENCH SHAPER.

A new crank shaper that is especially adapted to tool room and bench work has just been placed upon the market by L. E. Rhodes, Hartford, Conn. Taking into consideration that a large percentage of shaper work is small and of a light nature, coming well within the range of 7 inches, this length of stroke has been selected. The greatest distance from the table to the ram is also 7 inches. The driving arm reaches well into the interior of the ram and is connected by a link which is located at a point in a direct line with the greatest resistance of the cutting tool. The shaper is provided with ratchet cross feed and both cross and down feed screws have micrometer adjustment. The table is of box pattern, provided with a vise having quickly adjustable jaws and a swivel base graduated in degrees. Upon the driving shaft is mounted a three-step cone and also a handwheel. Although designed for a bench machine, it may be supplied mounted upon an iron stand if desired. It occupies a floor space of 22 x 24 inches, and weighs, with the countershaft, 290 pounds.

VERTICAL BORING, FACING, AND TAPPING MACHINES.

Figs. 1 and 2, next page, show two types of boring, facing and tapping machines that are the product of Baker Bros., Toledo, Ohio, and are designed for the heaviest kind of work in locomotive shops and shops manufacturing large steam fittings. The main spindle is driven by means of a cross arm in the housing shown on top of the driving gear. This arm is about three times the diameter of the spindle in length and is provided with broad bearing surfaces, which work in vertical grooves on either side of the housing. This construction avoids the excessive friction that is occasioned by the usual method of driving by means of a feather in the hub of the driving gear. The thrust of the spindle is taken on roller bearings.

The entire train of gearing employed is very heavy, the main driving gear being 28 inches in diameter by a 4-inch face, and 2 pitch. Triple back-gears are provided giving, with four steps on the cone pulley, twelve changes of speed. The ratio of gearing with the triple back-gears is 1 to 82. The twelve spindle speeds range from 2 to 45 revolutions per minute, and for each spindle speed there are six belt-driven feeds, varying from 0.54 to .003 inch per revolution of the spindle. In addition to the belt feeds the machine is provided with a positive geared feed which, by means of change gears, will give any feed from .07 to ¼ inch. These are arranged so that a positive lead corresponding to any number of threads from 4 to 14 may be obtained for tapping. The spindle, which may be made with either 14 or 20 inch travel, is provided in addition to the belt geared feeds above-mentioned, with lever feed, hand-worm feed, an automatic stop, and is counterbalanced.

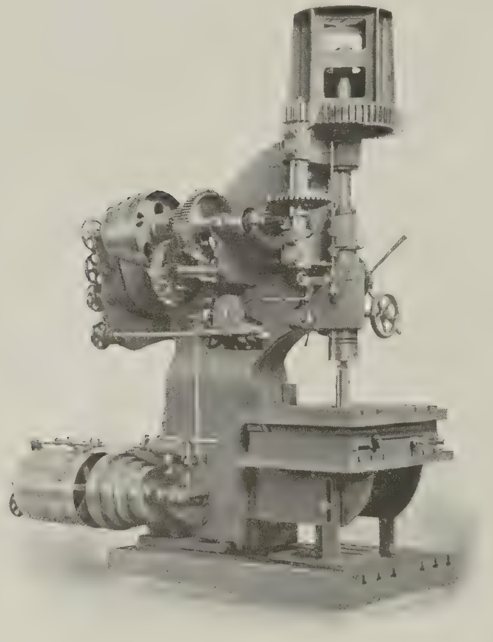

Fig. 1. Single Vertical Boring, Facing and Tapping Machine.

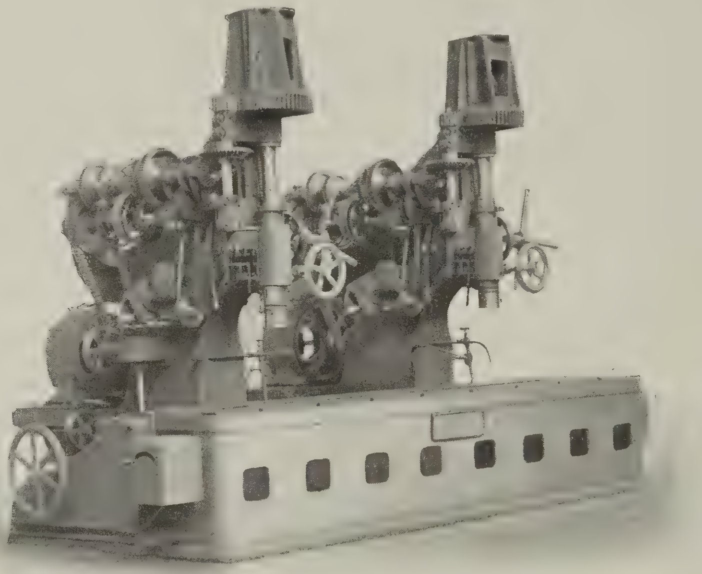

Fig. 2. Duplex Vertical Boring, Facing and Tapping Machine.

The machine is furnished with a compound table, 30x36 inches, which is placed under the regular table and is very handy for use in chucking work, as the piece may be clamped approximately in position and then, by means of the table screws, brought into line with the spindle or boring bar. This table has a right-and-left adjustment of 20 inches, and an in-and-out adjustment of 14 inches, and with it the machine may often be used to advantage for milling.

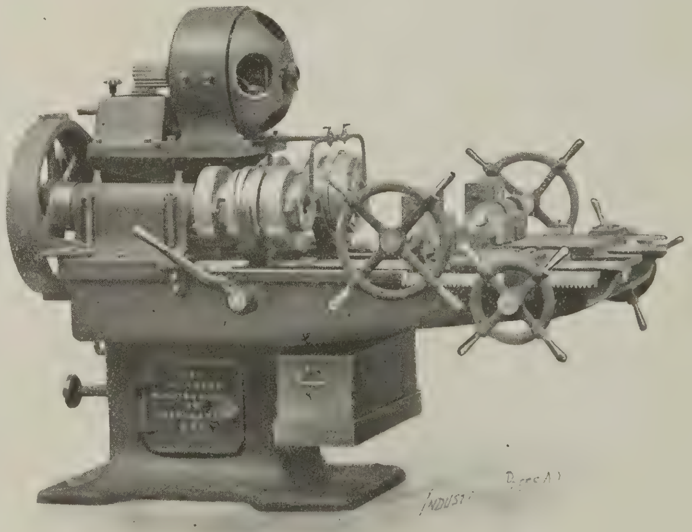
Fig. 2 shows a combination of two of these machines upon a single base, each spindle being driven by a 10 horse power General electric motor, by means of a Renold silent chain. The ratio of the gearing to the spindle is 175 to 1 and triple back-gears are employed which, being again compounded, give six changes of speed, varying from 3½ to 43 revolutions per minute. Intermediate speeds are obtained by means of speed control. There are twelve changes of feed positively driven by Renold silent chain and ranging from .1 to .005 inch per revolution of the spindle. Both frames are adjustable along the base, to vary the center distance, and the left-hand frame may be moved by power.

NEW 17-INCH LATHE WITH TURRET ATTACHMENT.

Greaves Klusman & Co., Cincinnati, Ohio, have entirely redesigned their 17-inch engine lathe and are placing it upon the market fitted with power feed automatic turret. In addition to the feeds of this turret, which are obtained by the usual cone pulleys, it has three changes of feed on the front side of the turret where they are directly under control of the operator by means of a lever placed near the pilot wheel. The lathe is provided with a five-step cone pulley for 2½ inch belt, and is strongly back geared. All feeds are reversed at the apron and arrangement is made for preventing the engagement of feed rod and leadscrew at the same time. The cross and longitudinal feeds, however, may be operated simultaneously. Provision is made for cutting threads from 2 to 48 per inch, including the 11½ pipe thread, without change of spindle gear, the change from right- to left-hand thread being made by a reversing lever at the headstock. There are four changes of belt feed, and gear feed is also provided, so that all feeds needed can be obtained with the feed rod, reserving the leadscrew solely for thread cutting. The countershaft has friction pulleys with a special arrangement for oiling without throwing off the belt.

A DUPLEX MOTOR-DRIVEN BOLT-CUTTER.

The accompanying half-tone illustrates a 2-inch double bolt cutter, with motor drive, that has just been brought out by the Reliance Machine and Tool Company, Cleveland, Ohio. This is the same as their standard machine, with the exception that the belt pulley is replaced by a motor, which is placed between and above the headstocks, where it is free from oil and chips and occupies no valuable floor space. A 3 horse power Crocker-Wheeler reversible, variable-speed motor is used, giving a speed variation of 3 to 8. A nest of gears placed between the pinion on the motor shaft and the main pinion of the machine increases this ratio to 1 to 6. By means of a Cutler-Hammer speed controller used in connection with the motor, eighteen spindle speeds are obtained. While this arrangement has proved so satisfactory as to be adopted as the standard drive for this machine, the builders inform us that they are prepared to furnish any other electrical equipment that may be desired, and connect the same either by direct gearing, belt or silent chain.



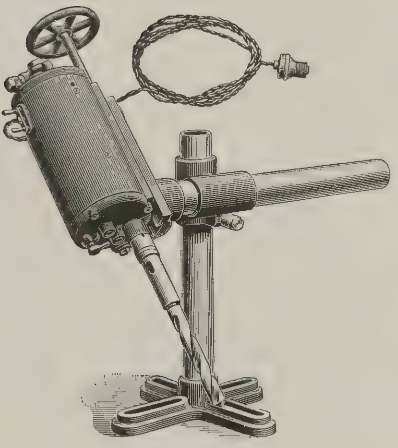
Two-inch Duplex Motor-driven Bolt Cutter.

PORTABLE ELECTRIC "SCOTCH" DRILL.

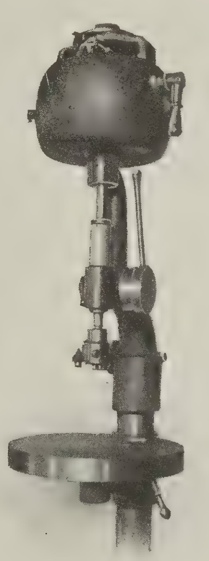
The portable, electrically-driven "Scotch" drill, illustrated herewith, is being placed on the market by the Hisey-Wolf Machine Co., Cincinnati, Ohio. This machine has a capacity for carrying drills up to 7/8 inch in diameter and has a feed of 7 inches by the handwheel. The adjustable bracket upon which the drill is mounted has a movement of 20 inches in any direction, making the machine universal. The drill has two speeds, the power being obtained from any incandescent lamp circuit where direct current is employed, the motor being wound for 110 and 220 volts. The motor is inclosed and dust proof and is suitably geared to develop the necessary power up to the capacity of the drill. The machine may be carried from point to point around the shop, its sphere of action being limited only by the length of the flexible wire connection. Its weight is 95 pounds and extreme height 30 inches over all.

TWELVE-INCH ELECTRIC-DRIVEN SENSITIVE DRILL.

A novel and very practical application of the electric motor for machine tool operation is illustrated by the 12-inch sensitive drill shown in the accompanying photograph. In this machine the motor is mounted upon the frame directly over the spindle and has a hollow shaft through which the spindle slides and is driven by a key. By this arrangement the power is applied directly to the spindle and none is wasted in belts, gears or friction wheels. The spindle has but three bearings, and as there is no side pull from belts or gears the wear is reduced to a minimum. Four speeds are provided, ranging from 500 to 1,500 revolutions per minute, all obtained by simply moving the starting handle, shown on the side of the motor, to different positions, which are clearly marked, to show the speed at each point. A higher range of speed may be provided for, if required. This drill is designed and built by James F. Willey, Jeffersonville, Ind., and is being placed upon the market by Jas. Clark, Jr., & Co., Louisville, Kentucky.



Portable Electric Drill.

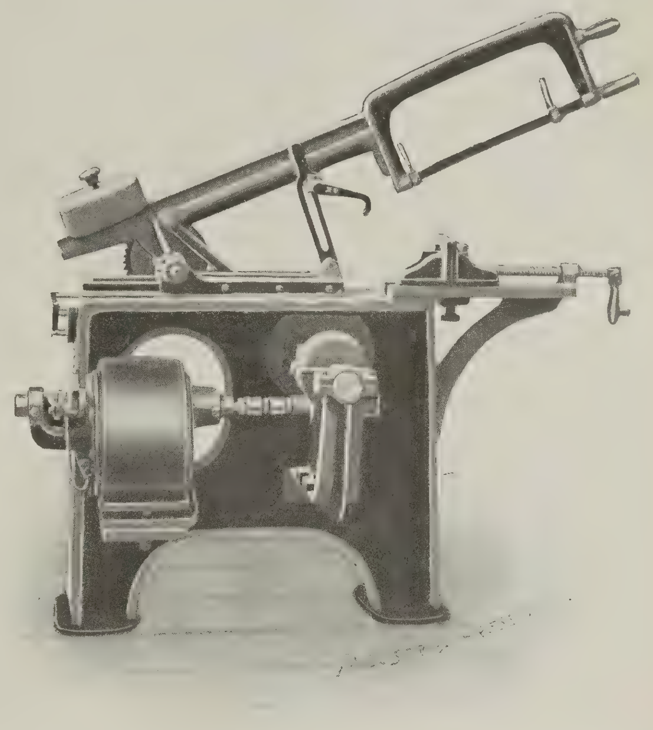


Sensitive Electric Drill.

MOTOR-DRIVEN HACK SAW.

The Patterson Tool and Supply Co., Dayton, Ohio, are equipping their "Challenge" power hack saws with motor drive, as illustrated in the accompanying cut, so that they may be used in stores or stock rooms where belt driving power is not available. The motor by which this saw is driven is made by the Sterling Electric Co., Dayton, Ohio, and is especially wound so that the usual rheostat or starting box is dispensed with, a knife blade switch on the back of the machine frame being used for starting or stopping. This switch is automatically thrown out at the end of the cutting. The motor is usually wound so that it may be connected with the ordinary electric light current and the saw operated through a worm and worm gear, but a slow speed motor and belt drive may be furnished if desired.

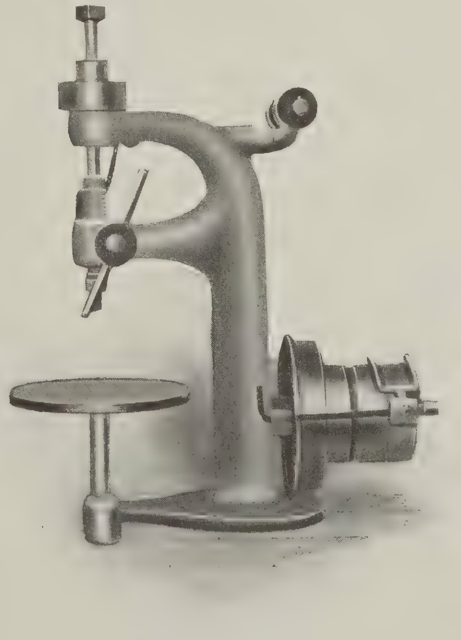
The saw has a capacity of 6 x 6 inches, and is fitted with a vise that is adjustable, forward and back, so that when one end of the saw is worn out the other end can be used. The friction arrangement, in connection with the sliding counterweight, gives a positive feed, but on the return stroke relieves the saw and prevents it from dragging over the work. The same machine may also be furnished with a pulley substituted for the motor and worm gearing and either type of saw can, when desired, be supplied with a raised arm, which makes it capable of cutting 12-inch I-beams, channels and similar work.



Electrically-driven Hack Saw.

NEW TEN-INCH BENCH DRILL.

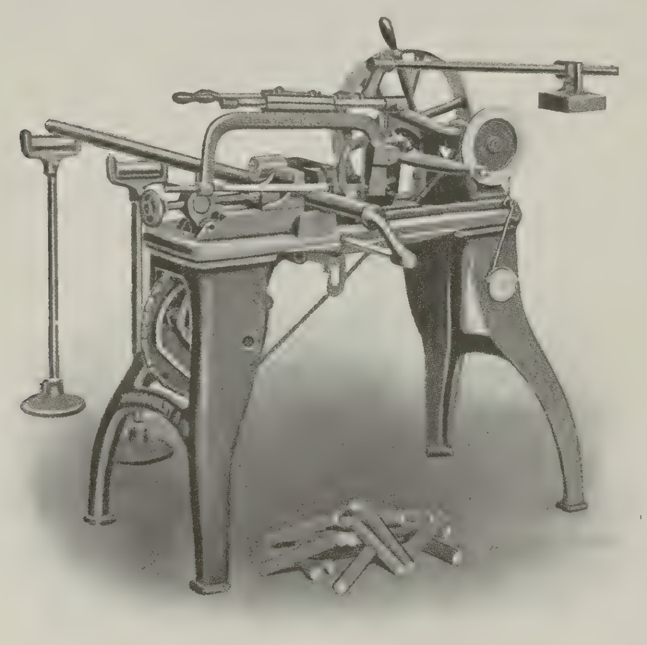
The Miami Valley Machine Tool Co., Dayton, Ohio, have just brought out the bench drill illustrated in the accompanying photograph, which, although following quite closely the ordinary lines of design of such tools, has been built with especial attention to simplicity and rigidity of the parts. The swing of the drill is 10 inches and it is provided with counterbalanced lever feed and a two-step driving cone. It is driven from the countershaft by tight and loose pulleys, having a belt shifter so located as to be readily accessible to the operator. The total weight of the drill is about 55 pounds.



Ten-inch Bench Drill.

AUTOMATIC HACK SAW.

The hack saw which is illustrated in the accompanying photograph is a full automatic machine which cuts up bars or pipes into pieces of uniform length without any attention other than starting it upon the first cut. On the completion of a cut the saw rises, vise opens, the work is fed forward the required length and the vise closed. Then the saw falls and a fresh cut is commenced. When the bar has been entirely cut up a bell rings continuously until the machine is attended to. If a saw blade breaks the bell also rings for attention. The machine can be set for single cuts when the bell rings on the completion of the cut.

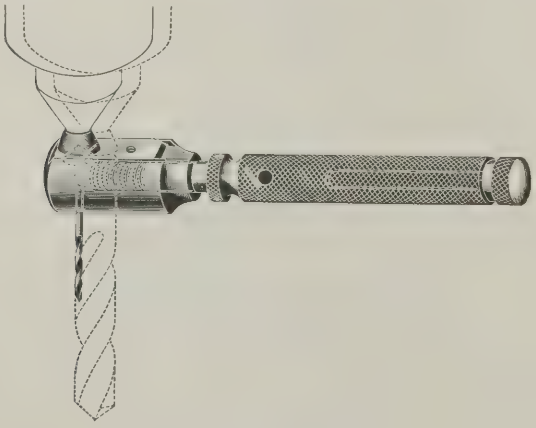


Automatic Hack Saw

No adjustment is required other than setting the gage for length, as with the ordinary saw. The length gage moves clear of the work while the cutting is in progress and so prevents the detached piece from jamming and breaking the saw. The counterbalance weight, by means of a simple mechanism, alters its position automatically to compensate for the blunting of the saw through use. The machine handles stock of any length and of any size and shape up to 4 inches. It is simple in construction so that it will not easily get out of order and may be operated by unskilled labor. It is being placed upon the market by Montgomery & Co., New York, N. Y.

A HOLDER FOR SMALL DRILLS.

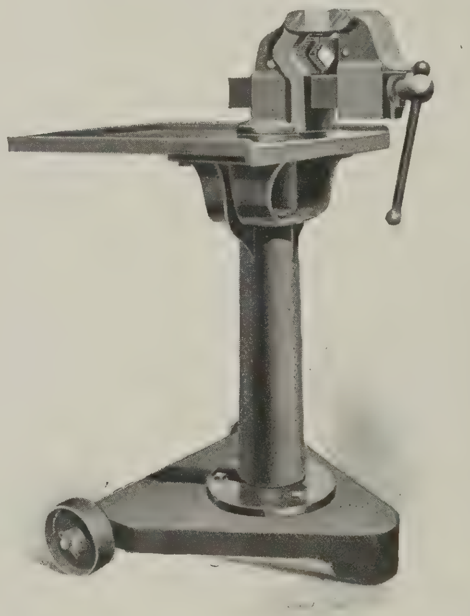
The little device illustrated herewith will be appreciated by any one having to use small drills in connection with lathe work. Ordinarily, drills up to one-half inch are pointed on the back end and in order to use them in the lathe this point must be ground off and a female center made on them, or else they must be held in a drill chuck fitted to the tailstock spindle. With this device small drills may be used without any alteration whatever. It consists of a holder in which the drill is secured by a few turns of the handle, while on the back of the holder is a floating female center into the inner side of which the pointed end of the drill fits and thus locates the center exactly in line with the point of the drill. The female center is then used with the tailstock center in the same manner as when using large drills. With this holder the operator is at all times able to tell the exact tension to which the drill is subjected and breakages are largely avoided. Inserted in the end of the handle is a small bar which may be removed and used for tightening the drills, by placing it in a hole drilled at right angles with the handle. The cut shows how the holder is applied to the smallest size of drill, while the dotted lines illustrate its application to the largest drill within the capacity of the machine. At present this holder is made to use drills from No. 60 up to 5-16 inch, but larger sizes will be made later. It is the product of the O. K. Tool Holder Co., Shelton, Conn.



Adjustable Drill Holder.

PORTABLE VISE STAND.

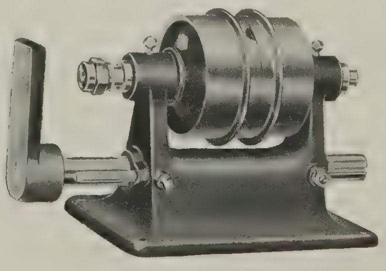
The Western Mfg. Co., Springfield, O., believing that it is sometimes the easier course to take the mountain to Mahomet, have just brought out a novelty in the way of a portable vise stand which is designed for moving around the shop to any place where it may be desired to do any filing or fitting. Thus, instead of having to carry piles of castings to a bench, the stand, which is in effect both bench and vise, is rolled to the pile of castings and as soon as that job is done it is rolled along to the next. The device consists of a cast-iron base and column, weighing about 225 pounds, and having mounted at the top a table 17 x 21 inches, and a regular machinist's vise which may be fitted with plain or combination pipe jaws. On two corners of the triangular base are placed wheels so that the whole device may be easily moved, while the third corner is formed into a substantial foot which prevents any movement of the device when it is in use.



Portable Vise Stand.

TAPPING DEVICE FOR SMALL WORK.

The tapping device illustrated below has just been placed on the market by Blomquist & Welander Co., Cleveland, Ohio. The driving pulleys run on hollow studs, thereby relieving



Device for Tapping Small Holes.

the spindle from all pressure due to the belt and making it very sensitive to the tap. The spindle is driven by a steel clutch working between the pulleys which are operated by open and crossed belts, thus insuring instant reversion. The spindle is also provided with a spring clutch with a long taper to give a perfect grip to the tap. The tailstock is mounted on a round steel rod which slides in the frame and is adjustable to any length of work. This device has a capacity for tapping holes ranging from the smallest up to ¼ inch in diameter.

* * *

FRESH FROM THE PRESS.

In our review of the book, "Iron, Steel and Other Alloys," published by Sauveur & Whiting, Boston, Mass., we stated that the price was $8.00. It should have read $5.00.

Gas Engine Troubles and Remedies, by Albert Stritmatter. Published by the Gas Engine Publishing Company, Goodall Bldg., Cincinnati, O. 112 12mo pages. Price $1.00.

The title of this book is an explanation of its contents, which consist of nine chapters, as follows: Gasoline feed supply; starting; fuel consumption; ignition; timing; two chapters on general troubles; lubrication; detecting trouble by sound. It is essentially a book on the care and operation of the gas engine, and will be found useful by those who have such engines in their care.

The Drafting of Cams, by Louis Rouillon. Pamphlet published by the Derry-Collard Co., New York. Price 25 cents.

This is No. 2 of the single-copy series of practical papers published by this company—the first being on the subject of tapers, as previously noted in these columns. The matter on cams which is given in this pamphlet is, in part at least, made up from articles by Mr. Rouillon for Machinery, and it is a concise and practical treatise on the subject, showing methods of laying out cams of various kinds.

Emery Grinding Machinery, by R. B. Hodgson. Published by J. B. Hodgson, Birmingham, England. For sale by J. B. Lippincott, Philadelphia, Pa. 180 12mo pages. Illustrated. Price $2.00.

This volume, it seems to us, would be of very little value to any American mechanic. It is a compilation of information and descriptive matter very general in character, and does not contain anything like the amount of practical information to be found in various technical articles that have been contributed to American mechanical publications. While it would undoubtedly assist a novice to an understanding of grinding machinery and processes we doubt if the practical mechanic would derive much benefit from its perusal.

Experiments on the Flexure of Beams, by Albert E. Guy. Published by the D. Van Nostrand Company, New York. 122 12mo pages. Illustrated. Price, $1.25.

The most, or the whole, of the matter in this volume first appeared in the pages of the *American Machinist*. It consists of a treatise on the flexure of beams and columns by a new analytical method based upon experiments. Mr. Guy has undoubtedly discovered some laws connected with the problem that have previously escaped investigation, and his discussion will be found an interesting and valuable acquisition to the science of the strength of materials.

Gas Engine Design, with an introduction on compressed air, by E. J. Stoddard. Published by Parker & Burton, Detroit, Mich. In large pamphlet form, 98 pages. Illustrated. Paper cover, 25 cents; cloth, $1.00.

The author states in a preface that the formulas in this work have received the approval of so many scientific men that he has presented it with confidence. The book has many drawings and consists of two parts—the first of which is a rather elaborate discussion of air when under compression or expansion, and the second relating particularly to proportions of the parts of gas engines. It discusses the dimensions of the cylinder to produce a given amount of power; the reciprocating parts; flywheel; valves; ignition apparatus, and general proportions. The treatment is mathematical—much more so than Roberts' well-known handbook.

Illustrated. Published by John Wiley & Son, New York. Price $1.50.

Electrical Engineering. Translated from the German of E. Rosenberg, by W. W. H. Gee and Carl Kinzbrunner. 267 8vo pages.

This book had its origin in a number of lectures delivered to the workmen and engineering staff of a large electrical firm, and the author states that the class of readers for whom the book is intended is the same as that to whom he lectured. It is designed to give to workmen, draftsmen, students and others a knowledge of electrical machinery and apparatus, and a good general education is all that is required to understand the treatment. We believe this volume fills this field satisfactorily, although it must be remembered it is a foreign work, not dealing with American apparatus to any extent. It has one merit in particular—that of treating alternating-current machinery, which is seldom taken up in elementary books of this character. It of course takes up continuous-current machinery, including generators and motors, and discusses electric lighting, accumulators, alternators, working dynamos in parallel, and high-tension currents.

Design of a High-speed Steam Engine, by J. F. Klein, Professor of Mechanical Engineering at Lehigh University. Published by D. Van Nostrand Company, New York. 257 pages, profusely illustrated with diagrams and tables. Price, cloth, $5.00.

The first edition of this book was published with the intention of making it Part 1 of a treatise on the dynamics and design of a high-speed engine, second part being planned to treat of the dynamics and design of shaft governors. This second part, proving to be too voluminous to be suited for undergraduate work in technical schools, it was decided to issue the two works independently, and the present edition of engine design is, therefore, presented without reference to the work on shaft governors. Much new material has also been added to that contained in the first edition, in the form of appendices. The arrangement of the subject is in the form of a problem in engine design. Stating at the start the conditions that would be given to the designer, the order of calculation then presents a systematic arrangement of the steps to be followed in consummating the entire design, and the succeeding chapters of the book are devoted to the investigation of each step in the calculations in the order in which they are outlined. The treatment is especially suited to the student who wishes to investigate the theoretical conditions governing the design of high-speed engines; and the treatment, which is thorough and clear, is confined strictly to this class of engine work. Solutions of the various problems involved are presented both mathematically and graphically. The chapters devoted to the subject of valve diagrams are unusually complete and are illustrated by numerous diagrams of the leading types of both single and double valves. In the appendix is a treatment of the subjects of the inertia resistance of the rod, determination of pin pressures and a chapter upon the subject of link motions including Stephenson's, Gooch's, and Allan's.

A Handbook on the Steam Engine. By Herman Haeder, and translated from the German by H. H. P. Powles, with additions and alterations. 458 pages, 1,085 cuts, and about 180 tables. Published by Crosby, Lockwood & Son, London; and D. Van Nostrand, New York. Price, $3.

That this book has proved to be quite a valuable one is indicated by the fact that the copy sent for review is of the third English edition. It is a work that should be appreciated by many mechanical engineers, designers, and draftsmen, especially those who care for European practice, as, with much other data, it gives a large number of tables of dimensions of Continental and English steam engines. The theoretical part has been treated briefly, and where formulas are necessary they are given, but are not intruded where there is no need for them. Following the historical notes the first section takes up the types of engines, giving outline diagrams showing arrangement of frames and cylinders; then follows the section on details, covering 118 pages. The section on governors is not so complete as it should be to attract the designers of American high-speed steam engines, but this is in a measure compensated for by the chapter on valve gears which gives in concise terms a great deal of matter regarding the leading types. The following sections are: Condensers, Air-pumps, and Feed-pumps; Examples of Engines of Continental Make from Actual Practice; Particulars of Engines by English Makers; Compound Engines; Indicators and Indicator Diagrams; Calculations for Power and Steam Consumption; Effect of Inertia on Reciprocating Parts; Boilers, etc. While a book of this nature always contains considerable obsolete matter and is necessarily behind the most advance engineering practice—a condition, by the way, that attaches to all engineering literature—it is, we consider, a good work for the library of the mechanical engineer and designer who cares to know the details of European precedents. We may add that all measures have been converted into English denominations.

NEW TRADE LITERATURE.

Jno. T. Burr & Son, Brooklyn, N. Y. Illustrated catalogue of the "Burr" cold saw, with full description of same.

E. G. Smith, Columbia, Pa., announces that he wishes to sell his filter business in order to devote all his time to his line of fine tools.

The Boston Gear Works, Boston, Mass. Catalogue "P" of gear specialties for 1903. Bevel, spur and internal gears with teeth planed theoretically correct, also spiral and helical spurs are there listed.

Wyman & Gordon, Worcester, Mass. "A Short Story of Elias Howe." This is a sketch of the life of the great inventor of the sewing machine. Also leaflet illustrating the drop forgings manufactured.

American Steel & Wire Co., Chicago and New York. Pocket catalogue, May, 1903, of the "Juniata" horse and mule shoes and toe calks, which are manufactured of iron or steel, are of different weights and for many purposes.

The Crocker-Wheeler Co., Ampere, N. J. Pamphlet illustrating the Crocker-Wheeler railway generator. Three fine half-tone views of the field, the armature and the brush rigging are shown, with brief description of each.

The Williamson Mfg. Co., Bradford, Pa. Folder illustrating and describing the "Williamson" vise. By one motion of the hand, pulling the lever forward, the jaws can be moved to right or left, up or down, forward or backward.

The C. W. Hunt Co., West New Brighton, S. I. Illustrated circular of coal tubs and contractors' tubs for the prompt handling of coal. They also make a special "side catch" tub for handling gravel, stone, sand, clay, mortar, concrete, etc.

The Yale & Towne Manufacturing Co., 9-15 Murray Street, New York. Pamphlet illustrating the "Triplex" hoisting blocks, for use in warehouse, press room, erecting shop, machine shop, boiler works, etc., in fact for all hoisting purposes.

The Emerson Electric Manufacturing Co., St. Louis, Mo. Small folder just from the press containing much condensed information about small induction motors. This is to supplement the Emerson bulletins already issued, all of which are sent on request.

The Sawyer Tool Co., Fitchburg, Mass. Illustrated price list of fine tools and hardware specialties. This supersedes all previous matter issued by the company and those writing for it should ask for "Catalogue F."

The R. D. Nuttall Co., Pittsburg, Pa. Booklet calling attention to the Nuttall motor gears and pinions. This company is occupied with the manufacture of gears only, and the booklet illustrates street railway motor gears from small size to 30 feet in diameter.

The Rand Drill Co., 128 Broadway, New York. Circular No. 10 of "Imperial" piston air drills, piston air wood boring machines, pneumatic hammers, etc. Examples of the work done—that is, reaming, tapping, flue rolling and wood boring—are shown, together with the tools used.

The Standard Welding Co., Cleveland, O. Illustrated catalogue, pocket size, of seamless steel tubing for all purposes. This shows only a part of the large line manufactured. Standard steel rims, clincher rims, bicycle parts are listed, and samples of electric welding are shown.

The J. Morton Poole Co., Wilmington, Del. Circular describing and illustrating the company's new line of vertical boring and turning mills, which are shown in our last number. These are made in the following sizes: 6-foot, 7-foot, 8-foot and 10-foot, and they state that they are preparing to build larger sizes of regular and extension boring mills.

The Joseph Dixon Crucible Co., Jersey City, N. J. Booklet entitled "An Index to Find the Fact you Need to Know," meaning, of course, facts about pencils for all possible uses. It explains what pencil is best suited to the work to be done, and no less than 54 pencils are described for merchants, metal workers, office workers, railroad companies, etc.

The Boston Gear Works, Purchase and Pearl Streets, Boston, Mass. Catalogue "P" and price list of gear wheels and gear cutting of every description. This treats of bevel, spur and internal gears with teeth planed, and of spiral and helical spur gears for smooth running or for high speeds. Besides the advertising matter contained herein there is considerable information and a number of tables on gearing, which will prove useful.

The Graham Manufacturing Co., Providence, R. I. Booklet calling attention to the "Universal" jig vise for use in plain and duplicate drilling. The company state that this saves time in the changing of pieces, and the jig attachment furnished enables the operator to drill as accurately as with a special jig. By using a simple drilling plate the vise may be used for drilling several holes in definite relation to one another.

The Emerson Electric Manufacturing Co., St. Louis, Mo. Bulletins Nos. 3041, 3042, and 3044, of direct-current power motors, direct-current motors and of polishing and grinding motors respectively, with considerable data regarding each type. The company manufacture alternating-current desk, bracket, ceiling and column fans; direct-current exhaust fans and power motors; alternating current power motors, pressure blowers, forge blowers, water pumps, etc.

The Pittsburg Blueprint Co., Pittsburg, Pa. Catalogue of electric blueprinting machine. Type A is the machine with upright wall; type B with tilting wall; type C with upright wall and automatic; type D with tilting wall, and automatic. Self-contained machines, types E. F. G. and H, are shown. The "Imperial" blueprint wringer —an improved apparatus for the purpose—which is driven by a small electric motor is also illustrated. This is built in three sizes, for rolls 34, 40 and 46 inches long.

The Consolidated Press & Tool Co., 96-100 N. Clinton Street, Chicago, Ill. Bulletin No. 1 describing a new line of power presses recently gotten out by this company. These are of the inclinable, open-back type, and possess a number of new features which are here described. Various styles and sizes of this machine are made, and the company also build presses for other work, such as wiring, blanking, punching, notching, etc., and special machinery for the manufacture of metal specialties.

The Billings & Spencer Co., Hartford, Conn. Pamphlet descriptive of small tools such as sportsmen's knives, magazine screw drivers and knives, adjustable pocket wrenches, combination pliers, an improved key ring, etc.; and drop forgings and machinists' tools. Also leaflets illustrating by line drawings the Lemoine front axle forgings for 1½-inch automobile axle, designed mostly for touring cars of from 12 to 30 horse power. Circular and price list will be furnished on application.

The Northern Electrical Mfg. Co., Madison, Wis. Crane motor Bulletin No. 32, of steel crane motors specially adapted to the requirements of crane service. This is electrically-driven, doing away with belts, is of the enclosed, dust-proof type, with bosses on the side for conveniently fastening to any required mechanism. The motor and its parts are illustrated and described at length, and on the front page is a view of Machine Shop No. 2 of the Northern Electrical Mfg. Co., showing their crane equipped with these motors. A cut also shows a "Northern" type of generator mounted on an Atlas Corliss engine.

The Cincinnati Machine Tool Co., Cincinnati, O. Standard size catalogue 1903, of upright drilling and tapping machines. These range from 21 to 42 inches in swing and a number of them are being built with the company's patent geared tapping attachment, by the use of which the operator can tap right and left-hand threads equally well, and which can be disengaged when not required. Among the new things are their motor-driven drills and their drills with compound tables and geared revolving tables. The catalogue is profusely illustrated.

E. G. Smith, Columbia, Pa., has issued a circular whose purport is that a number of his calipers, all sizes and styles shown in his catalogue, have become slightly shopworn from being exhibited, which he will dispose of at less than actual cost. A few hundred "Which Way" pocket levels only slightly rusted, but which will wear bright if carried in the pocket, are for sale at 25 cents each. Also parallel strips one-half inch square and any length up to thirty inches, can be purchased at 2 cents per inch in length. The circular also shows a combination micrometer which any mechanic can construct himself, either singly or in quantities.

Boynton & Plummer, Worcester, Mass. Catalogue and price list No. 2 of shaping machines, and upright hand and power drills. The catalogue is illustrated and, it seems to us, covers the line of tools manufactured very thoroughly. Traverse head shapers, upright self-feeding drills, upright bench drills, upright power drills, overhead or hanging drills, horizontal drills, self-feeding swivel clamp drills, bolt cutters, and nut tappers, tire benders and shrinkers, various types of forges, etc., are listed. Twenty-eight pages are devoted to an illustrated list of duplicate parts, for repairs to the company's machines, by the use of which they may be ordered by name or number.

The Ajax Manufacturing Co., Cleveland, O. The "Ajax Brown Book," 1903, of "Ajax" forging machines. The Ajax Company are the sole manufacturers of this machine, which is the invention of Mr. J. R. Blakeslee. It has recently been improved and a number of important features added, and is here illustrated and described, and samples of the work turned out are shown in half-tone views. It is built for work ¾ inch, 1, 1½, 2, 2½, 3, 3½, 4, 5, and 6 inches. Other tools shown are bolt-heading and open die rivet machines; automatic feed rivet machines; forging rolls; bulldozers; hot pressed nut machines; and a multiple spindle drill. Also a special axle machine with large die opening, made in any size. A number of useful tables appear in the back.

The International Mining Directory, 1903. Price $10.00. This publication, containing 523 pages, gives concise and reliable data regarding location, ownership, management, character of ore, development, equipment, etc., of the principal operating mines and metallurgical plants in Western United States, Mexico, South and Central America, Canada, Africa, Australasia, India, Japan, Korea. The book should prove exceedingly valuable to any interested in the subjects of mining and metallurgy, comprising as it does the names of all the reputable concerns engaged in the operation of mines or in the building of mine machinery. It is published by the Western Mining Directory Company, Denver, Colo., and San Francisco, Cal.

The Newton Machine Tool Works, Inc., Philadelphia, Pa. Catalogue No. 36, standard size, of machinery for army, navy, railway and general machine shop equipment; also engineering specialties in metal-working machinery. This is a catalogue of 236 pages, and is most complete. It lists plain milling machines, special milling machines for railway work; ten sizes and varieties of duplex milling machines; vertical slabbing machines; universal milling machines; rotary planing machines, with fixed heads, and swiveling heads; portable combined milling, drilling and boring machines; slotting machines; cold saw cutting-off machines; floor boring machines; a large variety of boring machines. All of these are illustrated, and the nature of the work for which each machine is specially designed is mentioned. A keyseat milling machine is shown, with two spindles, for keyseating shafting, which is an improvement on the usual method of keyseating, and secures a perfect keyway. This method is explained and illustrated in the catalogue.

The American School of Correspondence, Armour Institute, Chicago, Ill., have recently issued a catalogue containing much information of interest to those who are giving any attention to correspondence instruction. This method of securing an education is growing more and more popular, filling, we are told, a real want; and the School has, besides its large number of students here, quite a number abroad—even including the Fiji Islands, the Falkland Islands, and 300 students in New Zealand alone. The instruction is under the direction of members of the faculty of Armour Institute of Technology; and Dr. Gunsaulus, president of that Institute, has given the work his enthusiastic support and personal supervision. Due credit for the work covered by correspondence will be given any student who, later, may wish to pursue his studies at Armour Institute. The instruction papers are prepared especially for home study and a true indication of their value is the fact that they are used as text books in some of the universities and other educational institutions of this country. The catalogue contains also a list of the instructors, text-book writers, the Advisory Board, and of the School's graduates.

Charles A. Schieren & Co., New York. Illustrated pamphlet entitled "The Art of Tanning and Currying Belt Leather." This is a brief but interesting record of the history of tanning, and gives an account of the art as practiced at the company's "Dixie" tannery, Bristol, Tenn. A description is given of the preparation of the rock oak bark which is used in the process of tanning, a number of half-tones showing the machinery used, etc. Then comes an explanation of the manner in which the hides are prepared for the tanner, one feature being the "stuffing" of the leather with cod oil and pure beef tallow, which preserves the belt and makes it strong and durable. The company state they were the first to make a rivetless belt, joined only by cement, which prevents slipping. Their other products are their "Excelsior" belt, made with an extra dressing that renders it waterproof; their "Electric" belt so treated as to prevent its being damaged by mineral oil; their "perforated electric belt," specially made for all electric light and street railway service; and special wide main driving belts for factories and mills. Some of their larger sizes of belts are: 101 feet long by 60 inches wide; 112 feet by 58 inches, 160 feet by 60 inches, and 165 feet by 78 inches, and are made to stand the most trying service. The company's New York office is 79 Cliff Street.

MANUFACTURERS' NOTES.

Mr. P. E. Montanus, president of the Springfield Machine Tool Co., Springfield, O., and secretary of the American Tool Builders' Association, is running for Congress in his district.

The Miami Valley Machine Tool Co., Dayton, O., are offering a cash prize of $25 for the best design submitted to them on a taper attachment for their new 13½-inch lathe. Details will be furnished on application.

The Diamond Drill & Machine Co., Birdsboro, Pa., have opened an office in Pittsburg, in the Farmers' Bank Building, in charge of G. B. Nutt, the Pittsburg representative of Pilling & Crane; Pilling & Crane being their Pittsburg agents.

The Niles-Bement-Pond Co., London, Eng., branch, report that on October 3, Mr. W. S. Accles, their European manager, and Mr. G. T. Reiss, chief engineer at the Hamilton, O., works of their company, were received by the King of Spain, at San Sebastian.

The Ingersoll Milling Machine Co., Rockford, Ill., are building a new erecting shop of concrete, 55x200, and 30 feet high in the clear, equipped with a Pawling & Harnischfeger crane, motor drives to all machines, and other modern appliances. The new building, it is expected, will be ready for occupancy in December.

The Reeves Pulley Co., Columbus, Ind., are just completing a new pattern shop, 22 x 60 feet, two stories high. Their new foundry is now in operation. They recently had a large order for variable speed transmissions for the new plant of the Alma Portland Cement Co., Wellston, O.

Schuchardt & Schutte, importers of American machine tools, announce that in addition to their houses in Cologne, Berlin, Brussels, Vienna, St. Petersburg, Stockholm, and New York, they have just opened two more branch houses—one in Paris, France, Rue Reaumur 85, and one in Bilboa, Spain, Gran Via 29.

E. W. Roberts, designer and consulting engineer, who is well-known to the gas engine trade and is the author of the "Gas Engine Handbook" and other works on gas engines and automobiles, is fitting up a laboratory at Clyde, O., for the testing of gas and gasoline engines and gasoline automobiles, as well as for calorimetry and the analysis of both gas and liquid fuels.

The Huetter Machine & Tool Co., 418 So. Pennsylvania Street, Indianapolis, Ind., announce that they have a fine tool plant, equipped with machinery for the manufacture of fine tools, dies, model work and first-class special machinery of all kinds, at reasonable prices. They will be glad to give to anyone interested, prices on anything in their line.

M. H. Treadwell & Co., Lebanon, Pa., report that the outlook for business is very bright and that their plant will, in all probability, run at its full capacity during the entire winter. Their plant covers seven acres of land and their machine shop is equipped with the latest types of machinery. Since the incorporation of the company in January, 1901, the output has been practically doubled. An electrical department has recently been installed.

James Bonar & Co., Inc., Pittsburg, Pa., have taken over the business heretofore known as James Bonar & Co., and will continue to manufacture and handle a full line of first-class steam appliances. They are erecting a new machine shop and brass foundry for the manufacture of their own specialties and for other machine work. The shop will be equipped with new machinery of modern design, specially adapted to the manufacture of special work.

The Indianapolis Blue Print Co., 142-148 N. Illinois Street, Indianapolis, Ind. Illustrated catalogue of architects', engineers' and draftsmen's supplies. This catalogue is very complete, containing 254 pages, and includes everything in this line of goods. An eight-page index appears in the back. The price of the catalogue is 25 cents, but it will be sent prepaid without charge to professional architects and engineers.

The Norwalk Manufacturing Co., Norwalk, O., successors to the Baker & Wilson Machine Co. and the Norwalk Foundry & Machine Co., have issued a preliminary catalogue calling attention to the line of standard bolt cutters and nut tappers and dies which they manufacture. They announce that they are extending this line in many particulars and will illustrate and describe their products as opportunity permits. The pamphlet we have shows their ¾-inch and 1½ and 2-inch bolt cutters with automatic opening head.

The American Machinery Co., Grand Rapids, Mich., are just putting on the market a new type of band saw especially designed for patternmakers' work. They have already received orders for these band saws from the N. Y., O. & W. Ry.; the Exeter Machine Co., Pittston, Pa.; the Crocker-Wheeler Co., Ampere, N. J.; the Westinghouse Electric Co., Pittsburg, Pa.; and the Ruemmell, Dawley Manufacturing Co., St. Louis, Mo. They also report a very satisfactory trade on their other larger machines. They have just furnished the Washington Navy Yard, 24-inch hand jointer; the Portsmouth Navy Yard, Oliver universal saw bench; Santa Fe Ry. Co., 4 saw benches, 1 hand jointer and 3 bench trimmers; Erie Ry. Co., saw bench and 2 bench trimmers; Southern Florida Ry. Co., saw bench and hand jointer; Grand Trunk Ry. Co., saw bench, all of which are of the Oliver type.

The Norton Emery Wheel Co.'s (Worcester, Mass.) employees extended to Mr. Charles L. Allen, the secretary and general manager, a welcome home from his recent European trip on October 8. The entertainment took place in the immense works at Barber's Crossing, which were handsomely decorated with autumn foliage and occasional flags. A heavy silver cup was presented to Mr. Allen who, during the evening, shook hands with every one of the 400 employees. A light lunch and other refreshments were served and there was quite an attractive musical program. Among other features were a boxing match, in which we are told no blood was shed and which afforded much amusement. Also a series of stereopticon views showing Mr. Allen, Mr. Norton, the inventor of the emery wheel, the old time employees and those of the present day, the old shop and the new works—all of which were of considerable local interest.

MACHINERY.

December, 1903.

TOOL MAKING.—1.

A WORD TO THE BEGINNER—CUTTING SPEEDS—REAMERS.

E. R MARKHAM.

E. R. Markham.

IN many shops the term "toolmaker" is unknown, or, if known, is seldom used; the term "machinist" is applied to the class of men doing the general machine work, as well as to those making jigs, fixtures, gages, and cutting tools.

Until the advent of interchangeability of the parts of machines and of other products of machine shops, the use of jigs, fixtures, etc., was not generally known. The work was done mostly by what was then termed skilled labor and even then the assembling of the article was done by skilled workmen, because it was necessary to fit the various parts to each other.

It was found that by the use of suitable fixtures, jigs, etc., to hold the work and guide the cutting tools, work could be made to gage, which, of course, facilitated matters very much when the article was assembled. As this system of working was perfected, it was found that if these fixtures, jigs, etc., were made sufficiently accurate the various machining operations could be done by other than skilled workmen, thus materially reducing the cost of manufacture. As these men became accustomed to the work they were doing, they could, by the aid of accurate gages, produce work that could be assembled by unskilled help much faster and in a more satisfactory manner than it was formerly possible with skilled labor.

But in order to make the fixtures, jigs, gages, and cutting tools sufficiently accurate to produce work of the desired quality, it was necessary to educate the machinist to a point where he could do the work more accurately.

The system of interçhangeability of parts was not a thing to be accomplished in a minute; it has been a gradual development that took over forty years, and is to-day far from being realized in many shops.

The machinist who has had this higher education is generally termed a toolmaker. In large shops where there is enough work of one kind to keep a toolmaker busy, one man is given the gages to make, another the jigs, another the dies, and another the models. These men are then called gage makers, jig makers, die makers, and model makers, respectively. The object attained is that a man working on one class of work all the time will be more skillful in this one line than if he were working on various classes of work. In most shops, however, it is expected that the toolmaker will make all the fixtures, jigs, models, and cutting tools. The fact that, generally speaking, there is enough tool work to keep a toolmaker occupied all the time, has led some men to learn to make tools without learning the trade of machinist; but, however skillful this man may be, he is handicapped, because he may at any time be called on to build *special* machinery. This is generally considered work that should be given a machinist who has the experience of working on tool work, and unless a toolmaker understands the principles involved in machine construction he is liable to slip up, no matter how skillful he may be as a workman.

Machinery used in the construction of tools, as well as that employed in their use, has changed very much during the past forty years; yes, even within the last ten years there have been many radical changes which tend to make more practical the construction of tools used in producing duplicate work. And not only has machinery been perfected, but measuring tools are now built that make it possible to work within a limit of variation that was not dreamed of a few years ago. As measuring tools have been perfected, methods have been devised whereby work can be done very accurately, in less time than it was formerly possible to do a half passable job.

In constructing special machinery, fixtures, jigs, etc., it was formerly the custom in many shops to give a man a piece of work, or a templet, describing to him roughly what was wanted, and letting him go ahead himself and make the article. Everything was done by a "cut and try" method, and the result was often anything but satisfactory, both as regards practical utility and cost of construction. To-day the custom in most shops is to make drawings of all tools of this character, the drawings, or at least the designing being done by one man. These all agree as to working dimensions and working or locating points. How common it was under the old system to find a drill jig designed so that the piece of work was located from a certain point or surface, and the milling machine or other fixture designed to locate from an entirely different point, thus making it impossible to produce duplicate work!

Where one man makes designs for all the tools that go with a certain piece he makes them so that the working points of his jigs, fixtures, and gages agree; and when it is necessary, for any reason, to change a locating point he makes sure that in so doing he does not undo all he is attempting to accomplish and for which he is to build costly tools.

To attain success as a toolmaker a man should have a certain amount of education. He must be able to read a drawing, he must understand decimal fractions, and must be able to add, subtract, multiply, and divide both whole numbers and decimals. Right here I think I hear some one saying that "one of the best workmen he ever knew couldn't add 3 and 2 and get the proper answer—to say nothing of decimals." Well, what a valuable man this fellow would have been had he had a good education!

I recall a man who was in my employ for several years, who was an excellent workman, yet he could not take a drawing and work from it without having it explained to him, and as to anything that involved a knowledge of arithmetic, he was all at sea and some one had to do it for him. This man often deplored his lack of knowledge, and said he "would give a good deal" if he could take a drawing and figure out the calculations necessary to a proper understanding of it.

The man who wishes to become a successful toolmaker should also learn to work *accurately*. Accuracy is very essential in places where it is necessary; yet undue accuracy is never to be indulged in, because it consumes valuable time. If within 1-16 inch is near enough, it is folly to spend the time necessary to work within a limit of variation of 1-10,000 inch. But there are places where the latter limit of variation—or even less—must be observed, and in such cases the required time must be taken to do work of this character.

The successful toolmaker discriminates between the portions that must be approximately correct and those that must be exact, and governs himself accordingly.

As an example of the two classes of measurements under consideration, we will take a plug gage like that shown in Fig. 1. Now, it is essential that the portion marked *A* be *exact size*. The utmost care must be exercised when grinding and lapping to size, as no variation from the size given would be allowable. But when machining the portions marked *B* and *C* no such accuracy is necessary, neither is it desirable that time be spent on these to get them accurate within a limit of variation of 1-32 inch. Not that any such variation as this should be indulged in when dimensions are given, but the variation mentioned would not in any way affect the accuracy of the tool or its efficiency as a gage.

For the benefit of the beginner let us consider a few points that must always be observed if we want satisfactory work. The center punch should have a good sharp point, which should be at an angle of about 60 degrees. This angle is given not because absolutely essential, but because it is generally customary to make at about this angle, and it is always best for the beginner to have something definite to work to—it tends to make him a more careful workman.

He should be careful as to the condition of his center reamer, which should not only be sharp but should be exactly the shape of the centers of his lathe—generally 60 degrees.

It is impossible to do accurate turning if the countersinking in the end of the piece to be turned does not fit the lathe center. Fig. 2 gives two views showing the results when the countersink is not the same shape as the point of the center.

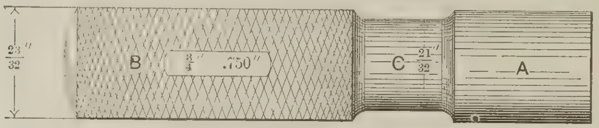


Fig.1

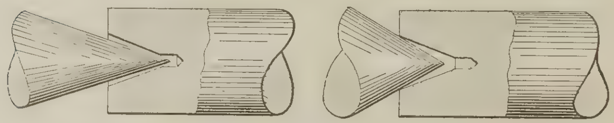

Fig.2

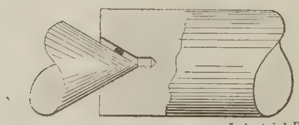

Fig.3

Industrial Press, N.Y.

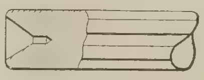

Fig.4

It is also highly important that the centers of the lathes fit well in the spindles, that they fit the center gage accurately, and that the live center runs true. It is especially necessary when the finish cut is taken on a piece. Many toolmakers never think of taking a finish cut after roughing without truing up the live center; or, if they find it necessary to remove the live center from the spindle, they always true it after returning to place before taking any finishing cuts.

Another precaution that is sometimes neglected is to always be sure there is no dirt in the spindle hole, or on the shank of the center before it is put in place. Then, again, he should always make certain that there is no dirt in the countersunk hole or on the point of the center, as this will cause the work to run out of true when the dirt is removed. I have seen valuable pieces of work ruined because of lack of attention to this simple precaution. A man turned a piece to grinding size—.005 inch to .008 inch large; when it was taken to the grinder he cleaned the centers out carefully and removed a chip which had become imbedded in the piece. When turning in the lathe this chip held one side of the countersunk surface from the center, as in Fig. 3, and when this chip was removed the piece ran out so badly that it was not possible to true it, consequently it was of no value.

When countersinking the ends of a piece of stock care should be taken to use a drill of *suitable* size, and not to make the countersinking out of proportion to the size of the piece. It looks unmechanical, to say the least, to see a ⅜ inch reamer having a countersunk hole in the end, of the size shown in Fig. 4; and it *is not* mechanical, as it weakens the reamer, which is very apt to break when in use, or is more liable to crack when being hardened than if it were countersunk the proper depth.

A peculiarity of steel—both machinery and tool steel—is that it is very liable to go out of straight when the surface—skin—is removed. For this reason it is always advisable to rough the piece all over, removing all the exterior surface before finishing any portion to size.

A point I hesitate about mentioning because careful workmen will say that "any boy should know that," is that when starting to machine a piece in the lathe the ends should always be squared to length first, or at least before any portion is turned to size; and all work on the ends that is in any way liable to affect the center should be done before sizing any portion, otherwise the work may be thrown out of true.

Cutting Speeds.

The metals generally worked when making tools are cast iron, machinery steel, and tool steel. A workman who has the welfare of his concern at heart will always use speeds and feeds best adapted to the work he is doing, that he may turn out the maximum amount of work. Generally speaking, it is possible to run at faster speeds and use coarser feeds when machining cast iron than when either machinery steel or tool steel is being cut. The speed which gives best results when machining any form of iron cannot be stated arbitrarily, as very much depends on the condition of the metal being cut, and also on the condition of the cutting tool. Yet it is necessary to know the speeds that give best results under ordinary circumstances. It has been ascertained by experiment that the following rates of speed give good results under ordinary conditions: Cast iron, 40 feet per minute; machinery steel, 30 to 34 feet per minute; tool steel, 20 to 25 feet per minute. If the cut is light and the metal soft, these speeds may be exceeded, but if the cuts are heavy or the metal hard it will be found necessary many times to run much slower.

In order to know how fast to run the machine, for stock of various diameters, the following simple rule is given: Multiply the diameter of the piece in inches by 3.1416 to obtain the circumference, or the distance around the outside of the piece; now reduce the number of feet the piece should be run per minute to inches. That is, if it is cast iron, reduce 40 feet to inches; 40×12=480. Then divide 480 by the circumference of the piece to be turned in inches and the answer will be the number of turns per minute at which the lathe should run. If the workman is not familiar with decimal fractions, he may multiply the diameter of the piece by 3 1/7, instead of 3.1416.

To illustrate the above, suppose we were to turn a piece of machinery steel 3½ inches diameter and desired to know the correct speed to run the lathe, first multiply 3.1416 by 3½ inches and our answer is 10.99. We next reduce 34 feet—the speed we can run machinery steel at—to inches, 34×12 inches = 408 inches; then divide 408 inches by 10.99 and we get as our answer 37 and a fraction. So we know that in order to get good results as to time we must have the lathe run about 37 revolutions per minute. The experienced mechanic can tell by observation when a piece of stock is running at about the right speed, but for the benefit of those whose experience is somewhat limited the above is given.

Reamers.

The principles involved when making tools can best be explained by considering each tool or class of tools separately. We will first consider the reamer.

The reamer is a tool used in making a hole true to size and smooth. The term "reamer," however, is oftentimes applied to a tool used to enlarge a cored hole, or a hole already drilled, without any reference to the size or condition of the hole. Reamers may be arranged in classes, according to shape, as follows: Straight reamers, taper reamers, and formed reamers. They are made solid, adjustable, and with inserted blades, which constitute the cutting teeth.

Solid reamers are made of *one* piece of stock, and are so named because the cutting teeth and head are solid with each other; they are not adjustable as to size. Fig. 5 shows a solid, fluted reamer. Inserted blade reamers are so called because the cutting teeth or blades are made from separate pieces of steel and inserted in slots in the head, as shown in Fig. 6. When making the adjustable form of reamer, we can have the cutting teeth solid with the head, or the reamer may be made with inserted blades, but it must have some means of adjustment as to size.

Fluted Hand Reamers.

The first form of straight reamer we will consider is the fluted hand reamer. This is straight on the cutting portion, except for a short distance at the end, as shown at *A*, Fig. 5, which portion is slightly tapered so that the end of the reamer may enter the hole.

In selecting tool steel for tools whose cutting edges are around the circumference of the piece it is necessary to take stock somewhat larger than finish size in order that the decarbonized portion at the surface may be removed. This surface becomes decarbonized by the oxygen of the air acting on the carbon at or near the surface of the steel when it is red hot, during the various operations in the steel mill and forge shop; and if this portion is not removed it will be found impossible to harden the very parts we wish hard. Knowing this, we select stock 3-32 to ⅛ inch larger than finish size.

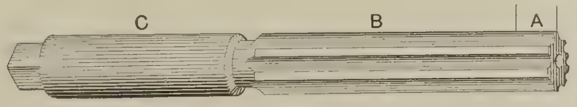

Fig. 5

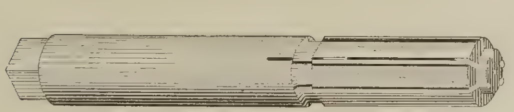

Industrial Press, N.Y.

Fig. 6

When centering, be sure and have the centers central with the outside of the piece, as shown in Fig. 7, so that an equal amount of the decarbonized portion may be removed all around the piece. Should the piece be centered as shown in Fig. 8 we must necessarily remove all the decarbonized portion on one side and very little on the other, and when the article is hardened it will be found hard on one side and soft on the opposite side; or, if this side is hardened at all it will not be as hard as that opposite, and, moreover, the piece will be very apt to spring from the unequal contraction on the opposite sides of the piece.

Having centered the piece properly, first square the ends to length and clean all burrs and dirt out of the center hole. Turn a chip off the outside surface to a depth of 1-32 inch, then anneal the steel. It is advisable to anneal before turning to size, even though the steel may be soft enough to work well without it, the object being to remove the strains set up in the steel mill by the various operations of rolling and hammering, otherwise these strains may be set up in the forge shop when the piece is forged to shape. When the piece is heated for annealing the tendency to crack or spring when it is hardened is overcome or reduced to the minimum.

The method to be pursued when annealing depends on the facilities afforded in the shop where the work is done. If we have at hand the necessary furnaces and annealing boxes, it is a good plan to pack the steel in charcoal—finely granulated—in an annealing box, place in a furnace and run for a sufficient length of time to have the steel become uniformly heated. The box should be removed from the furnace and allowed to cool slowly. An excellent method consists in placing the steel when red hot in *hot* lime or ashes, burying it well and allowing to cool as slowly as possible. It must not, however, be placed in damp or cold lime or ashes.

If the piece of steel from which we are to make the reamer is comparatively short there will be little liability of its springing by the process of annealing; but if it be long it is very liable to spring from the cause mentioned; that is, from the strains due to uneven heating or cooling, or that may be set up by the operation of rolling or hammering in the steel mill or forging in the forge shop, which manifest themselves as the steel heats. Consequently the steel crooks. Now, if the tool is to be hardened after it is completed the steel must not be straightened when cold. Should it spring enough so it could not be machined without straightening, it must be heated red hot and straightened, as otherwise it is almost sure to spring when it is hardened.

After annealing clean out the center holes with the center reamer, in order that no scale or dirt of any sort be in them, then turn *B* and *C*, Fig. 5, to sizes from .010 to .015 inch larger than finish size, necking down between cutting portion and shank, as shown. It is always advisable to mill the square portion before cutting the flutes. This is usually done by holding the reamer between centers on the milling machine and elevating the knee of the machine, thus feeding the stock to be cut up past the milling cutter, which must, of course, be an end mill. After the cut has been taken and the knee of the machine has been lowered, the index head of the milling machine may be revolved one-quarter turn, which places the reamer in position for the next cut. This must be continued until all four of the square sides are milled. After milling the square portion to size, a suitable dog may be placed on the square end, and the flutes which form the cutting edges may be milled.

Some manufacturers of reamers mill the flutes straight, while others claim best results if the teeth are cut spiral, using what is termed a left-hand spiral in order that the reamer will not have a tendency to draw into the work, as would be the case were the opposite spiral used.

Mechanics generally agree that a reamer with straight teeth gives good results when reaming holes in sound stock, or where there are no grooves or other depressions in the walls of the hole; when these difficulties are encountered then the reamer with the teeth cut spiraling seems to be the most satisfactory.

The Number of Cutting Edges.

As fluted reamers are generally intended for removing but a small amount of stock, and to produce smooth holes of accurate size, it is necessary that certain rules be observed as to the number of teeth they have. It is not generally considered good practice to give such reamers less than six flutes. However, in order that the reader may know the number of teeth generally given, a table of cutting edges for fluted reamers is given.

TABLE I. CUTTING EDGES FOR FLUTED REAMERS.

$\frac{1}{8}$" to $\frac{7}{16}$"	diameter	6 teeth.
$\frac{1}{2}$" to $\frac{11}{16}$"	"	6 to 8 "
$\frac{3}{4}$" to 1"	"	8 "
$1\frac{1}{16}$" to $1\frac{1}{2}$"	"	10 "
$1\frac{9}{16}$" to $2\frac{1}{8}$"	"	12 "
$2\frac{1}{4}$" to 3"	"	14 "

It is necessary when milling reamers having the number of teeth in this table to use milling cutters made especially for the purpose, so as to obtain the correct shape of tooth and a flute that will hold the necessary amount of chips.

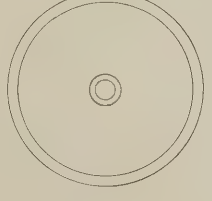

Fig. 7.

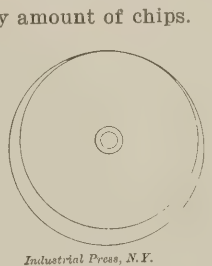

Industrial Press, N.Y.

Fig. 8.

A mistake often made in making cutting tools is paying too little attention to the matter of chips. Stock is removed from steel, when machining, in the form of chips, and unless provision is made for these chips they are in the way. They fill the flutes of the tool, get in front of the cutting edges, and are forced into the surface of the work, tearing it and making unsightly work. Then, again, they wedge between the tool and the work, clogging it, and as a consequence the teeth are broken; or perhaps when sufficient force is applied to move it the tool is broken.

Now, to secure a tooth strong enough to stand up to the work without springing, and yet provide a flute that will take care of the chips, special cutters are sold. The herewith table shows the number of the cutter suitable for any size reamer.

TABLE II. NUMBER OF CUTTER FOR REAMERS.

No. 1	cutter	cuts	reamers	from	$\frac{1}{8}$"	to	$\frac{3}{16}$"	diameter
No. 2	"	"	"	"	$\frac{1}{4}$"	to	$\frac{5}{16}$"	"
No 3	"	"	"	"	$\frac{3}{8}$"	to	$\frac{7}{16}$"	"
No. 4	"	"	"	"	$\frac{1}{2}$"	to	$\frac{11}{16}$"	"
No. 5	"	"	"	"	$\frac{3}{4}$"	to	1"	"
No. 6	"	"	"	"	$1\frac{1}{16}$"	to	$1\frac{1}{2}$"	"
No 7	"	"	"	"	$1\frac{9}{16}$"	to	$2\frac{1}{8}$"	"
No. 8	"	"	"	"	$2\frac{1}{4}$"	to	3"	"

It was formerly considered necessary, to avoid chattering, to mill an odd number of flutes in reamers. The writer remembers the first reamer of this style that he was given to make. It was impressed on his mind that it was almost a crime to make a fluted reamer with an even number of teeth. It has, however, been settled beyond the shadow of a doubt that an even number of teeth *unevenly* spaced gives as good results as an odd number. And such reamers are much easier to make, on account of the ease of gaging as to size when grinding. The teeth being opposite each other, can be gaged by a micrometer caliper, while it is necessary to gage those having an uneven number of teeth with a *ring gage* of the correct size, which is not only costly, but the liability of getting the centers out of line, or a particle of emery dust in the center holes while gaging, is very annoying. Should any dust get into the countersunk hole, as mentioned, it will, of course, cause the article to run out of true. In many cases the operator will grind the piece before noticing the trouble, and when a piece of work is nearly to size a very small particle of dirt of any character will cause it to run out enough to spoil it if touched with a revolving emery wheel.

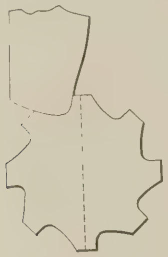

Fig. 9.

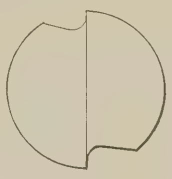

Industrial Press, N.Y.

Fig. 10.

Fig. 9 shows a form of cutter made especially for milling the flutes in reamers. The number of the cutter to use for each size of reamer is given in Table II. This form of cutter makes a tooth that is strong enough to cut and not spring, and the flute is of proper size to take care of the chips removed.

The cutter should be set so as to cut the face of the tooth somewhat ahead of the center, as shown in Fig. 9. This is known as a negative rake; the amount should be about 5 degrees. Generally speaking, a reamer will cut smoother if the cutting edge of the tooth has a negative rake—rather than radial—that is, running toward the center, as shown in Fig. 10.

It has been ascertained by experiment that when the form of milling machine cutter shown is used in milling the flutes, the depth of the cut can be accurately determined. It should be of a depth that will make the land one-fifth the average distance from the face of one tooth to that of the next. Should it not be as deep there will not be room in the grooves to hold the chips; should it be deeper, the teeth will not be sufficiently strong, and will spring out into the stock being cut, producing a very unsatisfactory hole which will in all probability be larger than the reamer.

When the piece of work has been milled square on the wrench end, and is ready to have the grooves milled, the cutter is located so as to give the face of the tooth a negative rake, as described. As stated, we can give it an even number of teeth provided they are unevenly spaced, yet in order that the size may be handily calipered when grinding, the teeth must be diametrically opposite each other. The irregularity of spacing must occur between teeth adjoining (next to) each other. To accomplish this we cut one tooth, then turn the index head of the milling machine one-half revolution and cut the opposite tooth.

For the benefit of any who may not be familiar with the working of the index head used on the universal milling machine we will say it is so constructed that it is necessary to give the index pin arm 40 revolutions in order that the work held between the center may make one revolution; of course it is necessary to put the pin in the hole we started from. To turn the reamer one-half way round we would turn the index pin twenty revolutions. Having cut the first pair of flutes—opposite each other—we turn the index head to bring the reamer in position for the next tooth. As previously stated, it is best to cut the teeth so they will be *unevenly* spaced; the irregularity of spacing is obtained by moving the index pin a greater or less number of holes than would produce evenly-spaced teeth. It is generally considered good practice to have a variation of about 3 degrees from an angle corresponding to regular spacing; it is not necessary that it be just 3 degrees—anywhere from 2 degrees to 4 degrees will answer.

In order to produce a variation of a few degrees from even spacing it is necessary to calculate the number of holes necessary to move the index pin for each move, so as to produce an unevenness of spacing that shall vary at least two degrees and not more than four degrees from an amount equal to even spacing; and as an explanation of this would cover more ground than should be taken up in this article we will consider this in our next.

THE EUCALYPTUS TREE AS AN INEXHAUSTIBLE SOURCE OF FUEL.

In 1882 Mr. Hutchins and Sir A. Brandis, as the result of their experiments, discovered that eucalypts planted on tropical mountains produce fuel at the rate of 20 tons—dry weight at 60 pounds per cubic foot—per acre per year in perpetuity. The eucalypt plantation reproduces itself when cut without further expense, and its dry timber, heavier than coal, has an equal or a higher thermal power, bulk for bulk, than coal. This result was obtained as a measurement of the maximum yield of the Eucalyptus on the Nilgiris, southern India. If a chance tree on a chance mountain in a chance soil can produce the equivalent of 20 tons of coal per acre per year, it seems not unreasonable to suppose, as Mr. Hutchins suggests, that by selection double this, or 40 tons, can be produced. A powerful sun, a heavy rainfall, and a very rapid forced growth are the essentials of such a production of wood fuel. A glance over the rainfall map of the world shows these conditions are fulfilled over about 8,000,000,000 acres of its surface, which is between one-fourth and one-fifth of the total land surface of 35,200,000,000 acres. One half of this area under forest might thus yield the equivalent of 160,000,000,000 tons of coal yearly, which is more than 288 times the world's present consumption of coal, assuming that coal and eucalypt timber are of approximately equal heating power. On the basis of the actual forest yield of the present day, we have half of this, or the equivalent of 80,500,000,000 tons. In Germany, one-fourth of the total area is under forest, and taking the German standard of one-fourth forest, on the basis of the present maximum yield we should obtain 40,250,000,000 tons; while if the maximum forest yield be converted to an average forest yield there would still remain a yearly product of 20,175,000,000 tons, which is rather more than thirty times the world's present consumption of coal. Thus it is seen that the yield of firewood from the world's tropical and extra-tropical forests, wherever they are fully stocked and scientifically worked, will yield the equivalent of from 30 to 122 times the present consumption of coal, or even up to 243 times that consumption, if the present timber yield be doubled by cultivation.—*Journal of the Franklin Institute.*

Mechanics are familiar with the hand drills, screw drivers, etc., which have a long spindle, spirally threaded, on which is a nut of peculiar construction that can be moved back and forth, to drive the tool at a rapid speed of rotation. Mechanics who are also sportsmen will be interested to know that the device has been applied to the handles of fly rods, for operating the reels. A sleeve slides on the outside of the rod handle and operates the spiral spindle, which is inside, through a slot in the handle. Bevel gears, with ratchet, connect the spindle with the reel. The inventors are Allen E. Hall and William G. Smith, of Philadelphia, Pa.

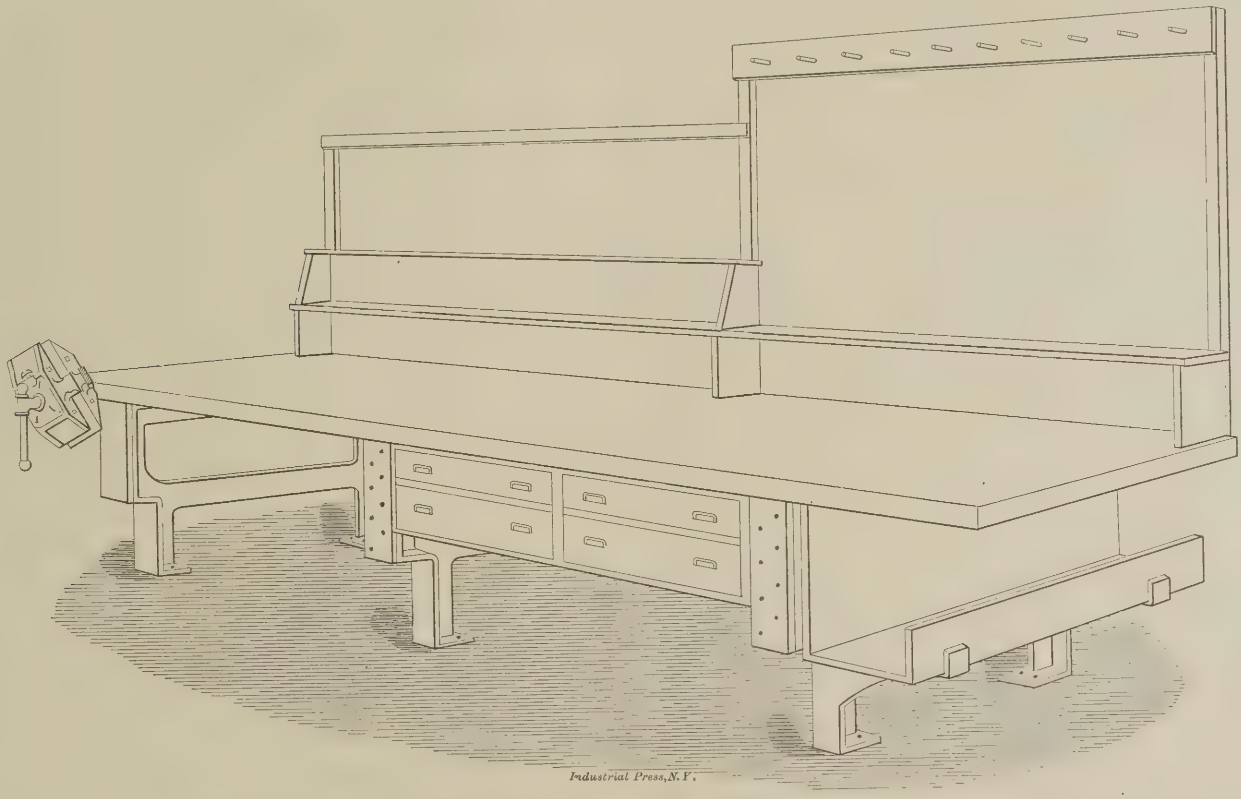
MACHINE SHOP EQUIPMENT.—4.

EQUIPMENT OF THE PATTERN SHOP AND PATTERN STORAGE ROOM.

OSCAR E. PERRIGO.

Next to the drawing room in the usual order of the production of new machines, and the development of new plans and ideas into their practical form for commercial purposes, comes the pattern shop, with its proper equipment of woodworking machines, its work benches for the expert workmen, and the conveniences for those associated with them in getting out dimension lumber, and other similar work in connection with it; and closely allied with this department, and really forming a part of it, the pattern storage room, wherein patterns may be properly catalogued, stored and issued to the foundry as occasion may require.

In the pattern shop proper the designs of the draftsmen are first brought into tangible form, as patterns for the production of those parts to be made of that most common of all materials used in modern construction, namely, cast iron, as well as those for brass, malleable iron and steel castings.



Industrial Press, N. Y.

Fig. 1. Patternmakers' Bench.

It is proper, therefore, as well as convenient, that the pattern shop should be placed next to the drawing room. In this case it opens out of it, and has also its convenient passageway to the machine shop by way of a wide door opening upon the machine shop gallery, which, being reached by the large traveling crane, affords a ready means for moving any heavy or bulky articles to and from the pattern shop as readily as to any part of the machine shop.

The pattern shop occupies the space over the tool room and store room portions of one of the fifty foot square structures, and extends, also, over the space taken up by the main driveway on the ground floor. It is thus fifty by seventy feet, affording ample space for all the ordinary uses of this department.

In Fig. 2 is shown the plan of the pattern shop and the pattern storage room, and the location of the tools, machines, benches and other fixtures therein, as well as those in the pattern storage room, giving the location of the pattern storage racks, and the trap doors, one of which opens over the storage space in the yard and the other over the flask room of the foundry.

As to the capacity of the pattern shop and the number of workmen who may be employed in it to advantage, assuming that the arrangement is in force of having special men for special work, there may be fourteen men as its regular force. These will be divided as follows, namely, one foreman, six regular pattern makers, one man at the lathes, one man at the planers, one man for the rip saw and the cutting-off saw, one man at the band saw and for building up segment work, one man at the varnish bench for varnishing patterns, and one man to letter and keep a record of patterns, and one general laborer.

If the product of the shop is in a regular line where nearly the same work is turned out year after year, we have only to provide for the necessary changes of patterns due to the usual changes of form and style that may be required by the demands of trade. In this case the force above provided for could well be considerably reduced. If the product of the establishment is of such a nature that improvements, both in the work turned out and also in the tools necessary to accomplish that result are constantly in progress, the force above specified will not be too great. If the product is such that a majority of the orders are for such machines as have to be made special, or with important features specialized to meet individual cases, then the force described above may not be sufficient to maintain an evenly balanced arrangement and division of the working force of the establishment.

Where the latter condition is found it may be necessary to use a portion of the pattern storage room adjoining the pattern shop, and well lighted for such use, should it become necessary.

The equipment of the pattern shop has been carefully worked out, with the end constantly in view of so arranging the available space and of so equipping it with such woodworking machinery as may be necessary to carry out the plan of keeping the skilled pattern makers constantly at work on that which is essentially pattern work, and requiring a man skilled in that vocation, rather than of allowing them to use their time in getting out dimension lumber, varnishing patterns, and similar work, which may be just as well done by men of less ability and a lower rate of wages.

Consequently the machines, such as surface planer, jointer, rip saw, cutting-off saw, etc., are handled by men who are practically "mill men" who, while they know little or nothing about pattern making, are capable of getting out such dimen-

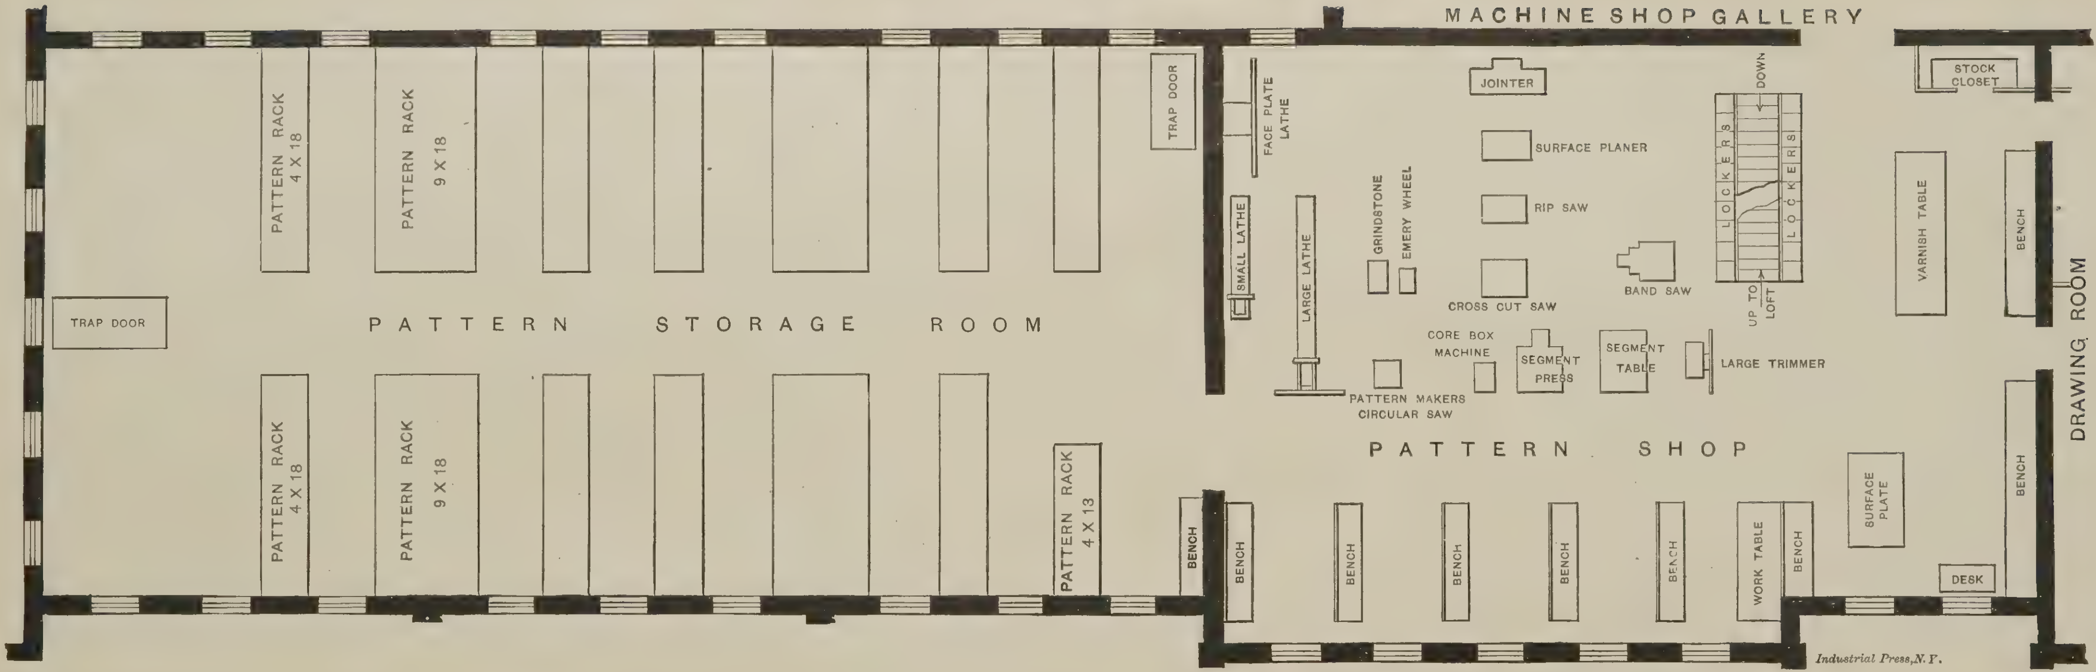


Fig. 2. Plan of Pattern Shop and Pattern Storage Room.

sion lumber as may be called for by the pattern makers in much less time and at less cost than if it were done by the pattern maker himself. So it is with the man who handles the band saw, whose principal work is that of cutting out segments for the building up of the rims of wheels, gears, etc. Being constantly at this particular kind of work, the man need not be a skilled pattern maker and yet can exceed one in the output and the economy of doing this class of work. In the same manner for varnishing of new patterns and the revarnishing of old ones, a pattern maker is not needed. Neither is it necessary to employ one to mark, letter, arrange and catalogue the patterns when completed, as this work may be just as well and much more economically done by a special man at a less rate of wages.

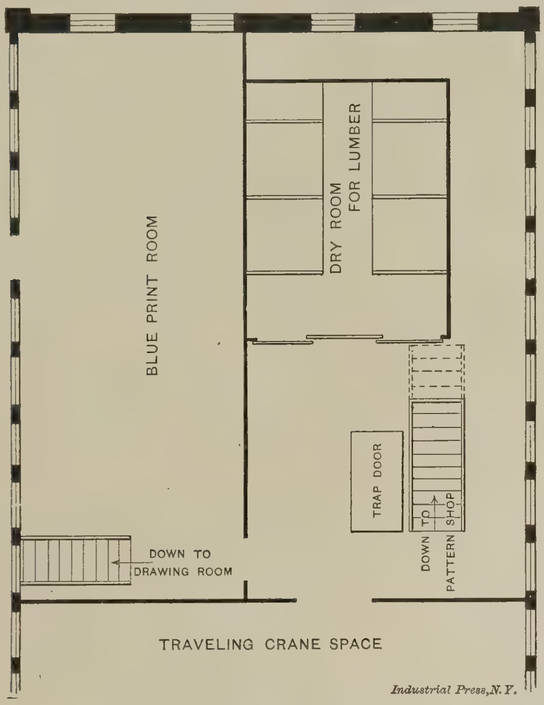
The equipment of machinery and fixtures for the pattern shop, and the location selected for them to insure convenience of their operation and of the handling of stock and product without unnecessary labor, is fully shown in the general plan in Fig. 2, and is as follows: Next to the machine shop wall is placed a jointing planer, provided with the usual guides and gages by which the various angles or bevels may be cut upon any length of stock up to sixteen feet. Beside this is an ordinary surfacing planer capable of taking in twenty-four inches in width and, also, sixteen feet in length. Upon the jointing planer stuff may be planed "out-of-wind," and then passed to the surfacing planer for reducing it to an even thickness. If much large work is to be made where large and perfectly true surfaces are necessary to be obtained, it will be advisable to have a Daniels, or vertical planer, to which this stuff is first taken. From the surface planer the stuff passes to the rip saw, and from there to the cutting-off or cross-cut saw. In many cases it must be passed back to the jointer to be finished on the edges.

Shop trucks with proper racks should be provided, upon which the lumber may be placed, so that unnecessary handling or carrying may be avoided.

Next to the segment press is a core-box machine, which is a very convenient, if not almost indispensable, machine where many boxes for round cores are to be made, as it accomplishes the work in a fraction of the time required to do it by hand.

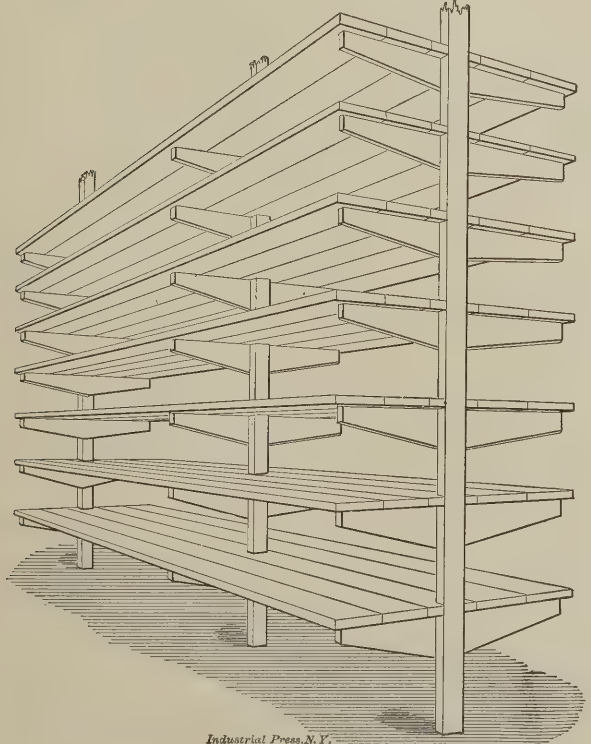
Next to the core-box machine is a special pattern maker's circular saw bench, which is so arranged as to carry both rip saw and cutting-off saw, either of which may be brought into use as needed; and a table capable of being set at any desirable angle. The table is provided with guides and gages for cutting any angle wanted. This saw is of special value in pattern-shop work, and saves much hand labor, even in cutting out the quite small parts of patterns. The Colburn universal saw table is an excellent example of this class of machine.

As a large part of pattern making often consists in laying up segment work, special provision is made for it. From the planers the stuff is taken to the segment table, laid out, then to the band saw where it is cut into segments, from whence it goes to the trimmer, the ends are cut and the segments are fitted into circles on a wooden faceplate. This plate has formed on its under side a recess which fits over the iron faceplate of the lathe. A circle of these segments having been fitted together, they are glued at the ends and small steel dogs inserted to hold them. Another circle is formed and glued at the ends and to the first segment, the dogs being placed in the edges, out of the way, and the whole placed in the segment press, which holds it firmly until the glue has set; and so on until the job has been completely laid up. It is convenient to have two faceplates to work on alternately, as one may be in the press while an additional circle of segments is being fitted to the other. The segment press is of the vertical type, and may be constructed with a large screw acting upon a follower, or it may be built similar to a Greenerd arbor press with a rack and pinion arrangement. A convenient form is one with a vertical screw having fixed to its upper end a large wormwheel which engages a worm upon a horizontal shaft, which extends to one side of the press, where a handwheel is attached to it for convenience of operating. With this arrangement segments may be made and laid up in much less time than where hand clamps are used and applied as each segment is laid on, while the evenly distributed pressure insures good contact of all the pieces. They may be nailed, or not, as desired.



Industrial Press, N.Y.

Fig 3. Plan of Loft over Pattern Shop.



Industrial Press, N.Y.

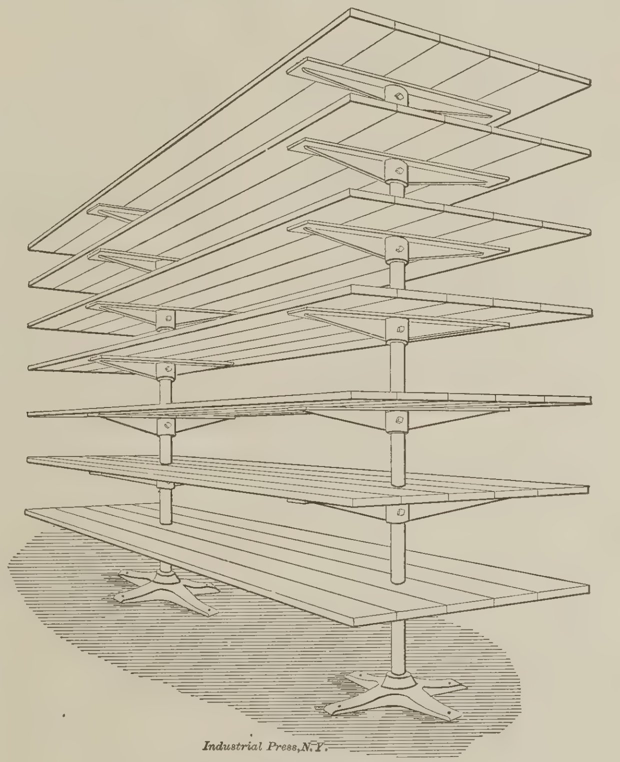
Fig. 4. Pattern Rack.

For small turned work a wood lathe to swing eighteen inches, and with a ten-foot bed, is provided. For larger work a lathe of thirty inches swing and with a sixteen-foot bed will be a good size. Both should be provided with slide rests, and the larger one with a faceplate on the back end of the spindle for turning large work from a floor rest. When much larger faceplate work is called for, a faceplate head is needed, and one is located near the rear wall and in line with a rear window. This head carries a faceplate capable of swinging ten feet. In front of this, may be arranged a compound rest, supported by a pedestal, and capable of covering the turning, inside and out, and of facing the largest work to be done.

Near the lathes the grindstone and the emery wheel are located. The latter should be provided with wheels of different form for grinding the various shapes and sizes of gouges and similar tools in use.

The foreman's corner is next to the drawing room, so as to be in convenient communication with that department. He has a bench, more as an occasional convenience than for regular use, and a desk, as a necessary part of his equipment.

The first pattern maker from him has, in addition to the regular equipment, the use of a cast-iron surface plate, say five by eight feet, its dimensions regulated, of course, by the kind of work to be done. This is an indispensable convenience in building up many of the more complicated patterns, and there should be at least one in every pattern shop.



Industrial Press, N.Y.

Fig. 5. Pattern Rack with Metal Frame.

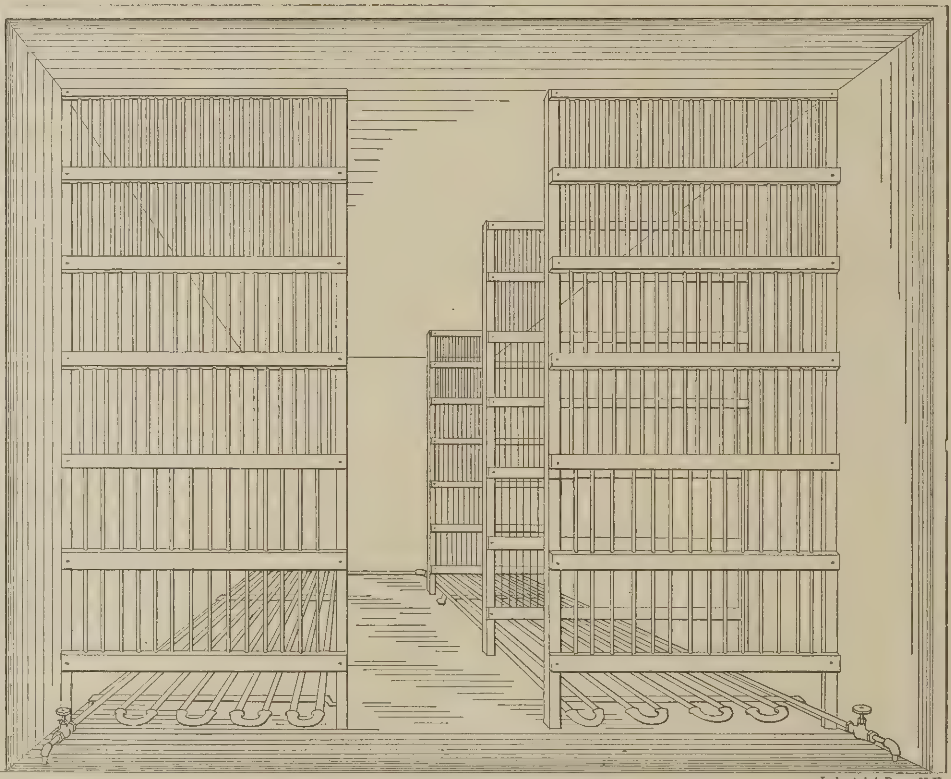
The pattern maker's bench is shown in perspective in Fig. 1. The top is thirty inches wide and ten feet long. It stands thirty-four inches high. It is composed of hard maple at the front, twelve inches wide, and the rear portion of white pine, both two and a half inches thick. It is supported on three cast-iron bench legs, the front feet of which are set back five or six inches, so as to be out of the way of the pattern maker's feet. The upper sixteen inches of these legs has a facing of hard maple, that on the center and rear legs having holes for the introduction of pins for supporting long work when held on edge. Four drawers, with flush pulls, are placed in a case under the rear portion of the bench, for holding small tools, files and a variety of similar articles found necessary by every pattern maker. At the rear end is formed a compartment under the bench for holding short pieces of hardwood stock, dowel pins and similar materials. At the head of the bench is located an Emmert universal vise, which seems to be the best device yet put on the market for this purpose, as it may be placed in almost any position convenient to the workman, and will hold a piece of almost any form with equal facility. At the back of the bench is a shelf or tool rack extending the whole length, and at a proper height above it is one extending one half the length. These are to be properly perforated for the reception of the ordinary tools of the pattern maker, such as his chisels, gouges, auger bits, twist bits and drills, screw drivers, and all similar tools. Over this short tool rack the backboard is extended up to a light rail, so as to provide a space for hanging larger tools, such as bit-stocks, back saws, and tools of this nature. At the back of the rear half is an open frame whose top bar is provided with pins for hanging large saws and similar articles. If the kind of work renders it necessary a bench trimmer should be attached at the rear end. This style of a bench is at once rigid and substantial, does not occupy unnecessary floor space, is compact and complete in all its arrangements, and for a first-class bench it is economical in cost.

These benches are arranged with the head toward the wall and two feet from it, so that private tool boxes or cupboards may be conveniently arranged upon it. Their positions are clearly shown in the plan.

A large work table is provided for the second pattern maker, and one should be provided for the others when the nature of their work requires it. It may be placed either between the benches, or near their rear end, as may be most convenient.

It will be noticed that the benches and machines are so arranged that they leave a broad alley through the shop, and to the door leading to the machine shop gallery.

There is a regular wall bench and a large center table provided for the varnisher and the workman having charge of the marking, numbering and cataloguing of the patterns. From this point they may be taken on properly-arranged platform trucks, to the pattern storage room, or to the foundry, as the case may require.



Industrial Press, N.Y.

Fig. 6. Dry Room for Lumber.

At each side of the stairs leading to the loft the individual lockers for the use of the men are arranged. These are of the expanded metal type, as built by Merritt & Co., or of some very similar material and construction, but never of boards, or any construction which excludes thorough ventilation and safety from fire.

The stairs just mentioned lead to the loft shown in the plan in Fig. 3 and in which is constructed a lumber drying room, as laid out in the plan and shown in interior perspective in Fig. 6. This room is tightly closed by double sheathing on the top, the back and both sides. The front is closed by three sliding doors, arranged to pass each other, so that any portion of the front may be opened for the purpose of putting in or taking out lumber. The lumber racks are of wood construction, the posts being 4 x 5 inches, the two lower horizontal timbers 3 x 6 inches; the next two are 3 x 5 inches, and the upper three are 3 x 4 inches. These timbers should be firmly bolted together and to the sides of the room by through and through bolts as there will necessarily be much shrinking of the timbers, and consequently no nails should be used. The sheathing may be put on vertically or horizontally, as preferred, but both thicknesses should run the same direction, and should break joints. The studding or timber work supporting the sheathing should not be over three feet apart, in the direction of the length of the sheathing.

In the drawing, Fig. 6, only the front frame is shown on the left of the room, to avoid a confusion of lines, as the form and location is fully shown on the opposite side. The frames should be placed seven feet apart, so as to accommodate lumber from eight to eighteen feet in length. The lumber is placed on edge, supported by three racks, or frames of this kind and held in place by round iron rods, five-eighths inch for the three lower sections, and one-half inch for the three upper sections. These rods should be placed five inches apart in the lower section, four inches in the second, three and one-quarter inches in the third, two and one-quarter inches in the fourth, one and three-quarter inches in the fifth, and one inch in the sixth, from center to center. The distance apart, in the clear, for the horizontal supports, should be eighteen inches for the lower four spaces, and sixteen inches for the upper two spaces, if lumber of the ordinary widths is to be used.

Heat may be applied by a steam coil as shown in Fig. 6, or hot air may be admitted from the regular air pipes of the heating system. The degree of heat should not be high as the seasoning process is apt to be too much hurried and so produce an unnecessary number of "season checks" by drying and consequently shrinking the outer portion of the lumber before the center has the opportunity to contract with it. Some have advocated the plan of standing the lumber on end, and then turning it "end for end" once a week. This causes an unnecessary amount of labor. If the lumber is placed in the racks as shown, it will not be necessary to even turn it over, provided too high a temperature is not maintained. The necessity for a dry room is apparent from the fact that it is very difficult to obtain properly kiln-dried lumber fit to put into pattern work, whatever price we are willing to pay for it. And unless we dry it ourselves we are never sure of its condition. Patterns are too expensive to take any chances of improperly seasoned lumber.

For convenience in passing lumber to and from the dry room, a trap door, as shown in Fig. 3, may be made in the floor of the loft. Pattern lumber may be delivered on the machine shop floor, passed to the gallery by the traveling crane, then up through this trap door to the dry room. After it is properly dried, it may be passed back to the pattern shop in the same way. Or, it may be passed in through the trap door over the pig iron storage space, and thence into the pattern shop.

The pattern storage room is a continuation of the pattern shop, a door eight feet wide giving ample access to it. In the inner corner, next to the pattern shop, is a trap door four feet by eight, opening over the pig iron storage space, and at the other end of the room is a trap door four by ten feet, opening over the flask room of the foundry. Over this trap door is a quick-acting hoist by which patterns may be readily lowered to the foundry, or brought back to the pattern storage room. This room is amply lighted so that patterns may be easily found, stored, or taken from the shelves as needed.

The system of storing patterns is upon a series of shelves arranged so as to form alcoves connecting with a wide passage way in the center, the pattern racks being placed with the end against the wall, and regularly between the windows. Opposite the broad spaces in the walls where the pilasters are located, and space between windows is wider, the pattern racks are made of double width, and are used for the storage of larger patterns, which may be more conveniently stored on very broad shelves. Should the patterns be generally of small size, so as to make narrower shelves advisable, the racks may be all made of single width and located without regard to the windows. In this case they are placed two feet from the wall. In the arrangement shown, the single racks have shelves four by eighteen feet, and in the double racks the shelves are nine by eighteen feet. Thus, the latter style will accommodate from four to nine feet in length.

At the end of the pattern storage room next to the foundry, a space is left clear for the care and storage of patterns too large for placing upon the shelves. It will, of course, be understood that in every shop special arrangements must be made for the care of patterns peculiar to the kind of work done, and that the arrangement here given is only such as may be useful in a general way, and that it is subject to whatever modification may be necessary to suit individual conditions. For instance, if there are many heavy patterns like lathe beds, planer beds, or engine beds, etc., it will be necessary to provide a larger space for them, and also, to arrange for readily lifting and moving them. A convenient method is to suspend an I-beam overhead, and upon this to run a trolley with a chain or rope hoist, by means of which the patterns can be picked up and moved wherever they are wanted. These may be put up with branches and switches, so as to cover any desired space. If these large patterns are placed entirely upon the floor they will occupy too much valuable space. They may be arranged in this manner: One bed pattern may lie upon strips not less than an inch thick laid on the floor. Over this pattern are placed two or more trestles, high enough to clear it. Upon these a second pattern may be placed. Over this place still higher trestles, and upon them support a third pattern, and so on. The advantage of this method is that the patterns may be always kept in good condition and "out-of-wind," while if, as is often done, strips are laid upon one pattern, and another pattern supported upon it, there is a strong probability that it will be marred and injured, or warped out of shape.

Various forms of racks, both self-supporting and attached to the building, have been devised. The common form used to be that of supporting the shelves by a series of posts placed four to eight feet apart, and spiking to these horizontal strips, upon which the boards or planks forming the shelves were placed. Frequently a strip three or four inches high was placed around the shelves to prevent the patterns from falling off. This made a receptacle for dust and dirt which was not only disagreeable but difficult to get rid of. In this form of racks the numerous uprights obscured a good deal of light, and were very much in the way of conveniently handling patterns.

Considering these conditions, the best arrangement of pattern racks seems to be of the forms shown in Fig. 4 and Fig. 5. The form shown in Fig. 5 is composed of two heavy cast-iron bases, into which are screwed pieces of three-inch wrought iron pipe. Upon these are fitted cross supports of cast iron with rough-cored holes. They are held at any desired height by two setscrews in each support. Upon these supports the shelves are built, their thickness being according to the weights of patterns to be stored. For ordinary patterns the shelves should be of one and a quarter inch planks, and the distance between supports not over eight feet. Where heavy patterns are to be placed on the shelves the planks should be one and a half inches thick, and the distance between supports reduced to about six feet. In this case setscrews should not be depended upon to hold the cross supports in place. Pieces of wrought iron pipe, large enough to easily slip over the upright supporting pipes, and cut the exact length necessary, should be used, by first placing one over the pipe and resting on the cast-iron base. Then put on the cross support, then another piece of pipe, and so on to the top. The planks are fastened with heavy wood screws passing up through the cross supports. The bases should be fastened to the floor with lag screws.

If inconvenient to construct these tracks with iron supports as just described, they may be constructed entirely of wood. If this is to be done the uprights are fastened to the floor and also to the overhead timbers by nailing, or still better, by iron knees and wood screws, so as to be held firmly in their proper position, as shown in Fig. 4. To these uprights are spiked cross pieces or supports of the form shown, and upon these are laid plank shelves as described for the shelves when iron supports are used. If the patterns are very heavy, the cross supports may be let into recesses in the uprights, and fastened with through and through bolts. The proper distance between supports will be the same as with the iron construction of supports. For ordinary and usual conditions the vertical distances will be about as follows: From the floor to the top of the first shelf, two feet; from the top of the first shelf to the top of the second, twenty-two inches; to the next, eighteen inches; to the next, sixteen inches; to the next, fourteen inches; and to the top, twelve inches. Of course these shelves may be continued higher up than this, but on account of the difficulty of access the above arrangement would seem to be quite high enough.

Several light step ladders should be provided for conveniently reaching the patterns on the upper shelves. Obviously, the heavier patterns will be placed on the lower shelves. Large gears, pulleys, balance wheels, etc., may be set on edge, in racks similar to those used for holding rolls of belting, but are somewhat more liable to become warped than if they are laid down flat on the shelves that are true and level.

In the case of the double width shelves, as called for in the plan, Fig. 2, there should be two upright pieces of wrought iron pipe to carry the cross supports, the latter being made of appropriate form, and having cored in it two holes, four feet apart, from center to center. A similar modification should be made in the wooden construction. For racks of eighteen feet in length there should be three supports, the outer ones placed thirty inches from the ends, and the third one in the center. This will provide for three wrought iron pipe supports in a rack four feet by eighteen feet, and for six supports to a rack that is nine feet by eighteen feet.

One of the greatest conveniences of this system of shelves for storing patterns, is the fact that they are free of access on all sides, with absolutely no obstruction whatever, either to light or the handling of patterns, while their appearance is much better than any of the older forms.

* * *

Some British economists have deplored the exportation of coal from the British Isles, claiming that in so doing they are living on their capital, inasmuch as coal *in situ* is regarded by them as capital. In an editorial on fiscal fallacies the *Colliery Guardian* says that if coal *in situ* is regarded as capital, it is destroyed equally as much if burned at home as though it was exported. If burned at home and the resulting product is exported, the result is exactly the same so far as future generations and the coal supply are concerned, as though the coal had been exported. It is, however, regarded as a fallacy by the *Colliery Guardian* to hold that coal *in situ* is capital; "it can only become capital by utilizing it." Another writer quoted says that "to sit on the lid of our grimy treasure chest until some Edison of the future has rendered its contents valueless, would be a foolish proceeding." From which we infer that while "you cannot eat your cake and have it too," by eating it, ways and means are made by which two cakes can be obtained for the next meal. Miserly saving does not create wealth, it only conserves it; consumption that stimulates a healthy supply does create commerce, wealth, inventions, manufactures and the other attendants of advanced civilization.

* * *

In the description of the new Springfield army rifle, published in the October issue, it was stated that the height of the maximum ordinate of the trajectory shooting at a range of 1,000 yards, is only 20.67 *inches*—a most wonderful result! This should obviously be corrected to read 20.67 feet, which makes it agree with the figures given in the table. The mistake could not have deceived anyone acquainted with the elements of gunnery and the laws of mechanics, but it is an example of the provoking errors that will creep into printed descriptive matter in spite of the most careful scrutiny. The range for a trajectory 20.67 inches high, shooting with this rifle, is about 1,000 feet.

BREECH MECHANISM OF THE 16-INCH COAST DEFENSE GUN.

Much interest, naturally, has been taken by the public in the great 16-inch seacoast defense gun, model 1895, which was recently completed at Watervliet Arsenal after a period of nearly nine years had elapsed since the contract for the great lathe and other machinery was made with the Pond Machine Tool Co. in 1894. Since the completion of the gun it has been transported to Sandy Hook Proving Ground, and has successfully passed the test to which all ordnance is subjected before being permanently mounted.

The 16-inch gun is the most powerful ever built, its 2,370-pound projectile with the normal powder charge (640 pounds of smokeless nitro-cellulose), velocity 2,300 feet per second, having a muzzle striking energy of over 88,000 foot-tons, but there are some doubts as to its practical utility in actual warfare. Nevertheless it is a triumph of design and mechanical construction; so far it is the largest gun built by the modern system of shrinking jackets and hoops upon a tube, giving the latter an initial compression nearly equal to its elastic limit. By this construction the initial compression must be overcome before there is any tendency to burst the tube. Partial details of construction, principal dimensions and other data may be found in MACHINERY for September, 1901, and May, 1902. The following matter has reference to the breech action which is presented as an interesting example of mechanism—not new, of course, but of interest to many readers nevertheless.

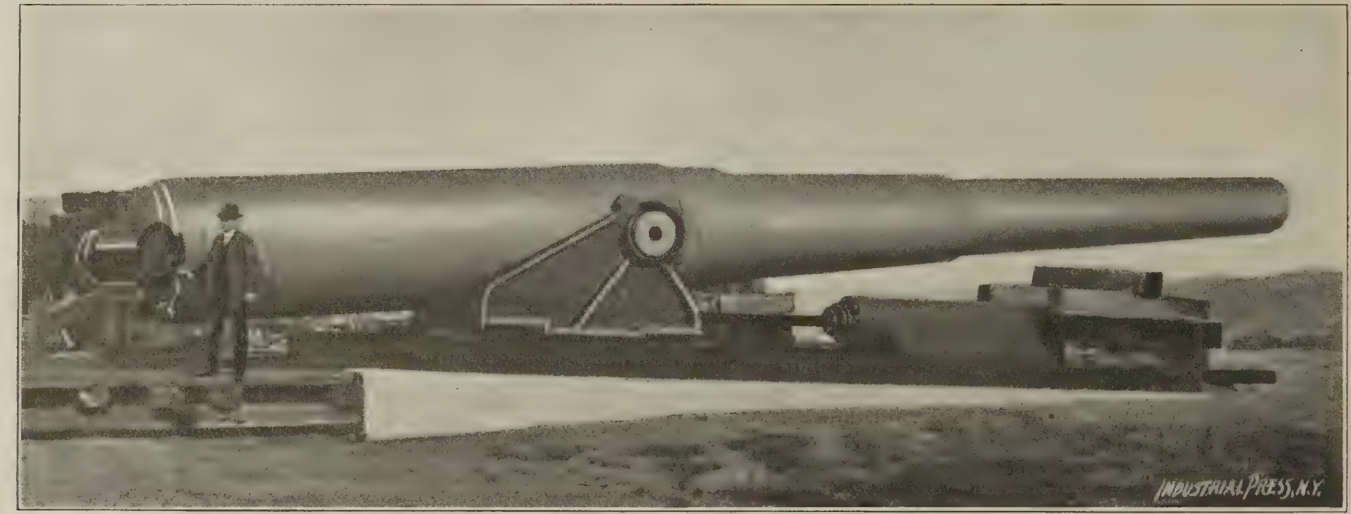


Fig. 1. Sixteen-inch Coast Defense Gun, at the Sandy Hook Proving Ground.

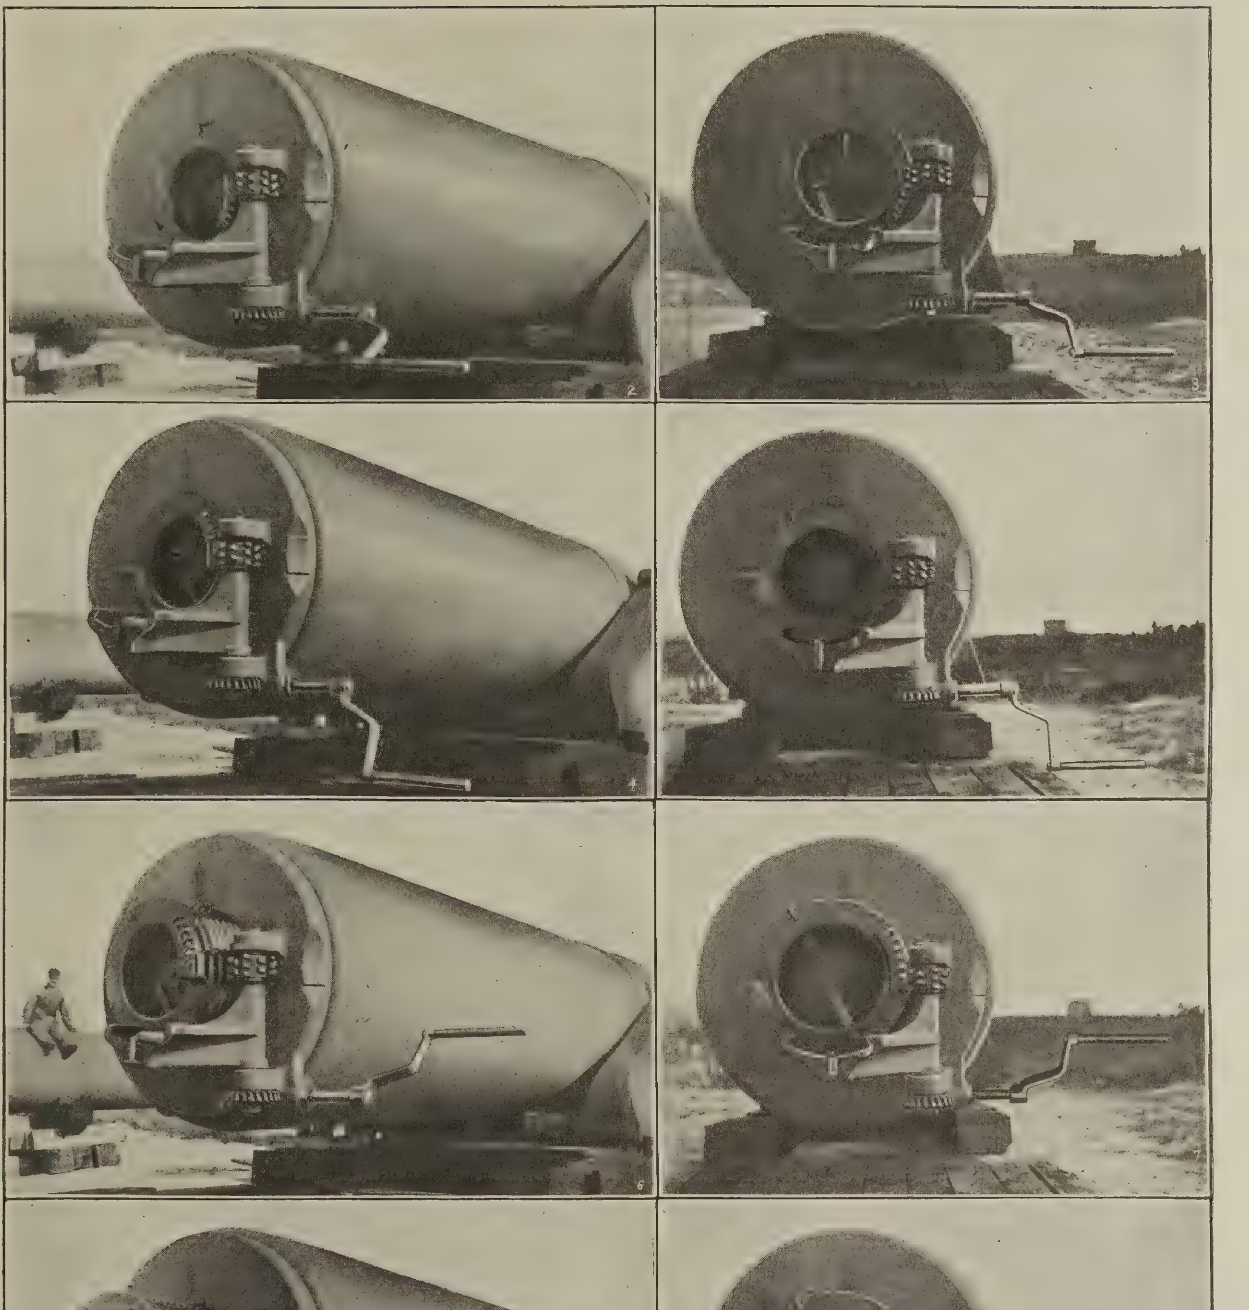
Fig. 1 shows the gun as it now appears on the temporary mounting where the proving charges were fired. The permanent mounting will be on Romer Shoal, a chain of rocks lying between Sandy Hook and the western end of Long Island. Just beyond it is the Gathmann 18-inch gun, which, however, is not nearly so heavy, and some distance beyond that is the Brown wire-wound gun which in a recent test fired a shot with an initial velocity of 2,500 feet per second. A government railway runs the length of the "Hook," and the temporary mountings are all located close to it. Further along the track towards the point of the "Hook" is the regular proving ground where the standard types of seacoast guns and mortars are proved.

The breech actuating mechanism of the 16-inch gun is known as the Stockett system, which does not differ greatly from the Farcot-Fletcher system used on the 10 and 12-inch guns, being a modification of same. It is an example of a simple mechanism which performs a somewhat complicated action by simply turning one crank. The views, Figs. 2 to 11 inclusive, show it in the closed and open positions, and in three intermediate positions. Two views are shown in each case, one from the rear and the other at an angle of about 45 degrees.

As stated, only one crank is used to open and close the breech. The action is continuous and entirely automatic in the matter of changing from one motion of the breech-block to another, there being three distinct movements of the block in all.

With the breech closed, turning the crank to the right first rotates the breech-block 30 degrees, or one-twelfth of a turn. This movement disengages the threads of the interrupted screw, there being six sectors threaded and six blank, each 30 degrees wide. To be exact, the width of the threaded sectors in the block is 0.05 inch less than 30 degrees of the total circumference, in order to give the necessary clearance. This completes one movement. Continued turning of the crank is now converted from rotation of the breech-block into translation of same longitudinally from the breech, the interrupted thread now being so disposed as to permit this movement. It will be noticed that the worm, engaging the section of worm-wheel cut from the solid on the end of the breech-block, is also a pinion, having both longitudinal and spiral cuts. It is thus enabled to act in a double capacity—as a worm when rotating the breech-block, and as a pinion when moving it longitudinally. When the breech-block has been rotated 30 degrees, further rotation is prevented by the compound gear coming into contact with that portion of the mutilated worm-wheel or rotating rack in which no tooth space is cut, but it is now opposite the translating rack cut from the solid in its side, and of the slide way prepared for it in the tray. The last tooth of the rotating rack is cut away on the inner side to avoid interference, and the first two teeth of the translating rack are modified also. The moment the breech-block stops turning, the end-thrust upon the rotating rack initiates the longitudinal movement and brings the translating rack into action. The change from one movement to the other is accomplished without perceptible shock or jar, as the writer witnessed. The mechanism is easily operated in either direction from start to finish with one hand.

The motion of translation now begins, which is movement number two. It ejects the breech-block upon the tray, or console, which is grooved with overhanging ledges for the reception of a corresponding section planed in the block. When the block has reached the end of its prescribed travel, the ledges on the tray bring up against stops on the block, and at the same time a latch is tripped which locks the tray to the end of the breech. This latch, the end of which is shown in the middle of the end of the tray, is pivoted near its center so that when the breech-block stop abuts against the upward projecting outer end, the inner hooked end is thrown upward and disengaged from the breech hook or catch. The tray and breech-block are now free to swing on the hinge pin, and are forced to do so, through an angle of about 123 degrees. This completes movement number three and leaves the breech wide open, 22½ turns of the crank having been made. The same number of turns are required, of course, for closing the breech after loading. The hinge pin and the vertical worm shaft are one, and as the worm shaft is mounted on hardened



Figs. 2 to 11 inclusive, showing five Successive Positions of Breech-block of 16-inch Gun at Sandy Hook.

ball bearings, the frictional resistance of operating the first two movements of the block and of swinging it around on the tray, are reduced to a minimum. This partially accounts for the remarkably free and easy movement, but careful fitting is shown in every detail and this is what counts on such work.

The fermeture is of the De Bange or French type. The breech block has an outside diameter of 25.96 inches; total length 27.3 inches; diameter at root of the thread of 24.82 inches; length of threaded portion 19.89 inches. The thread is of symmetrical section, having an inclined angle of 106° 24′ and a pitch of 1.71 inches. The top and bottom of the thread are rounded, the radius of the top being 0.17 inch, and of the bottom 0.11 inch. The shape of the thread differs from that of the naval guns, which is a modified buttress section, making an angle of 15 degrees on one side with the normal to the axis, and 45 degrees with the other. The circular pitch of the wormwheel or rotating rack cut in the block, is 1.577 inch; normal pitch, 1.5 inch. The translating rack has a pitch of 2.426 inches and the depth of the teeth is 1.11 inch. The compound gear operating the block has an outside diameter of 8.685 inches and is quintuple threaded, the threads having a lead of 7.885 inches and an angle of 18 degrees. The pinion teeth for translating the block, are ten in number, circular pitch 2.426 inches, of course, to agree with the pitch of the rack.

The obturator, which appears as the rounded inner end of the breech-block in Figs. 10 and 11, is the De Bange modified type. It consists of a mushroom head having a diameter of 18.85 inches, and a spindle 6.22 inches diameter at the forward part and 5.97 inches at the rear, which passes through the block and is secured by nuts on the outer end. Between the mushroom head and the end of the block packing is interposed to act as a gas-check. When the charge is fired the pressure on the mushroom head forces the packing outward against the walls of the powder chamber and prevents the escape of the gases. To prevent sticking of the action after a discharge, the obturator spindle is made to turn freely in the block so that it may remain stationary when the latter is first being opened. But the backward motion of the block, due to the pitch of its thread, releases the pressure on the packing and loosens it so that it moves freely by the time the block is turned 30 degrees. It is obvious that if the obturator had to turn with the block a heavy twisting moment might have to be applied under some circumstances to start the action loose.

The screw heads shown on the obturator head are for holding the crusher gages which are used when proving the gun, to indicate the pressure developed in the breech chamber by the powder charge. A crusher gage consists of a short steel cylinder inclosing a cavity in which is a copper shell. A hole is bored in the cylinder and in it is fitted a small piston to receive the pressure and transmit it against the copper shell. The latter yields when the charge is fired, and the amount of the yielding or crushing is an index of the pressure.

The firing of a charge is done electrically. The primer is screwed into the small hole in the outer end of the obturator spindle, which may be seen in some of the views. This hole is 0.2 inch diameter and is drilled clear through the spindle and obturator head, terminating in the powder chamber. Circuit breakers are provided so that a charge cannot be fired unless the breech is fairly closed. These may be seen, say, in Fig. 3, one being on the upper side of the breech-block and the other in contact with it and attached to the breech plate. If the breech-block is turned ever so little from the closed position, the contacts are separated and firing cannot be effected. An additional safeguard is a safety lever which is swung over in such a position that a primer cannot be screwed into the primer hole except when the breech is closed. Figs. 3, 5, 7 and 9 show this action.

Some confusion has arisen regarding the weight of this gun, partially, perhaps, because of the practice of the Ordnance Department of expressing weights in long tons. The weight engraved on the muzzle is 284,500 pounds, equivalent to 131 long tons. The 88,000 foot-tons striking energy is in long tons also; in short tons it would be 98,500 foot-tons.

The photographs from which the cuts in the preceding description were made were taken by the associate editors of this journal, acting under permission of the Chief of Ordnance, Washington, D. C., and the commanding officer of the Sandy Hook Proving Ground. The trip from New York City was made one clear day in October last, leaving Pier 12, East River, at 10 A. M. on the Government tug the *Edna V. Crew.* No one not connected with the Government service or not having a pass is permitted to take passage on this tug, nor to land at the Sandy Hook pier. A distance of nearly twenty miles is traversed across the Upper Bay, through the Narrows, and down the Lower Bay before reaching the destination. The route is the same as that traversed by all the larger vessels entering or leaving the port and is one that gives a good idea of the immensity of New York's harbor, and of the commerce that daily plies its waters.

As the name denotes, the "Hook" is a great sand bar curving into the ocean and marking the outer limit of the Lower Bay. It is a barren, desolate spot covered with a scrubby growth of trees and bushes, undisturbed save where the Government fortifications and buildings are located. The latter are mostly wood, but are being replaced with substantial brick structures that will be a credit to the country, which cannot be said of some of the wooden ones now in use. The fortifications are of great extent and appear practically impregnable. They have been greatly improved within the past two years, and the plans are by no means yet complete. The 10-inch and 12-inch guns are of the disappearing type, mounted on Buffington-Crozier carriages behind earthworks many yards in thickness. These earthworks are faced on the inner side with very heavy concrete walls. Below the gun mounts are the magazines in chambers also built of heavy concrete. The fortifications as a whole are an interesting example of the growing use of concrete for almost all purposes where masonry was formerly employed.

The regular proving ground is located so that firing may be directed toward the sea, save when armor or targets are to be tried. Firing is directed through two wire screens forming part of the Le Boulengé chronograph used for determining the velocity of the shot. When firing out to sea the horizon is carefully watched by the commanding officer through field glasses to see that no vessel is in range. The great shots ricochet across the water in leaps one-half to a mile long, at times throwing a spray of water fully 150 feet high. The report and concussion of a 12-inch gun is not so impressive as the great flash of flame and the peculiar screech of the shell through the air. A flying shell may at times be seen when the light is just right, but it requires a good quick eye to detect it. At the moment of firing the officers and men retreat to the bomb-proofs to avoid injury in case the piece proves defective.

* * *

One of the litle niceties that go to make up a well-designed machine are the dust-proof oil-hole covers which are coming to be adopted by manufacturers of nearly all types of machines, replacing loose plugs or caps, or bare oil holes having no covers at all. These devices not only locate the oil holes for the operator, and make sure that no oil hole will be overlooked, but prevent the holes from becoming clogged, conduct the oil to the right place, keep out dust from the bearing, do not become lost, and are directly responsible for a longer life of the bearing. Such covers have been particularly applicable to machine tools, where accurate fits and alignment are necessary, and to automobiles where dust works into bearings so readily. We find, also, that builders of paper machinery, printing machinery and woodworking machinery are also utilizing covers of the same description because of the superior finish and evidence of attention to details given by such devices to their products.

* * *

Holland has not granted patents for the protection of inventors, being the only civilized country having greatly diversified manufactures which has not thus stimulated the development of new ideas. But this glaring defect is soon to be remedied, steps having been taken by the government to pass laws for the protection of inventions and trademarks.

METAL COLORING.

TREATMENT OF COPPER, BRASS, IRON AND STEEL TO PRODUCE COLOR EFFECTS.

W. J. KAUP.

This is a subject that has received but scant attention in our technical papers, which is rather surprising when we note the natural inclination of the manufacturers of to-day to combine this artistic treatment with utility, and add to the severe straight-line plainness of our commercial product contrast of color, to make it more beautiful. There is nothing new in metal coloring to-day. Ages ago it was old in Japan, and to the Orient we must really turn for original authority on successful coloring of metals. To-day we only imitate the Eastern artisans. This is true, not because we lack the skill and intelligence of the Orientals, for we know full well that the commercial metals of Japan are inferior to our own and that our knowledge of metals from a scientific standpoint far exceeds theirs. It may be that to the very fact of the inferiority of their metals is due their success in coloring, for many impure metals (by that is meant alloys, found by combining two or more metals into one) are peculiarly subject to many variations of color.

For example, copper; commercially pure copper; ordinary commercial copper; or copper castings, when treated with the same solution, will have a different shade of coloring. The most pronounced difference will be found in the copper castings, due to the zinc that is combined with the copper for the commercial reason of obtaining sound castings. In these copper castings the color will be very much darker than in the other varieties of copper.

The purpose of this article is to give to those who are interested results of a number of experiments in coloring metals, solely from the manufacturing side, rather than from the chemist's standpoint. So many conditions enter into the work that no law can be laid down by which everyone can obtain the same satisfactory results, for with everyone the coloring of metals must be more or less of an experimental nature. A cheap monochrome color can be produced by the novice who is unacquainted with the metallurgical properties of metals and chemical actions of solutions used, but the very fact that the slightest change in alloy, as well as in the strength of coloring solutions, produces a different shade of coloring under the same treatment, makes it essential that the operator should have considerable knowledge of metallurgy and chemistry for any except the simplest work.

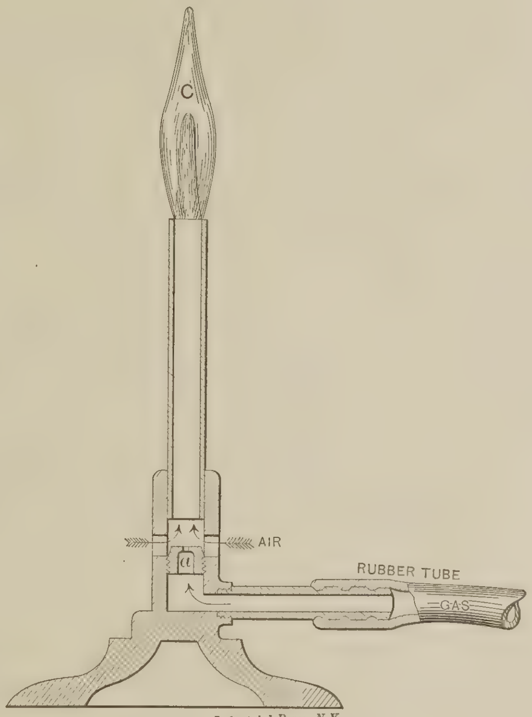
First, let us consider the different methods and conditions under which color can be obtained, viz., by heat treatment alone; varnishes and lacquers; and corroding agents or chemical compounds. We will treat each under its separate heading, but first will refer briefly to the Bunsen burner, by the use of which, together with a pot of heavy fish or lard oil and a pair of tweezers, one can color small pieces by the heat process.

Bunsen Burner.

We will take for granted that some readers, at least, are not acquainted with the Bunsen burner, or at least the principle of its operation. The cut herewith will explain its construction. The idea in this burner is to procure a flame capable of producing great heat, but which will not smoke any vessel or article, heated in it or over it, and if you will carefully note the construction it will be readily seen how this is accomplished. The force of gas, escaping through the small aperture at *a*, draws the air through the holes in the sleeve surrounding the jet. The air and gas mix together, consuming the carbon produced by the decomposing gases before it becomes incandescent, and produces the flame desired. The air is controlled by the sleeve, which turns around the inner tubes, thereby increasing or decreasing the size of the opening through which the air is drawn. A few minutes' use of the burner will enable anyone to get the flame right, but a few points in this regard may be useful. The flame should be about 2½ inches high only. It should not blow. Should burn with blue light, showing defined inner cone of blue-green light, immediately *above* which point *C*, the greatest heat is obtained.

Heat Treatment.

The work over such a burner is necessarily small, such as small screws, bolt heads, washers, pins, etc. The work should be thoroughly cleansed from all grease, either by dipping in a strong hot lye solution or alcohol, then dried in clean sawdust, for it is absolutely essential that the entire surface must present the same physical condition, to obtain uniformity of color. The work should be subjected to the flame immediately above the inner cone of light. Carefully watch the varying change of color and withdraw from the heat before it quite reaches the blue desired, hold in the air until the desired shade appears, then check by dipping in the oil and allowing it to cool in it. Very good blueing can be done in this way, by the beginner, on pieces of uniform shape, but much more skill will be required on pieces where shapes are irregular, large surfaces in one place and small in another, when the heat must be confined to the larger part for a longer period of time than is necessary for the small parts. In such cases the amount of heat contained in the larger part is usually sufficient to produce the desired effect after taking from the flame.



Industrial Press, N.Y.

Section of Bunsen Burner.

Another very common method, especially for flat work, is to heat a flat piece of iron or steel of mass sufficient to retain heat for a long time, and place the piece to be colored on the hot surface, sometimes in direct contact with the hot metal and at other times on a piece of sheet iron placed on the hot piece. When the desired color appears, brush off into an oil bath. Yet another way is the hot-sand method. A pan of sand is heated to a high degree, the parts are buried in it and rolled around, and when color appears check as before. In all these methods the colors that appear to the naked eye come in the following order: Pale straw, dark straw, brown, purple, blue and green, after which it loses itself—in white.

The wearing life of work done by these methods is naturally very short, as the colors rub off very quickly by handling.

Varnishing and Lacquering.

Varnishing and lacquering, as being apart from the subject matter, will be treated very briefly. The method cannot be used to produce an artistic color effect, but is nearly always used for the commercial reason—that of protecting the surfaces of instruments and machines from discoloration by atmospheric influence in which is combined the action of air, moisture and the various gases.

In nearly every instance lacquering is used only on the alloys. It might be well in this connection to note the coloring power of metals in the alloys, as given by Lebedur, a noted German authority. He states that discoloring action upon metals takes place to the greatest extent upon tin and the least upon gold. In the following list of metals the action becomes less from the first to the last: 1, Tin; 2, nickel; 3, aluminum; 4, manganese; 5, iron; 6, copper; 7, zinc; 8, lead; 9, platinum; 10, silver; 11, gold.

Corroding Agents.

We now come to the corroding agents, chemical compounds, by which the really successful results are obtained, by the dipping process, or wet coloring, as it is called. While there are many methods known as dry coloring which have been repeatedly tried, where compounds are mixed together, forming pastes that are applied with a brush and allowed to remain any number of hours and then rubbed off, all are more or less failures. The wet method presents many advantages, both as regards economy of time and uniform results.

To color copper articles, such as ash trays, pin dishes, receivers, etc., a solution of ammonium sulphide will give the best results to the beginner. The greatest variety of colors, from light brown to black, can be obtained by this simple method. Use a dilute solution, cold. A good working solution is produced by diluting a saturated solution of ammonium sulphide with 10 to 40 parts of water.

The light brown color is produced by dipping for a very short time in the solution and withdrawing and allowing to dry in the air. The darker shade of brown is obtained by a longer immersion, according to the color desired, after which dry in sawdust. To obtain a black coloring allow the article to remain quite a little while in the bath and, after removing, dip the article in alcohol, after which the alcohol is burnt off, leaving a black coating. These colors can be permanently fixed by a transparent lacquer. The objection to ammonium sulphide is the great care necessary in handling, as it leaves an indelible stain upon the fingers, and it also has a very obnoxious odor. The ammonium sulphide also decomposes in time, depositing sulphur. It should be kept in a dark-colored and glass-stoppered bottle. It is not good for brass, being adapted only for copper.

Another solution for coloring copper which yields very good results is:

Copper nitrate	1 part
Water	3 parts

This forms a deposit of copper salt and, if heated, the salt is decomposed into a black copper oxide. The greenish tints are obtained by the following solution:

Ammonium carbonate	2 ounces
Ammonium chloride	2-3 ounce
Water	16 ounces

This solution gives good results on both copper and brass, different colorings being obtained by repeated dippings in the solution, allowing ample time between each for the articles to properly dry. As with copper, so it is with brass, many varieties of color can be obtained by different chemical solutions, but the desirable colors for commercial use are dead black and steely gray.

The following mixture has also given very good results for brass:

Hydrochloric, or more commonly termed muriatic acid,
White arsenic,
Silver.

Take any given quantity of arsenic, say ½ ounce, dissolve in strong muriatic acid, snip off a small piece of a silver dime if no other silver is at hand, a piece about ¼ inch in size. Heat the article to a dull red and dip in the solution; allow to remain until cool. This produces the dull black result so often seen on mathematical instruments. The steely gray is obtained in the same manner, except the article is not heated to such a high temperature as in the preceding case. By arsenic solution many good results are obtained by cold dipping also.

In every case where chemical solutions are used it is well to remember that the slower the rate of deposition the better the results, from the wearing standpoint; hence, the longer a dilute solution takes to deposit its coating, the better the color will last, and that is, of course, a very desirable quality.

Coloring Iron and Steel.

The coloring of copper and brass, especially copper, is for its artistic value alone; but from the purely commercial standpoint the coloring of iron and steel is of greater value, because it is used for so many machine parts and parts of guns, small arms, etc., which are treated to produce a blue or black color for the purpose of preserving the metal against corrosion, as well as to give it a handsome appearance.

The following solution will give very satisfactory results with iron or steel if carefully treated:

Take equal parts of potassium nitrate and sodium nitrate and fuse by heating the mixture until it is completely melted. The melting point of the mixed nitrate salts is 339 degrees Centigrade, or over 600 degrees Fahrenheit. Dip the articles first in boiling lye or strong hot soda water to thoroughly cleanse from grease; dip in the hot mixed nitrate flux and from there into boiling water to rinse off the nitrate. Different temperatures of the solution will produce different shades of coloring, and sometimes it will be found advisable to use the flux at a temperature as high as 700 degrees Fahrenheit.

In many cases where tempered articles are to be treated it would not be possible to bring the steel to the desired color by this process, because the temperature of the fused nitrates would be so high as to draw the temper of the articles. In such cases the old nitric acid rusting process is generally resorted to. The nitric acid is placed in an earthenware jar and inclosed in a box that can be made practically tight by closing the lid. The article is suspended in the box and the lid closed, and the fumes arising from the acid oxidize the surface of the article, and if the article is moistened before placing in the box a very much more rapid oxidation is assured, saving considerable time.

Many experiments have been tried with different mixtures for coloring iron and steel, where there is danger of drawing the temper of the metal, of which the following has proved very successful: A wooden box is used, of a size according to the kind of work you wish to do. A small steam pipe connects with the box, so that a quantity of steam may flow into it continuously and moisten the air in the box. A bath made of the following ingredients is then placed in the box:

Iron chloride (muriate tincture of steel)	1 ounce
Alcohol (spirits of wine)	1 ounce
Corrosive sublimate (mercury bichloride)	¼ ounce
Aquafortis (strong nitric acid)	¼ ounce
Blue stone (copper sulphate)	⅛ ounce
Water	1 quart

The vapor arising from this bath forms a deposit on the articles which are allowed to remain in the receptacle a number of hours, rubbed off with a cloth, and the operation repeated if a darker color is desired. Very rich coloring can be obtained by this process, after a little experiment; and the temper is not affected.

Many other solutions more or less successful could be included in this article, but enough has been given to enable anyone to get a variety of coloring in different metals and alloys.

Cleaning Old Brass and Copper.

In conclusion, it will be well to touch upon the method of cleaning old brass or copper from impurities. This is accomplished by what is commonly called a dip. The brass articles are strung on a wire, which should be of the same material as the articles, and dipped in the following solution:

1 part aquafortis (nitric acid).
6 parts muriatic acid (hydrochloric acid).
2 parts water.

The articles are first dipped in a strong hot solution of soda in water, and then into the bath, where they are swirled around for a time, removed and rinsed in cold water and dried in sawdust. If the metal looks dark and is not quite bright, the aquafortis should be weakened.

Where many pounds of small brass fittings are to be treated, they are put in an earthenware pot containing numerous perforations.

Zinc is often cleaned by dipping into a solution of
16 parts water,
1 part oil of vitriol (sulphuric acid)
for a few moments, and then washing thoroughly to remove all trace of the bath.

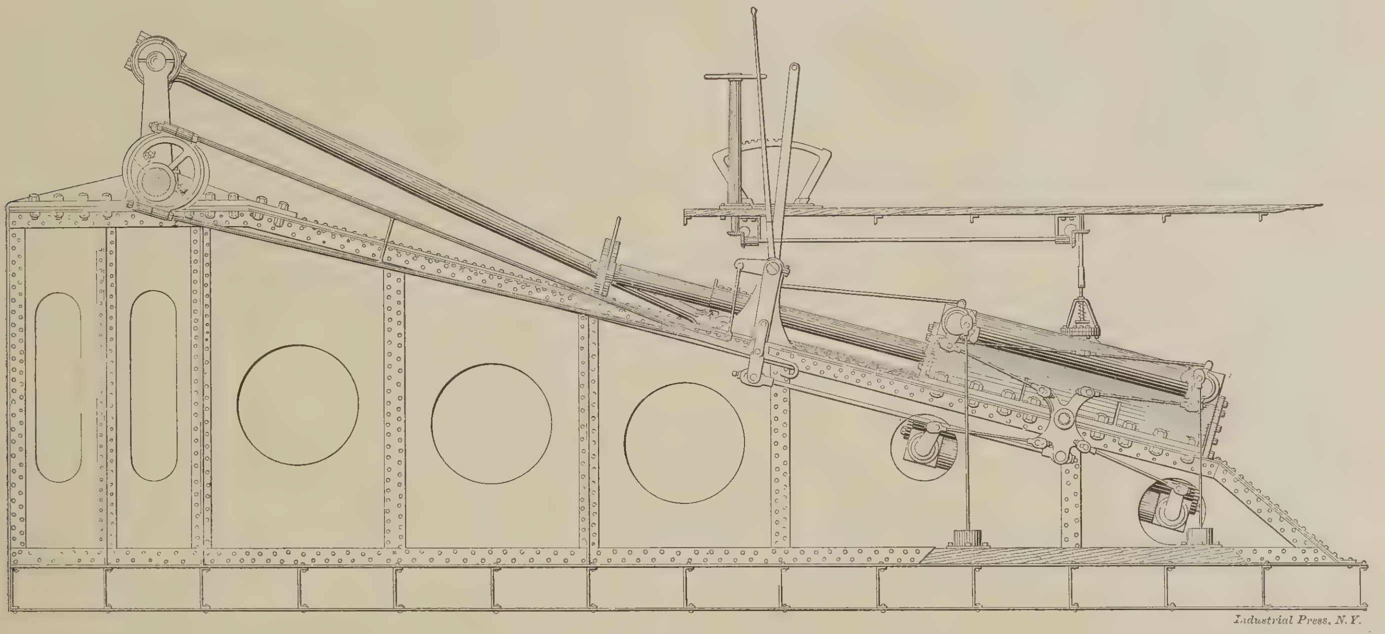
A MARINE ENGINE WITH CORLISS GEAR.

We show in the accompanying illustration an interesting type of river-boat engine that was installed on the steamer *H. B. Plant*, hailing from Port Tampa, Fla., by the Merrill-Stevens Engineering Co., Jacksonville, Fla. It was designed with special reference to extreme lightness, the steamer, complete, drawing only 32 inches of water.

The distinctive feature of the engine is that it is equipped with Corliss valve gear in place of the Stevens gear used so extensively here in the East, and the typical river-boat gear that is found on all the navigable rivers of the West. The Corliss gear gives an opportunity to change the point of cut-off in the engine cylinders, through changing the points at which the knock-off cams operate, without altering in any way the other features of the steam distribution, as shown by the indicator card. This leaves the link motion entirely free for reversal, without regard to steam distribution. Altogether, the Corliss gear appears quite as well adapted to marine work for slow-moving paddle-wheel engines as the more common marine types, and it is rather to be wondered at that it has not been more often applied for this purpose.



Inclined Corliss Marine Engine.

As a general description, the engine is a 24x60 inclined, direct-acting, sidewheel engine, with Corliss valve gear. The engine frame, as shown, is a double steel plate girder, stiffened with intersecting webs, and built into the boat. Nearly all the parts, with the exception of the cylinders and cylinder heads, are steel castings. The guides are hollow steel, 5 inches in diameter and ½ inch thick. The cross-heads have steel casting wearing surfaces, lined with white metal and hang below the guides, which are supported at the cylinder ends by bosses on the head and by steel guide bridges spanning the frames at the other end; the connecting rod is hollow, of forged steel. Main bearings and outboard bearings and wheel-centers all are steel castings, in order to get the lightest possible construction consistent with strength. The piston is a steel casting. The engine is operated with a surface condenser having 600 feet of cooling surface, supplied with circulating water by a direct-connected 6-inch circulating pump, with independent "Burnham" air pump. The performance of the engine has been very satisfactory, indeed; it has been driven at 40 revolutions with 100 pounds of steam, cut-off at 26 inches giving an indicated horse power of 440 and driving the boat at about 12¾ knots. The boiler supplying this engine is a Scotch boiler 8 feet 4 inches in diameter by 12 feet long, having 1,057 feet of heating surface; it furnishes steam for the maximum performance of the engine given above with natural draft, using wood for fuel.

"FACTOR OF SAFETY."

In the following, taken from a paper on grinding wheels, recently read before a trade association, what seems to us to be misuse of the term "factor of safety," appears:

"Professor Grübler, of Dresden, made a series of tests on abrasive wheels in May, 1902, for the Association of German Engineers. All manufacturers were invited to submit a 20-inch wheel, to be speeded till it burst. About 60 wheels, including nearly all the well-known kinds, were tested, and the results showed that all the specimens were safe if properly used. The proper working speed for a 20-inch wheel is 955 revolutions per minute, and the worst record for any wheel tested was 2,615 revolutions per minute, giving a factor of safety of about 2.7. The carborundum wheel tested gave the highest record, for it did not break till a speed of 4,340 revolutions per minute was reached, giving a factor of safety of about 4.5. This was one of the regular carborundum wheels made with a vitrified porcelain bond."

A factor of safety according to Rankine's definition, is the ratio in which the load that is just sufficient to overcome instantly the strength of a piece of material, is greater than the greatest safe ordinary working load. In this case the factor of safety is applied to the ratio of working revolutions to bursting revolutions. If the centrifugal or bursting stress was in proportion to the number of revolutions or peripheral speed, there would be no particular need for criticism, but the bursting force increases as the square of the velocity, so that in the first case, instead of the factor of safety being 2.7, it is the square of 2.7 or 7.29.

* * *

After certain tests of abrasive wheels made at Sibley College, the metal removed was micro-photographed. The photographs, it is said, show that the metal removed by emery wheels is in the form of minute globules; that from carborundum wheels is in the shape of chips or shavings. This seems to show that an emery wheel "grinds" or wears the metal off while the carborundum wheel cuts it off in a manner much the same as a milling cutter. This is an important distinction. It not only indicates that the carborundum wheel should be the most efficient in metal removed for the same power, but that heating should be much less since it is cut off instead of being abraded by friction. The wheel that heats the least, other things being equal, should give the most accurate work.

MACHINERY

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

CHICAGO OFFICE—1462 Monadnock Block.

LESTER G. FRENCH, Editor.
FRED E. ROGERS and GEO. H. HALL, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

DECEMBER, 1903.

NET CIRCULATION FOR NOVEMBER, 1903,—25,324 COPIES.

MACHINERY is issued in three editions—the Engineering Edition, printed on coated paper throughout, each volume comprising 650 or more reading pages and forty-eight 6 x 9 data sheets—price $2.00 a year; the Shop Edition, printed on super-calendered paper, comprising 430 or more reading pages, devoted to practical shop matter—price $1.00; and the Foreign Edition, which comprises the same matter as the Engineering but is printed on thin paper for transmission abroad—price $3.00 a year.

IMPROVING THE STEAM ENGINE.

Not infrequently an editor of a technical paper is called upon to give advice or express an opinion regarding some invention; or it may be that an invention is submitted to him for publication. Very many of such inventions are thoroughly good and must meet with favorable consideration, but there are so many more that are obviously of little value, or perhaps totally useless that it frequently becomes the painful duty of the editor to try to discourage the inventor in his work, and perhaps lose him as a friend for some time to come, or else say nothing at all and let the inventor hang himself with his own rope.

Some time ago we received a letter from a subscriber, inclosing a clipping from the local paper about a steam engine that the writer of the letter had invented. The machine was in operation in the printing office and from the fact that it made the wheels go round and seemed to run very nicely, the editor of that paper wrote a dissertation upon the wonders of the invention and predicted a rapid journey along the road to wealth for his friend, the inventor. The particular merit of the engine was that it accomplished a "long-sought-for method" for doing away with the tremendous losses incident to the crank and connecting rod of a steam engine. The inventor had discovered that designers of all other engines made the great mistake of letting steam into the cylinder at full pressure at the beginning of the stroke, and then cutting off the steam early in the stroke, allowing the pressure to drop to almost nothing at the end. Obviously this is wrong, so he thought, because the steam drops to a low pressure at or near the middle of the stroke, where the crank and connecting rod are in positions to exert the greatest power. Worse than that, the pressure is greatest at the beginning, where the leverage is small, and so, of course, there must be a great deal of power wasted. Why not arrange the valves to give the greatest pressure near the middle of the stroke where the leverage of the crank is greatest, and have the pressure small at each end? And this is what the inventor did!

In another clipping sent us is an elaborate description of a wonderful engine that is certainly an epoch marker. It says, "All mechanics know that the steam engine, as now used, loses one-half its strokes by its reciprocal movement," though we do not quite see what becomes of the lost strokes. The inventor has therefore produced a rotary engine which has no strokes to lose, and which he proclaims "has no motion and makes little noise." The remarkable thing is that it can make even a little noise without any motion.

But the most attractive proposition that has come to hand relates to a new engine which the inventor frankly admits "seems to embody a mechanical anomaly," for, while the mechanism gains power over the crank form of engine it requires less energy in the form of coal to develop power. It promises "to make navigation of the air perfectly practicable, to place the automobile within the reach of everybody who can afford a bicycle, to give railroad transportation the 125-mile-per-hour locomotive, and to give ocean navigation a power that will overcome the momentum of an ocean greyhound in one minute, instead of five minutes now required." He accomplishes this by the simple expedient of a coarse-pitch spiral operated by a nut, which is given a reciprocating motion by the piston rod, and thus saves the 101 per cent. usually lost by the cumbersome crank and connecting rod.

We know that many valuable inventions are made by men who approach a subject from the outside and are untrammeled by custom, or rule-of-thumb. The very fact that they are not familiar with what has been done and the way in which it has been done, enables them to bring a fresh mind to the problem, and to think independently and sometimes more effectively than one whose mental attitude has been influenced by a knowledge of the way others have accomplished a result. But where there is one commercially successful invention by a man not acquainted with the state of the art, there are hundreds that are not successful, and the safe rule to follow—a rule which we should like to impress upon such of our readers as cannot afford to enrich patent lawyers, without some return for themselves—is to first become familiar with what has been done, the way it has been done, and why it has been done. Then, in the light of this knowledge, go ahead with your invention if you think best. We could cite many instances of failures in invention, simply because the inventor acquired his knowledge after the patent was issued instead of before, but the three cases referred to above are sufficient to show what futile schemes a person will spend money on, when a little time devoted to study would have taught him better.

* * *

A press item states that the law in Ohio requiring stationary engineers to pass an examination has been declared unconstitutional. The decision was rendered in the case of an engineer who some months ago was fined for disobeying the law. Dispatches give very meager information, merely stating that the judge declared the statute to be a hardship against those engineers who, by years of practical experience, have thoroughly mastered the practical workings of an engine, but may not be able to answer technical questions.

We have no information about the circumstance of the case. In general, we do not believe in many of the questions commonly asked engineers at examinations. Safety valve calculations, for example, do not amount to anything at all, so far as determining the ability of an engineer to properly operate a steam plant, and many perplexing and useless questions are often propounded that may only serve to confuse a good man. Nevertheless we do not understand on what ground a judge should pronounce examinations unconstitutional. There is scarcely a law on the statutes which might not in some one of its phases abridge the rights of some person and so be "unconstitutional." It should be understood, however, that when a man takes charge of a steam plant he becomes nothing less than a public servant. The safety of the public depends as much upon the proper conduct of his plant and the public has as much right to demand that it shall be safely conducted, as in the case of a hotel, a railroad, a steamship or a mine. These and other public institutions are amenable to public safety and convenience and it is right that every means, legal if necessary, should be taken to protect the public. In the case of the railroad—usually a great system in which it is possible to take men from the ranks and train them for the important positions—examinations for engineers are not so necessary, though the general management of the road must be in conformity to the law. But in the case of individual power plants, owned and operated by Tom, Dick and Harry, who is to insure the safety of the public if the State does not?

HITCHING THE MOTOR.

In machine tools a noticeable feature is the changes in general appearance which the increasing use of the direct motor drive is developing. With lathes especially the first applications of the electric motor concerned the substitution of the motor for belt drive at the countershaft. Next the motor was mounted on a bracket of the machine and connected to the spindle or spindle gearing by means of a chain belt. As yet the lathe itself has not changed. In the later machines, however, the spindle pulley is removed and the motor itself mounted directly in the head—the necessary gearing being disposed around the exterior ends of the motor. These changes, together with those incidental to the modern quick-feed changing mechanisms, make the newest machines present a quite different appearance from the standard forms in general use until quite recently.—*Exchange.*

Contrary to the inference of the above, and unfortunately for the progress of electric machine-tool driving, it is, in the present state of the art, bad design to make an electric motor an integral part of a machine tool. This condition exists because of the still primitive state of the electric motor, which makes it quite necessary to be able to quickly replace a burnt-out armature, etc. If the armature is mounted on a shaft which forms a part of the machine, such as a lathe spindle, for instance, it is special, and its replacement is a matter of days or weeks, depending on the distance from the factory, their promptness, etc. But if a standard motor is used, the replacement of a burnt-out armature, or of the entire motor, is a simple matter. If one make of motor is not available, another generally can be readily substituted. It is true that one of the first attempts at driving lathes with electric motors was made by building the motor in the headstock and mounting the armature on a quill which corresponds to the cone pulley, but this design was a failure. A stroll through the machine shop of an electric concern, well known for their efforts along these lines, will discover a number of engine lathes, originally built with the motors in the headstock, but now equipped with standard motors mounted on the field rings of the old motors. They found that their lathes were lying idle too much of the time, because of repairs to the motors, and so abandoned the idea. When some better means of insulating the windings of motors are discovered than now known, it may be feasible to make them part of the machine tools, but it emphatically is not so now, except, perhaps, in the case of some small tools like grinders or drills.

LECTURE UPON "THERMIT."

On the evening of Nov. 13 an opportunity was given to hear a lecture by Dr. Hans Goldschmidt on the compound "thermit," at Columbia University. Since the illustrated articles upon thermit in the March, 1903, number of MACHINERY there have been numerous articles and items published upon this wonderful compound in various American papers, and a great deal of interest has been aroused in this preparation and its possibilities.

Dr. Goldschmidt has recently come from Germany for a short stay in America, for the purpose of further familiarizing engineers and chemists with his invention, and it is probable that an American company will be formed in the near future for the manufacture and sale of thermit in this country.

Thermit is a metallic powder, the main ingredients of which are aluminum and oxide of iron, and by inducing a chemical combination of these two elements through the use of a suitable igniting agent such as superoxide of barium, the whole becomes a molten mass at a temperature about equal to that of the electric arc. Ignition once started, the combustion is continued throughout the whole mass of the powder without any external supply of heat. Thermit is applied most profitably, and at the present time most extensively, in various welding operations, although it has certain metallurgical uses of great importance. By suitable preparation of the thermit mixture it is possible by the combustion process to produce pure chromium, pure manganese and other elements used in the manufacture of high-grade steel. It is also employed in the casting of steel ingots and to prevent piping which occurs at the ends of the ingots, due to unequal cooling of the metal in the mold. After the steel has become partially cooled and piping has set in, thermit is introduced near the center of one end of the ingot and by its combustion the steel is heated to a welding point. Steel which is held in readiness is then poured into the cavity and unites with the ingot.

The lecture was highly interesting, illustrated as it was by many experiments and a large number of lantern slides showing practical applications of thermit for welding. At present it is used more extensively for welding street car rails than for any other purpose, although a more striking illustration of its possibilities consists in certain marine repairs that are possible at trifling expense. For example, photographs were shown of stern and rudder posts that had been repaired in a comparatively short time, whereas by the usual method the forgings of which they were a part must have been removed and new ones substituted, while the vessel remained in drydock for several weeks at enormous expense of time and money.

In welding rails the rails are usually held together by suitable clamps, although this is not necessary. The joint is surrounded by a clay mold which fits the rail closely, and the thermit runs from the crucible in which it has been ignited into the mold. The rails reach a welding heat at the joint, and any space between is filled by the molten thermit which itself has a high tensile strength equal to about two-thirds of the strength of the rail; but as the mold is so shaped that the thermit forms a chair for the rail at the joint when it solidifies, it really makes the welded portion considerably stronger than the body of the rail. After the joint is completed the fin of thermit iron formed at the top of the rail at the joint is chipped off.

To say that a full-sized street railway rail was welded in about three minutes' time in the lecture room, as one of the practical illustrations of the application of thermit, will perhaps more forcibly impress upon the reader than any other statement what it is possible to accomplish by the application of intense heat at the point desired, and in just the necessary quantity. In contrast to this we have the labor and time and amount of heat wasted from forge fire by the usual process of welding.

To show the intense heat of thermit a little of the molten metal was allowed to flow upon a wrought-iron boiler plate about ½ inch thick and almost instantly it melted a hole through it 1 inch in diameter.

The experiment that captivated the audience, however, was the illustration of what could be done in welding wrought-iron pipe. It will at once be apparent that the application of such thin metal as is used in wrought-iron pipe would at once melt the metal and leave nothing to be welded. This would be true if thermit were poured directly into the mold surrounding the pipe at the joint, from the bottom of a crucible. Instead the thermit is poured into the mold from the top of a crucible, with the result that the slag formed on top first runs into the mold and adheres to the surface of the pipe, forming a thin layer over the surface. This coating of slag protects the pipe and instead of its melting, it is simply brought to a welding heat. The pipe is held by clamps and when the right temperature is reached the clamps are tightened slightly and then almost at once removed. The thermit iron is easily knocked off from the pipe since it does not adhere to the slag, and a perfect joint is the result.

There is no doubt that thermit and the many uses to which it can be put is one of the most interesting topics that has been brought to the attention of engineers during the past few years. The fact that welding can be accomplished by so simple a process would have been discredited by everyone, especially by those not acquainted with the development in thermo-chemistry previous to Dr. Goldschmidt's work.

In the articles which appeared in MACHINERY last March there were illustrations, from photographs, of welding operations, and the subject was treated so thoroughly that it will not be necessary to go into it more in detail at this time.

THE STEAM EQUIPMENT OF A MODERN SCHOONER.*

Until within comparatively recent times it has been customary for all of the work upon sailing vessels, such as raising the sails, heaving the anchor, etc., to be performed by the sailors; and with an increase of tonnage was required a corresponding increase in the size of the crew, so that one of our present "6-masters," had they then been possible, would have required a small regiment for her operation. The use of auxiliary steam appliances naturally began upon steam vessels where the power was at hand and was, from the first, used for operating the pumps and later for the windlass, ash hoist, etc. Having proved so useful upon these vessels it was not long before it was adopted upon sailing vessels, and at present all schooners of any size are provided with a steam equipment comprising a boiler, used both for power and heating purposes; steam winches, for anchor, sail and cargo hoisting, and an outfit of pumps which forms a complete local waterworks system.

This outfit is located in the "fo'castle," where room is scarce and the arrangement must, therefore, be as compact as possible. Fig. 1 shows a typical outfit such as would be found on the ordinary coasting schooner. The boiler is of the vertical, tubular type, and should be capable of carrying a steam pressure of 100 pounds although, except when raising anchor or discharging cargo, it is usually run at low pressure for heating purposes. A steam whistle is provided so that safety as well as comfort are ensured.

The principal appliance to be installed in the engine room is the steam winch, which is used for handling the cargo, hoisting the boats and for warping the vessel into dock. The engines are of the duplex type with cranks set at 90 deg., so that it is impossible for them to get on "center." The main drum is friction-driven and provided with a powerful band brake, which is used when lowering cargo into the hold. The winch shaft extends to starboard and port beyond the winch proper and, passing through the sides of the deck house, is provided with small drums, or "ends," over which a rope may be run, forward or aft, for sail hoisting, boat handling, or for warping purposes. On the larger schooners two or three auxiliary winches are often supplied, being placed at convenient positions near the masts.

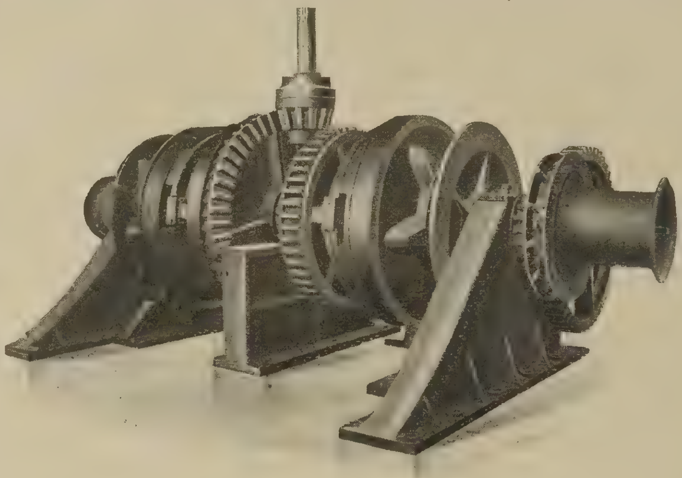

Fig. 2. "Providence" Elastic Windlass (arranged for Messenger Chain Attachment.)

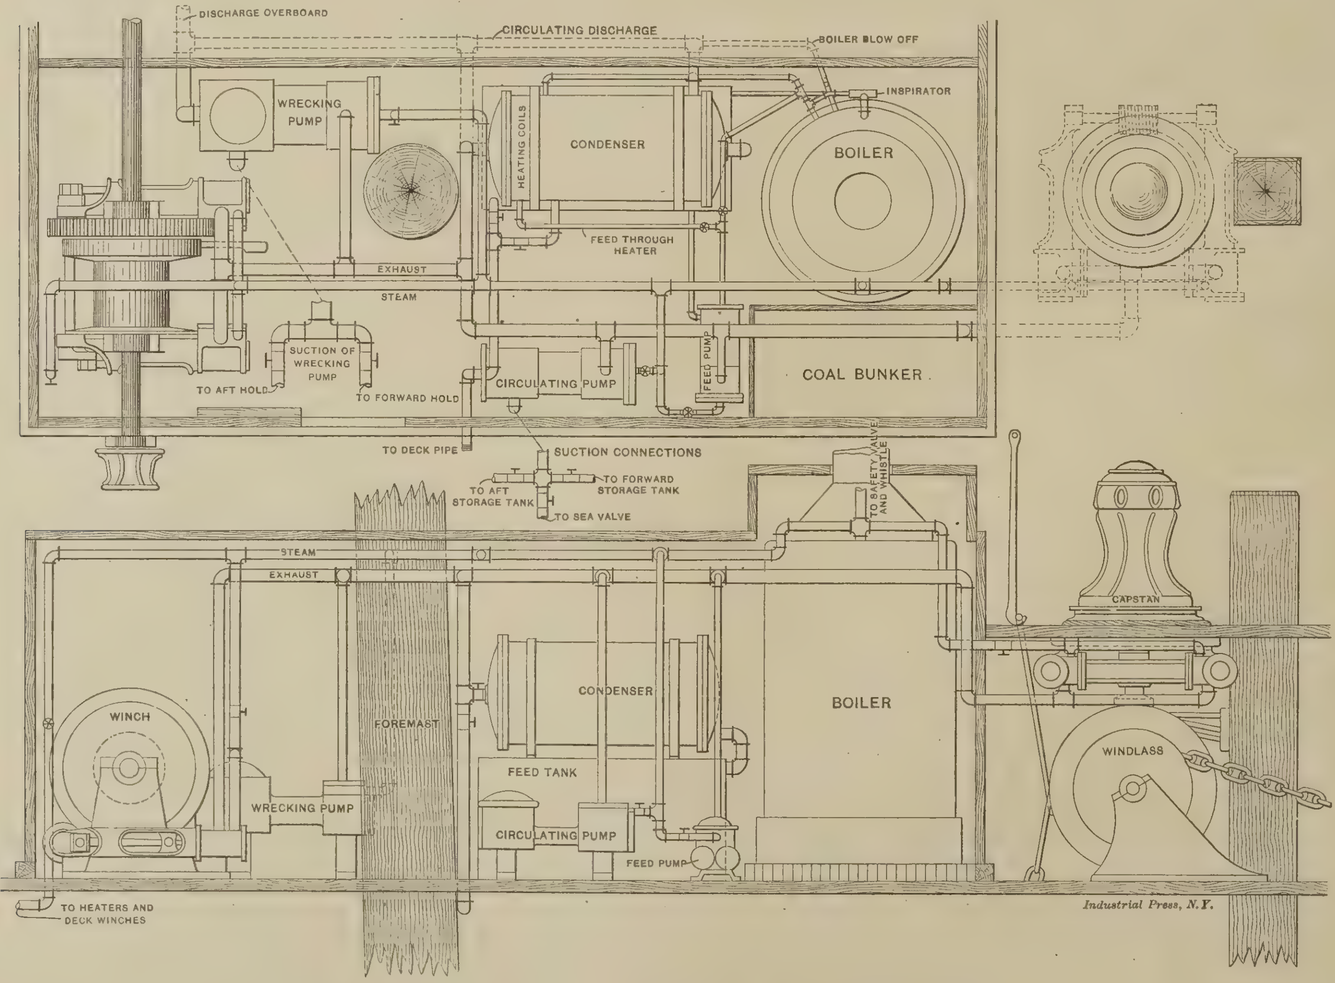

Fig. 1. Plan and Elevation of a Typical Steam Outfit for a Modern Schooner.

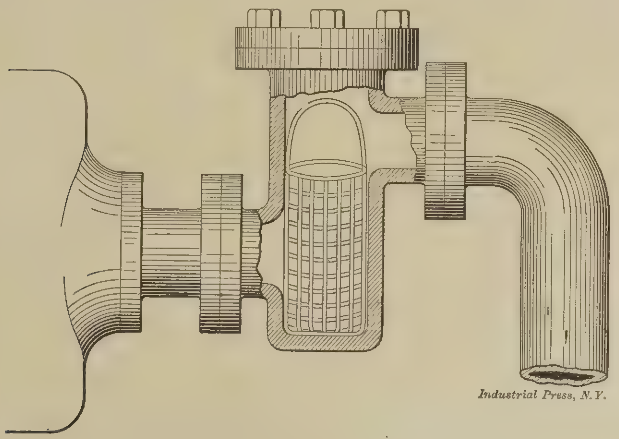
One of the most important items to be considered in this class of engineering is the economy of fresh water which must, of course, be carried in tanks and every provision is therefore made to prevent any loss. The supply for the boiler is carried in a tank placed in the engine room, while a reserve supply is held in large storage tanks located in the forward and after holds. Upon the top of the feed tank is placed a coil condenser, to which are connected the exhaust pipes from all of the engines and pumps in the system. Incidentally, the exhaust pipe is continued beyond the condenser, under the deck, and connects with the discharge from the circulating pump so that, in case of accident to the condenser, all of the exhaust steam may be discharged overboard. The first few coils of this condenser are separated from those used for condensing purposes, and are introduced into the boiler feed system so as to form a feed water heater. The remaining coils are connected to the circulating pump, which has a suction connection with the sea valve, and from the condenser the circulating water, as before noted, passes overboard. No air pump is used with the condenser and consequently no vacuum is obtained, as the object of the condenser is solely for water economy. We here find a great advantage in the unlimited supply of condensing water at hand and this is used without stint in order to effect a saving of the valuable fresh water.

---

* For much of the information embodied in this article, together with the photographs, we are indebted to the American Ship Windlass Co., Providence, R. I.



Industrial Press, N.Y.

Fig. 4. Basket Strainer used on Wrecking Pump.

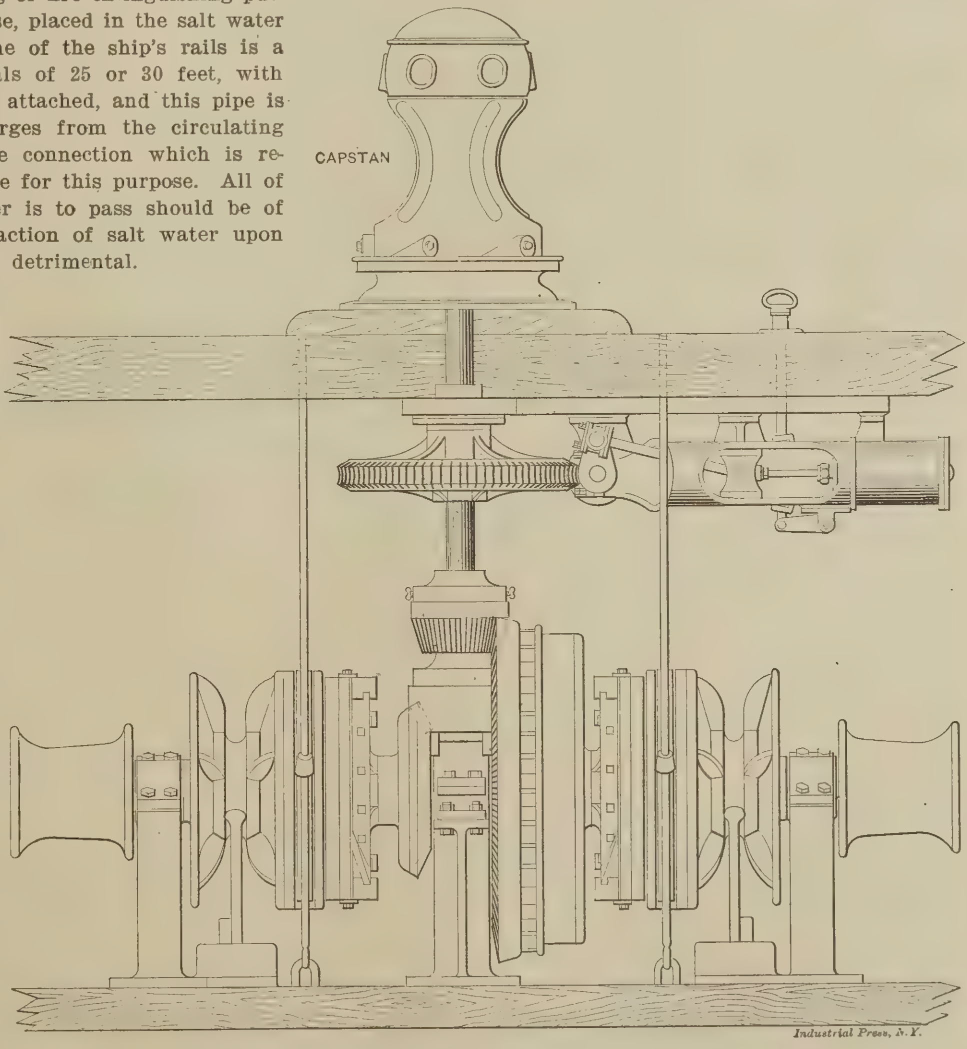
The circulating pump has by-connections whereby the salt water may be cut out and fresh water drawn from either forward or aft storage tank and pumped into the feed tank. This pump is also used for deck washing or fire extinguishing purposes, at which times it is, of course, placed in the salt water circuit. Extending along under one of the ship's rails is a pipe which is provided, at intervals of 25 or 30 feet, with plugs to which a fire hose may be attached, and this pipe is connected with one of the discharges from the circulating pump by means of a flexible hose connection which is removed when the pump is not in use for this purpose. All of the pipes through which salt water is to pass should be of brass or galvanized iron, as the action of salt water upon ordinary wrought iron pipe is very detrimental.

The boiler is fed by a small duplex steam pump and is also provided with an inspirator so that either system of feeding may be employed as desired and the one arrangement acts as a substitute for the other in case of accident. In the engine room is also placed a larger duplex pump which is used solely for wrecking purposes, that is, for keeping the bilge clear of water and when the vessel is leaking. The suction is divided, one part running directly down to the forward hold and the other aft to the after hold. Much care must be exercised in keeping these suctions clear, as it is of greatest importance that they should work freely in case any leaking occurs. A peculiar type of strainer is employed, being what is known as a basket strainer. This is placed in the first elbow of the pipe so that it may be removed and cleaned whenever desired and a surprising quantity of dirt and rubbish, to say nothing of dead rats, is often found in these strainers from the bilge.

Besides the important steam appliances here mentioned, steam from the boiler is also used for heating purposes so that the old fo'-castle" stove is now replaced by a modern steam coil and the captain's cabin aft is provided with radiators, and a bath room supplied with hot and cold water. A telephone also is often installed, establishing communication between the cabin and the engine room.

Last but by no means least of the appliances for which the steam equipment is installed, is the windlass, which is situated well forward and carries the two chains by which the anchors are raised. In the construction of windlasses there have probably been more improvements during the past few years than in any other single appliance used upon sailing vessels. Formerly the windlass was operated by a capstan, in the head of which were inserted long capstan bars. These were manned by nearly the entire crew and with a hearty "heave ho" song they tramped round and round until slowly the cable was wound in and the heavy anchor "weighed." The picturesque part of weighing the anchor is now passed but the capstan is still retained for use in case of a breakdown in the steam equipment. It may also be entirely disconnected from the windlass, by simply removing a block key. We then have an efficient warping capstan operated directly by the windlass engines.

As soon as it became customary to place a boiler and winch on board of a schooner, arrangements were made for connecting the winch to the windlass so as to do away with the necessity of manual labor; and this arrangement consisted of placing a sprocket on the winch shaft and connecting it by means of an open link chain called a messenger chain, to an auxiliary shaft mounted back of and geared to the windlass shaft. Although very serviceable, and still employed to some extent, the arrangement was at best only a makeshift, and gave trouble, owing to the stretching of the chain and its liability to break at just those times that it was most depended upon. A remedy for all of these annoy-



Industrial Press, N.Y.

Fig. 3. "Providence" Elastic Steam Windlass (built by the American Ship Windlass Co.)

ances was found by arranging for the direct connection of the windlass with an auxiliary pair of engines as illustrated in Fig. 3. Upon the windlass shaft is fixed a large bevel gear, which is driven by a bevel pinion on the vertical capstan shaft. Upon this shaft is keyed a worm gear, which is driven by a pair of horizontal engines, similar to those used on the winch, and fastened to the deck above the windlass. The chains pass over chain wheels, called "wild cats," which are loose on the windlass shaft and when paying out chain, or riding at anchor, their motion is regulated by means of friction bands. To raise the chain, block keys are inserted between the wild cat and a driving head which is keyed to the shaft and when the windlass shaft is driven by the engine the wild cats wind up the chain. One of the latest improvements to be applied to the windlass is the use of "elastic wild cats," for the purpose of relieving the strain on the ship, due to its rising on the surges when riding at anchor, and also when breaking out the anchor preparatory to raising. Fig. 6 shows a view of one of the wild cats and illustrates how this is accomplished. Between the driving head and wild cat is placed a secondary head, *A*, which carries four very powerful coiled springs that act as a connecting medium between the wild cat and itself. When the ship is riding at anchor these secondary heads are locked by means of the friction bands, so that no chain can be paid out. As the surge raises the vessel, the strain that would otherwise be brought as a sudden shock upon chain and windlass shaft is instead absorbed in a gradual compression of the springs. This greatly relieves the chain and lessens the liability of its parting. In breaking out the anchor the secondary heads are temporarily keyed to the regular heads, *B*, and the elastic principle again comes into play.

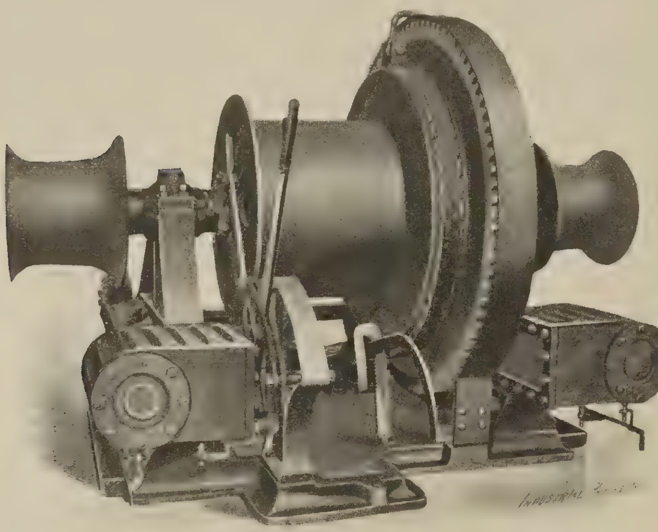


Fig. 5. Seven in. x 10 in. Steam Ship's Winch (built by American Ship Windlass Co.)

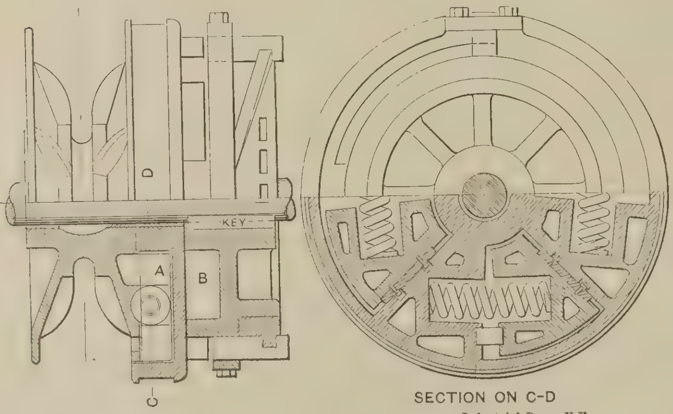

Industrial Press, N.Y.

Fig. 6. Section of Spring Head of "Providence" Elastic Windlass.

It would be practically impossible to provide engines of sufficient power in themselves to pull out the anchor when it is securely imbedded in the bottom, but the engines draw in the chain until the vessel lies directly over the anchor with the chain pulled up taut. As the ship sinks in the trough of the sea the cable is tightened still more so that as she rises on the succeeding surge her entire buoyant force is exerted upon the chain and the anchor broken out. The elastic movement of the wild cats, although only about three-quarters of an inch, is yet sufficient to prevent this strain from coming as a heavy shock upon the windlass and changes it to a gradually applied load which the windlass is fully capable of withstanding.

Thus the use of steam upon sailing vessels not only adds to the comfort and safety of the crew but has to a great extent reduced the number of men needed to handle a ship of given tonnage, and made practical the building of greater tonnages than was considered possible when all of the labor had to be performed by hand. The reduced force needed for handling these larger vessels has made the schooner, with full steam equipment, without doubt the cheapest carrying medium for all freight in which quick delivery does not have to be considered.

MACHINE TOOL BUILDERS' ASSOCIATION.

The convention of the National Machine Tool Builders' Association was held at the Hoffman House, New York, Nov. 10-11 and resulted in the agreement of the members to maintain existing prices for machine tools, in spite of the possibilities of a depression, resolutions to this effect having been adopted which will be issued in circular form and distributed among the trade.

This convention is looked upon as one of great importance to the machinery market, from the fact that the action in the matter of prices will tend to produce a more stable condition both among buyers and dealers of machinery who have, previous to the convention, not known what to depend upon in this regard.

Several addresses were delivered during the sessions. William Lodge, of the Lodge & Shipley Machine Tool Co., Cincinnati, in dwelling upon the future machine tool trade in the United States advocated the standardizing of parts of machine tools of different manufacture by adopting the same sizes of main bearings, nose of lathe spindles, etc., as well as widths and diameters of countershaft pulleys and countershafts themselves. Under the new order of things, with high-speed steels, he advocated two distinct classes of machines—one for cast-iron work and the other for steel work. He also advocated the maintenance of prices and urged upon the members to work honestly and faithfully to this end.

W. P. Davis, of Rochester, N. Y., related his experiences during a trip in Europe and stated that machine tools were being built at much less cost on the continent than in America excepting where we specialize and manufacture in large numbers, as is generally the case. In Europe concerns tend to produce a great variety of products, which renders them less able to compete. He fears most from Germany, where many large manufacturing plants are going up.

Joseph J. Flather, President of Flather & Co., Inc., Nashua, N. H., read a paper on "What Shall We Do on a Declining Market?" in which he contrasted present conditions with those existing in 1873. There is a great similarity between these periods, both in labor conditions and in the state of the market, but we have the advantage now in that we have stable money. He advocated the maintenance of prices and believed that the machine tool business would hold its own during any depression that may come.

P. E. Montanus, of the Springfield Machine Tool Co., delivered an address in which he held that many branches of the machine trade enjoyed greater advantages and were in a position to make greater profits than were machine tool builders who were producing higher grade products, but were receiving prices small in comparison with many firms building cruder machines by the aid of these tools.

William Lodge was elected president for the coming year; W. P. Davis, vice-president; F. E. Reed, second vice-president; Enoch Earle, treasurer, and P. E. Montanus, secretary.

BLOWING ENGINES WITH MECHANICALLY-OPERATED PISTON VALVES FOR AIR CYLINDERS.

The Westinghouse Machine Company have recently built six blowing engines of the long-crosshead type, three of which have been installed in the plant of the Toledo Furnace Company of Toledo, Ohio, and three at the plant of the South Chicago Furnace Company, at South Chicago, Ill., all under the general direction of Mr. Julian Kennedy, of Pittsburg, Consulting Engineer for the two companies.

These two plants are practically duplicates, each consisting of three engines arranged in line, with the intermediate unit designed to run as a low-pressure engine in conjunction with either of the other two which operate on high-pressure steam, compounding being effected through a receiver in the exhaust system of the high-pressure engines. The low-pressure unit is also arranged to run on high-pressure steam through a reducing valve. These three engines, each of a capacity equal to 2,000 horse power are designed to run in couples, either condensing or non-condensing, one being held in reserve. The steam cylinders of the high-pressure engines are 50 inches in diameter and of the low-pressure 96 inches diameter, and all have a stroke of 66 inches. The air cylinders of all the engines are 96 inches in diameter.

It is interesting to note that the materials entering into the structure of the engines were all supplied under the specifications of the International Association for testing materials. All large and important cast-iron parts were made of gun-iron melted in the open hearth or air furnace and possess a tensile strength of about 30,000 pounds per square inch. All steel castings were thoroughly re-annealed and all important forgings were made of steel, supplied by either the Bethlehem or Midvale Steel companies.

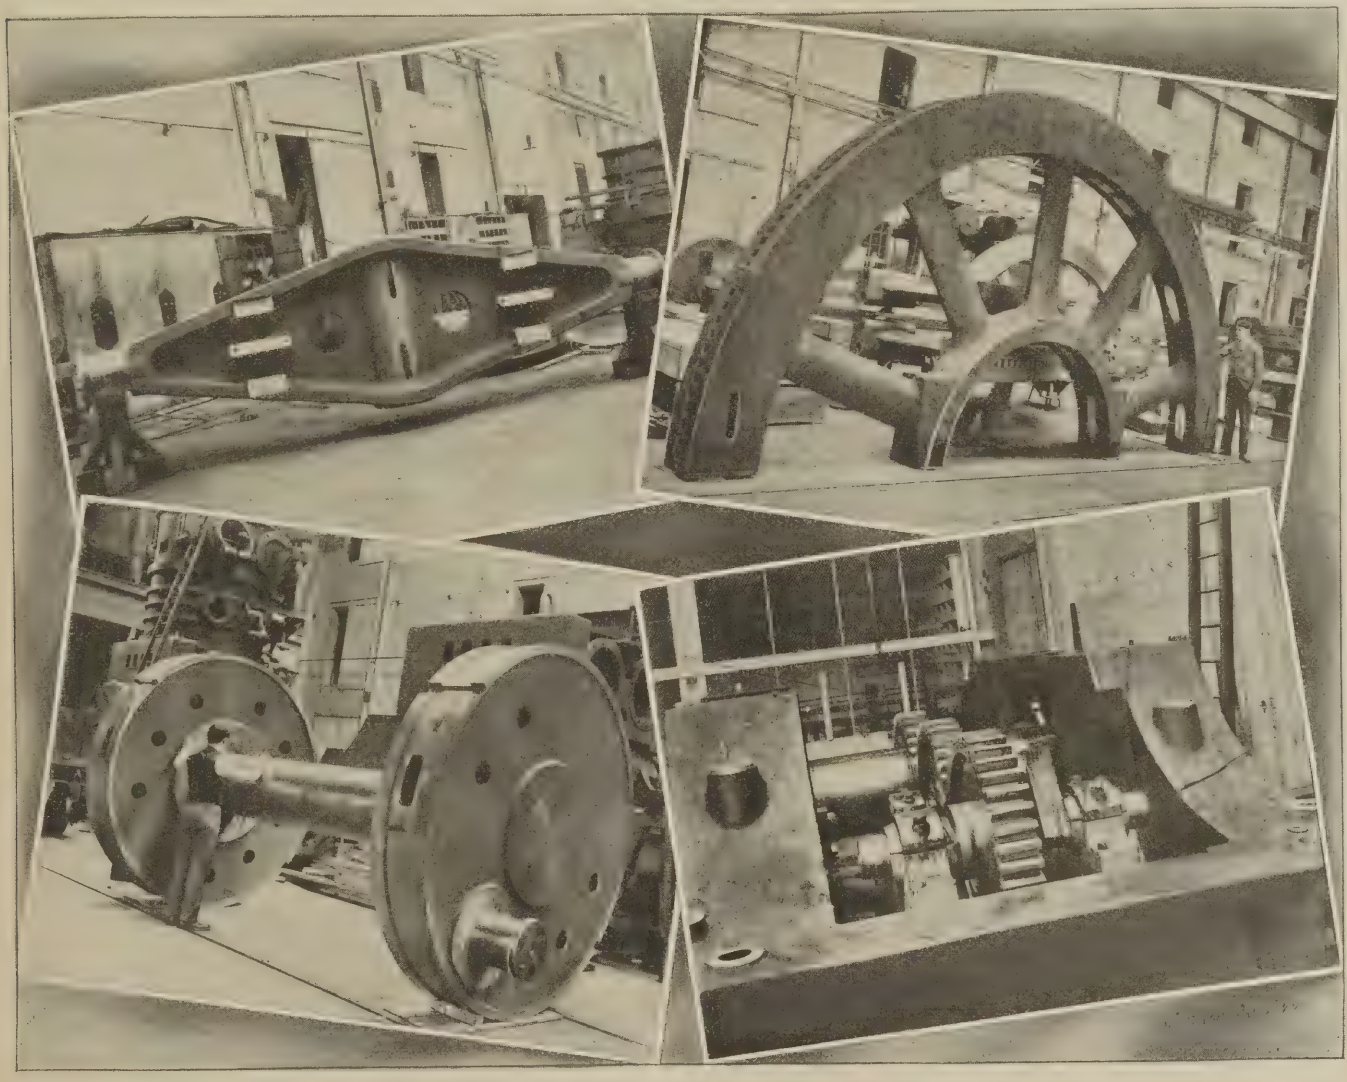

Fig. 1. Engine Details. The Crosshead is a Steel Casting 4 feet deep and 15 feet long. The Crank Disks serve also as Hubs for the Flywheels, which are bored out to fit. The Gearing in Bedplate is for Driving an Auxiliary Crank Shaft for Operating the Valve Gear.

The bedplate is cast in one piece. The bottom portion of the main shaft bearings is a removable shell; these bearings are lined with babbitt metal, pened, both bored to size at one time with a special boring apparatus to insure alignment. Caps for the bearings are in one piece having overhanging lips with scraped fit to prevent side play, and are babbitted. The flywheels are 22 feet in diameter, of air furnace iron, and weigh 63,000 pounds each. The hub of each wheel is a crank disk, faced and turned with a recess on its periphery. The rims and arms of the wheels are cast in halves and counterbored to form a collar which fits into the recess in the periphery of the crank disk. The arms are fastened to the hub by bolts, keyed to prevent turning, and the joints of the rim are secured by internal links.

The main shaft is of hydraulically forged open hearth steel of from .40 per cent. to .50 per cent. carbon. The crank pins are high grade steel forgings containing about .50 per cent. carbon. They were ground true on centers and forced into the crank disks by hydraulic pressure and afterward riveted. The parts which serve as bearings for the connecting rod boxes are 12 inches in diameter by 11 inches long.

Each engine has two connecting rods of open hearth forged steel of from .25 per cent to .30 per cent. carbon, finished all over. They are of the solid end type, each end provided with air furnace cast-iron boxes, babbitt lined and having adjusting wedges so arranged as to take up wear, while maintaining as nearly as possible a constant length. The piston rods are open hearth steel forgings containing .50 per cent. carbon. They are carefully machined and ground true and smooth.

The crossheads are of annealed steel castings of about .30 per cent. carbon. The ends are turned to form crosshead pins, each 12 inches in diameter, 11 inches long. The crosshead shoes are of cast iron, faced with babbitt metal and bolted to the crossheads, adjustment for wear being provided by inserting liners. Especial care was taken in designing the crosshead to have an ample amount of metal, so as to provide a large margin of safety, where the stresses are most severe. The castings were inspected to insure their being thoroughly sound and solid, and the initial foundry strains were eliminated by the annealing process. The pin surfaces were finished true by grinding, and the boring for both piston rod fits was made with a bar at one setting. An idea of the massiveness of these castings may be had from the fact that the depth along the vertical center line is 4 feet, 2 inches.

The crosshead ends of the piston rods are turned cylindrical and are inserted into sockets in the crosshead with a slip fit, so that each strikes the bottom of its socket. A taper steel key is driven through a keyway, cut through the crosshead and rod, to hold the two together, and this keyway is offset in the two pieces so that when the key is driven in it forces the rod with great pressure upon the crosshead at the bottom of the socket. By this means a positive connection is insured, there always being an excess of pressure in one direction, notwithstanding the alternations of stress in the rod, due to the reciprocating action of the engine.

Fig. 4. Cards from the High Pressure Steam Cylinder and the Air Cylinder.

The steam cylinders are of hard close-grained air furnace iron. The walls were cast sufficiently thick to allow of reboring ½ inch diameter larger than called for on drawing. The exhaust box is cast separate from the cylinder and does not come in contact with the walls, thus reducing internal

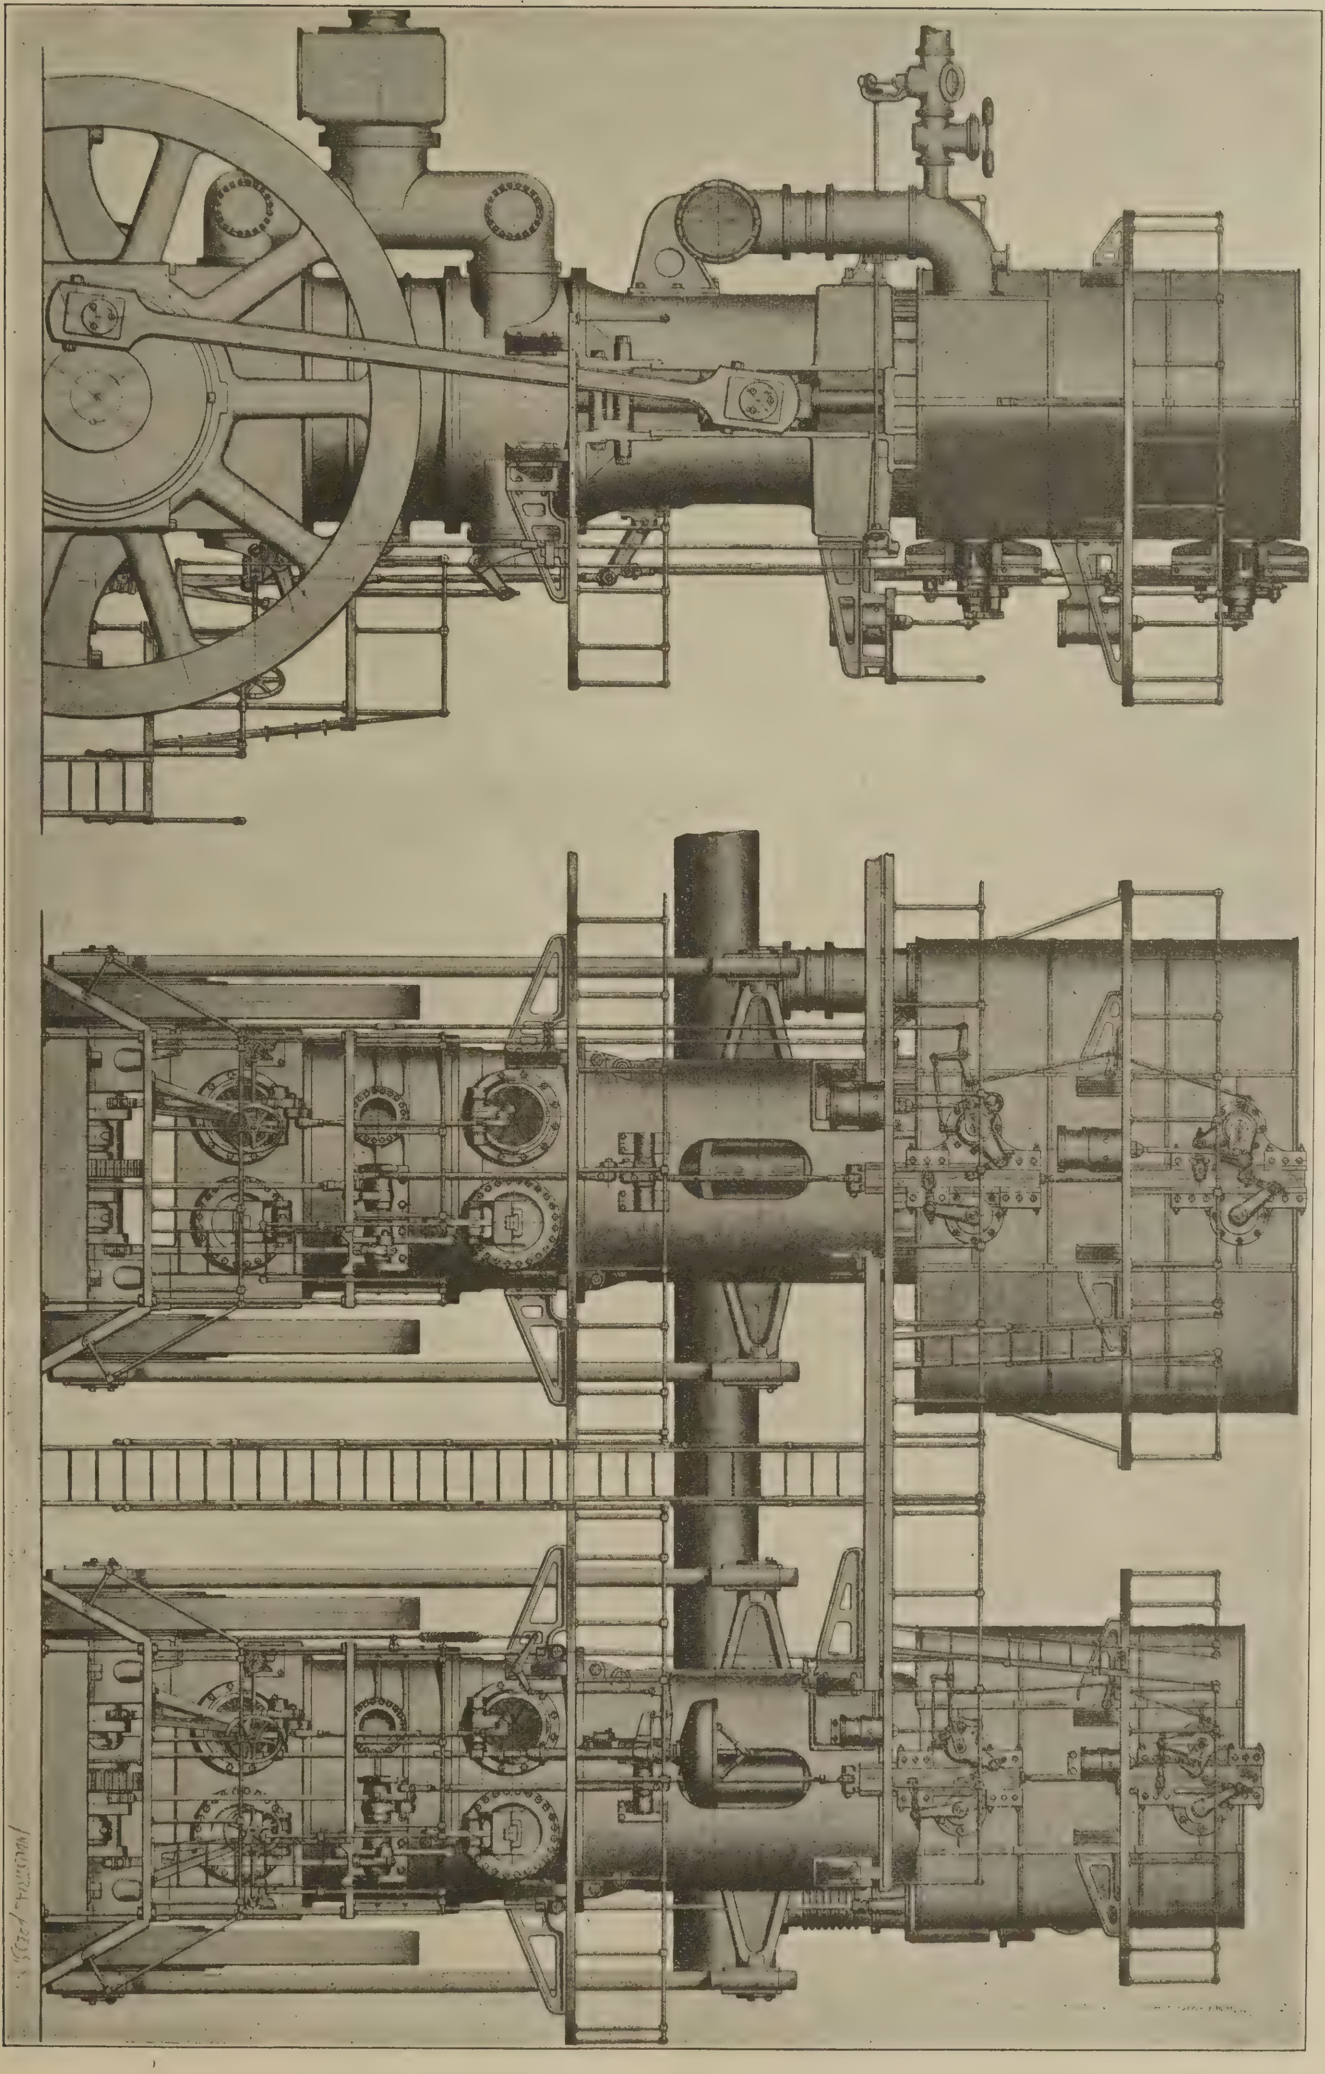

Fig. 5. 2000 H.P. Compound Blowing Engine. Steam Cylinders 50 and 96 inches in Diameter by 66 inches Stroke; Air Cylinders, 96 inches Diameter.

cylinder condensation. Lagging of the best grade of non-conducting metal is provided and the whole is covered with a steel jacket trimmed with corner angles. The cylinder heads contain chambers for Corliss type of valves.

The air cylinders are also of hard, close-grained air furnace iron. The walls are made sufficiently strong to act as the main column or frame work supporting the superimposed parts of the engine. A manhole is in the side and gives access to the interior of the cylinder to allow inspection and removal for repairs of the follower and packing ring, each of which is made in four pieces to facilitate these operations. Each head of the air cylinder is bored and fitted with two cast iron bushings or shells 27½ inches inside diameter, in which positively driven inlet and outlet piston valves operate. Two annular port openings with diagonal bridges are supplied in each shell. The air discharge chamber of each head is provided with a connecting pipe or elbow, and the two elbows unite to form a yoke or Y, terminating in a single outlet 28 inches in diameter, on which is attached a suitable check valve. There are automatic air relief valves in each head, set to operate at 35 pounds pressure. The air piston has two semi-cylindrical concavities running across it on both its top and bottom sides, which fit over corresponding convexities in the cylinder heads that contain the valve chambers. The whole outside surface of the piston head is machined, to reduce clearance at each end of the cylinder.

The air valves and valve motion constitute the most novel feature of the design of the engine. They are of the Kennedy horizontal double ported piston type. Both inlet and outlet valves are 27½ inches in diameter, fitted with cast-iron spring packing rings which were carefully re-turned after cutting the joint, the latter being protected by a keeper.

The inlet valves are operated by a simple harmonic motion through bell cranks. They open when the crank is slightly past the dead center, the piston having by this time traveled about one inch of its stroke, thus relieving whatever compression there may be in the clearance space. They close when the crank reaches the opposite dead center.

The outlet valves are worked by means of racks and sectors driven through a Corliss wristplate, and are arranged so as to give a quick opening and a very long dwell when closed. They are set to begin opening at the time the pressure has risen to 8 pounds per square inch in the cylinder. There seems to be no slip to these valves as they are very tight and close very rapidly.

This valve motion gives an indicator card at 15 pounds per square inch pressure, as nearly perfect as could be attained from an ideal poppet valve, and will operate within a range of from 6 to 20 pounds pressure, with a loss of not more than 1 per cent., due to the fixed point of valve opening, such loss being no greater than that in engines having the best type of poppet valve outlets.

The whole valve mechanism is positively operated and receives its motion from a lay shaft located in the bedplate of the engine, and geared from the main shaft. This lay shaft is provided with cranks instead of with eccentrics to operate the valve motion.

The high-pressure engines are fitted with a Corliss automatic releasing valve gear for the steam cylinders. The steam valves are closed by dash pots. Each high-pressure engine has a governor of the fly-ball type, positively operated by gearing, and has a speed-adjusting device which may be shifted by hand and is of sufficient range to give a speed of from 25 to 50 revolutions per minute, all without stopping the engine. The low-pressure engine is supplied with Corliss trip steam gear adjustable by hand from zero to half stroke.

These engines have been in operation for about three months and although they have not yet run compounded, owing to the incomplete condition of the plants, they show highly satisfactory results as may be seen by the diagrams, Fig. 4, which were taken merely to check the accuracy of the valve setting.

The steam cards were taken from the high-pressure cylinder only, the low-pressure engine not being as yet operated condensing. The air cards were taken simultaneously with those steam cards by the side of which they appear.

It must be borne in mind in examining curves on the air diagrams that both the inlet and outlet valves are worked positively. At the points, x and y, where peculiar breaks in uniformity of the curves occur, the outlet valves are suddenly opened, and beyond these points the engine forces air directly into the air pipes. A number of irregularities appear in the delivery lines at points where the air cylinders of the other engines either begin to deliver air into the receiving pipes or cease to do so.

The total weight of the high-pressure engines is 610,000 pounds and of the low-pressure engines 685,000 pounds, and these weights are thought to indicate that the engines are the heaviest and most substantial of any blowing engines of their size so far constructed.

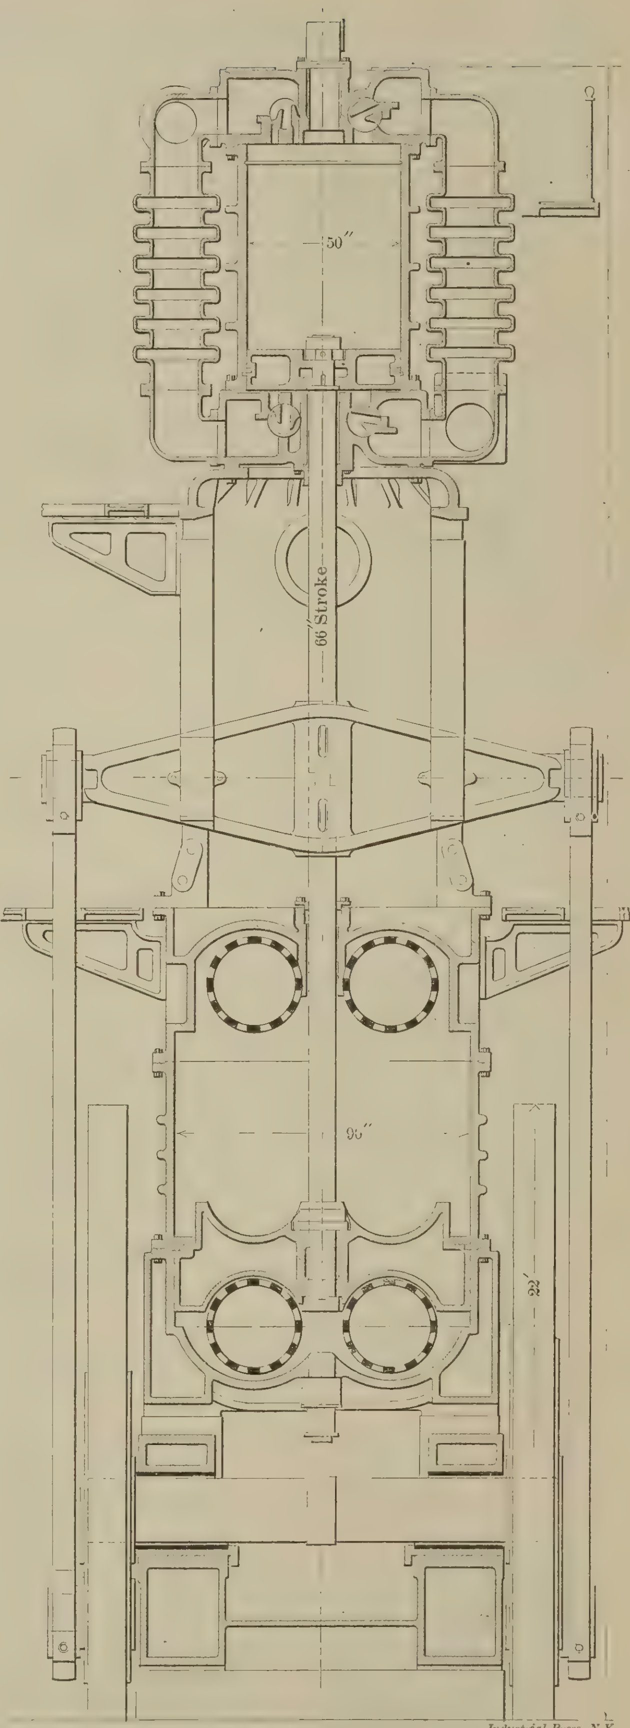

Fig. 5. Section through High-pressure Engine.

WROUGHT PIPE.*

ITS MANUFACTURE, CLASSIFICATION, STRENGTH AND CORROSION.

The development of the wrought pipe industry forms one of the great industrial achievements of the nineteenth century. It had its beginning about one hundred years ago, when the introduction of illuminating gas in England created a demand for pipe, which was promptly met by the manufacturers of gun barrels. The close of the long wars between England and France left on the hands of manufacturers large stocks of this commodity. These were converted into gas pipes by threading the large ends on the inside, and the small ends on the outside. They were easily connected by screwing the small end of one tube into the larger end of another.

The gas pipes of one hundred years ago were lap-welded by hand over a bar or mandrel. The process was slow and laborious.

The several steps were as follows:

1. Preparing a strip of iron of the required width, thickness and length.
2. Scarfing the longitudinal edges.
3. Heating to the proper temperature for bending.
4. Bending or rounding over a mandrel until the scarfed edges lapped.
5. Heating in a forge, a few inches at a time, to a welding temperature.
6. Slipping over a bar, and then hammering the lapping edges until welded.

The last two operations had to be repeated many times before the tube was completed.

The first decided advance in the manufacture of gas pipe was made in 1825, when James Russell, a manufacturer of gas tubes and gun barrels, discovered that a satisfactory weld could be made by butting and squeezing together the edges of a properly rounded and heated strip of iron. This was accomplished by means of a pair of semi-circular dies, slightly smaller in circumference than the width of the metal. As in the lap-weld process, the butt-welded tube was made by alternating heat and welding a few inches at a time.

Coincident with the invention of the butt-weld process of making pipe, Mr. Russell introduced the screw socket or coupling. This was an important step in the evolution of wrought pipe, since it permitted the sections to be made of uniform diameter from end to end.

Present Methods of Manufacture.

John Russell's method of butt-welding pipe was short-lived. It was soon supplanted by an improved process which consisted of drawing the prepared strip of metal, properly heated, through a circular die, thus welding the entire tube at one operation. This is the method of manufacturing butt-welded pipe at the present day, although, of course, many economic improvements have been made since its introduction seventy-five years ago.

The butt-weld process involves the following operations:

1. Clipping the corners of one end of a strip of metal, previously rolled to the required dimensions.
2. Heating to a welding temperature in the welding furnace.
3. Seizing the clipped end and drawing from the furnace with a pair of tongs, over which the operator throws a die or "bell" which drops into the bell holder; then connecting the handle of the tongs by means of a "hook" of special design, to a link of a moving chain which draws the strip through the "bell," thus welding it into pipe.
4. Delivering to a moving table, on which the pipe partially cools.
5. Feeding into sizing rolls, which shape and size to the required diameter.
6. Passing through straightening rolls.
7. Delivering to a slow motion shifting rack, and cooling.
8. Cutting off the ragged ends, and threading.
9. Screwing on couplings.
10. Testing by hydrostatic pressure.

With the development of steam engineering during the second quarter of the nineteenth century, came a demand for pipe of greater strength than the butt-welded pipe of that period. As the hand method of lap-welding was slow and expensive, the feasibility of making lap-welded pipe by machinery naturally occupied the attention of the more progressive pipe manufacturers. After a long period of experimenting, Messrs. Russell had the satisfaction of putting in successful operation, in 1835, the process of lap-welding, which (although somewhat modified and much improved) is used by the pipe mills of the present day. The operations are briefly as follows:

1. Beveling the edges of a strip of metal of the required dimensions.
2. Charging into the bending furnace.
3. Drawing from the furnace at a red heat through a die and over a mandrel, thus rounding the metal and over-lapping the edges. (For pipes of large diameters it is necessary to use bending rolls, similar to those used in boiler shops.)
4. Charging into the welding furnace.
5. Pushing from the furnace by means of a long rod, termed the "push bar," into the welding rolls. These rolls are grooved to correspond with the outside diameter of the pipe. A projectile-shaped mandrel held in position by a long bar, corresponds with the inside diameter of the pipe. As the pipe is drawn over the mandrel the rolls exert sufficient pressure on the laps to weld them. Each pipe as fast as welded is quickly disengaged by withdrawing the bar from the mandrel.

The finishing operations are the same as in the butt-weld process.

The great essential in the manufacture of welded pipe is a properly designed welding furnace, in which the skelp can be brought to a uniform welding temperature throughout its entire length. Next in importance is the personal factor. It is one man's business to see that the skelp is heated precisely to the proper point before it is taken from the furnace. If the temperature is below this point an imperfect weld results, and if overheated the metal is burned or hardened. It is another man's duty to inspect the pipe the moment it leaves the rolls, and to decide instantly and correctly whether the weld is perfect or otherwise. If imperfect the pipe is returned to the welding furnace, and is again passed through the welding rolls. These are responsible positions, and men who can fill them satisfactorily need not be out of employment.

Welded pipe is as small as one-eighth of an inch inside diameter, and as large as thirty-inch outside diameter. There is but one mill in the United States prepared to make the latter size.

This mill (which is now arranging to rebuild its entire plant at a cost of $10,000 000) contemplates making pipe of thirty-six-inch outside diameter as soon as the necessary equipment can be installed.

The minimum thickness of metal used in making lap-welded pipe is determined by the capacity of the tube to resist collapse when heated to the welding temperature. Standard casing and boiler tubes are close, if not quite, to the minimum thickness.

Lap-welding versus Butt-welding.

For many years the butt-weld process of making pipe was confined to the very small sizes, one and one-fourth inch being the maximum. During recent years, however, the process has extended to include larger sizes. At the present time it is the common practice among the pipe mills of the United States to make three-inch pipe and all smaller sizes by the butt-weld process, and larger sizes by the lap-weld process. This statement applies only to standard pipe, since the lighter classes of tubular goods can be made only by lap-welding. The strength of a butt-weld is dependent largely upon the thickness of the metal, and it would seem that the thicknesses adopted for standard pipe are very close to the minimum thicknesses that can be relied upon to give good results.

While it may be possible to make butt-weld pipe larger than three inches in diameter, the cost would greatly exceed that of pipe made by the lap-weld process, and therefore manufacturers have fixed upon three-inch pipe as the maximum butt-weld size, purely for economic reasons.

---

* Abstract of paper read before the Pacific Coast Gas Association, by Franklin Riffle, and published in "The Journal of Electricity, Power and Gas."

The question is sometimes asked, "In what respect, if any, is lap-welded pipe superior to butt-welded pipe?" Manufacturers of exclusively butt-weld sizes of pipe assert that butt-welded pipe stands the mill hydrostatic test as successfully as lap-welded pipe, which is perhaps true. The severer test of actual use, however, under varied conditions, has established beyond a question the superiority of lap-welded pipe. Butt-welded pipe may give equally good service when the conditions attending its use are not unusual, but it should not be used for important pipe lines, if for no other reason than for its tendency to open at the weld when subjected to the excessive torsional or bending stresses which cannot be wholly eliminated in the work of laying, especially where tight joints are an important consideration. Therefore, because of its reliability for work of this character, manufacturers use only the lap-weld process in making line pipe.

Screw-joint Pipe.

With reference to weight, or thickness of shell, screw-joint pipe may be divided into four classes of standards:

1. Embracing standard pipe, line pipe, drive pipe and tubing.
2. Extra strong pipe.
3. Double extra strong pipe.
4. Casing.

Taking the weight or thickness of Class 1 as a standard of comparison, and representing it by 1, then extra strong pipe is approximately 1 4-10, double extra strong pipe 2 8-10, and standard casing 6-10; or if standard casing is represented by 1, standard pipe is approximately 1 2-3, extra strong pipe 2 1-3 and double extra strong pipe 4 2-3; in other words, standard pipe is nearly twice the thickness of standard casing, and about 1-3 the thickness of double extra strong pipe, of the same diameter. Classes 1, 2 and 3 have the same outside diameter.

The standard pipe of commerce, commonly known as merchant pipe, is of lighter weight than standard weight or full weight pipe. Manufacturers specify that the latter may have a permissible variation of 5 per cent. above or 5 per cent. below the nominal or table weights. Merchant pipe, however, such as manufacturers and jobbers carry in stock, is almost invariably under the nominal weight. The actual weight varies somewhat among the different mills, but usually lies between the limits of 5 and 10 per cent. below the table weight. Line pipe, drive pipe and tubing are *full* weight, subject to the "permissible variation" of the manufacturer. The same is true of extra strong and double extra strong pipe.

Drive pipe is used chiefly in oil wells, and is designed to stand heavy driving. The ends, therefore, are turned in a lathe, in order that they may meet at the centers of the couplings to form a continuous column, which can be driven without damage to the threads. As tubing is used in wells for pump barrels it is both plugged and reamed to insure a smooth interior.

The smaller sizes of double extra strong pipe are made by driving one piece of extra strong pipe inside of another. The larger sizes, however, are made in the usual way.

Standard casing is the lightest screw joint pipe that can be made. Casing which is made heavier than the standard is termed "special" casing. The increased thickness reduces the interior diameter. Thus the outside diameter of five-inch standard casing is 5.25 inches, and the inside diameter is 4.95 inches. The nominal weight is 8.20 pounds per foot. Three "special" weights of this size are made, weighing respectively 9.86, 12.80, and 15.88 pounds per foot. The corresponding inside diameters are 4.87, 4.75, and 4.65 inches, the outside diameter remaining unchanged. This arrangement permits the use of standard casing couplings and fittings for all the special weights of casing having the same nominal diameter.

Strength of Screw Joints.

The holding power, or shearing strength, of a screw joint is much greater than is generally supposed. When all the threads have the maximum contact, as in taper thread couplings, their combined stripping strength is several times the ultimate tensile strength of the shell of the pipe. This statement applies no less to the fine threads of casing than to the coarse threads of line pipe; but it does not apply to the ordinary straight thread couplings, such as are used on merchant pipe, since in practice the contact area of the threads is somewhat less than in taper thread couplings.

Taking for illustration two-inch line pipe, and assuming the threads to be in perfect contact, the total contact area approximates five square inches, while the metal area of the pipe is 1.07 square inches. Assuming the tensile strength of the metal to be 60,000 pounds, and the shearing strength to be 45,000 pounds per square inch, then the ultimate tensile strength of the pipe is 64,200 pounds, while the stripping strength of the joint is 225,000 pounds. This leaves a wide margin of safety for straight thread couplings, imperfect threads, or carelessness in making the joints.

Steel Pipe versus Wrought Iron Pipe.

The crowning achievement of the pipe industry has been the successful use of steel in the manufacture of wrought pipe. This innovation by one of the leading pipe mills in the early '80's, met with a storm of opposition, not only from rival mills, but from engineers as well.

It was represented that a perfect weld could not be made with steel, that steel pipe could not be threaded, and that it was even more unreliable and treacherous when under pressure than cast iron pipe. As late as ten years ago many engineers refused to accept steel pipe as a substitute for wrought iron pipe, although manufacturers were prepared then, as now, to prove its superiority. Since then engineers have so universally adapted themselves to new conditions that when an occasional non-conformist specifies wrought iron pipe in preference to steel, it is assumed that he has not kept pace with the wonderful progress that has been made in the manufacture of steel tubular goods during the last decade. At the present time manufacturers are producing a uniform quality of steel for pipe, that for malleability, ductility and weldability cannot be excelled by the more expensive product of the puddling furnace, while for tensile strength it is vastly superior to the highest grades of iron.

Many persons are deceived by the high-sounding phrase, "Guaranteed Wrought Iron Pipe." This class of pipe is seldom made of puddled iron. On the contrary, it is oftener made of re-rolled scrap, which contains a varying percentage of steel. If any one desires to satisfy himself regarding the sort of product that results from re-rolling a mixture of iron and steel scrap, such as is collected by junk dealers, let him inspect the fracture of an average bar of so-called "refined" iron. He will probably discover that a considerable portion of the area is crystalline in structure, and that the steel crystals and iron fiber have little or no affinity.

In 1897 Professor Henry M. Howe, an eminent authority on the metallurgy of steel, made a series of experiments for the purpose of determining the relative bursting strength, tensile strength, and frictional resistance of wrought iron and steel pipe. The information derived from these experiments is probably the most reliable and conclusive that has ever been compiled, relative to the comparative merits of iron and steel pipe. Three classes of wrought iron and steel pipe were selected, viz., two-inch line pipe, two-inch tubing, and five and five-eighth-inch casing.

The following table shows in condensed form the average results of the experiments upon bursting strength:

BURSTING TESTS BY HYDROSTATIC PRESSURE.

	Bursting Pressure Pounds per Square Inch.		
	2-inch Lead Pipe.	2 inch Tubing.	5⅝-inch Casing.
Wrought Iron, minimum..........	1000	3300	250
Wrought Steel, minimum.........	2300	5150	1450
Wrought Iron, maximum..........	4000	5000	1400
Wrought Steel, maximum........	6000	6000	2750
Wrought Iron, average of all pipes tested	2918	4106	931
Wrought Steel, average of all pipes tested	4733	5800	2038

A comparison of the average results shows that the steel pipes excelled the wrought iron pipes by 62 per cent. in the line pipe, 41 per cent. in the tubing, and 119 per cent. in the casing.

For making tensile tests short pieces were cut from certain of the steel and wrought iron pipes. These were accurately threaded and fitted with special extra heavy couplings. They were then pulled lengthwise in a tensile testing machine until they tore in two.

TENSILE TESTS.

	Tensile Strength, Pounds per Square Inch of Net Section.		
	2-inch Lead Pipe.	2-inch Tubing.	5⅝-inch Casing
Wrought Iron, minimum........	43,107	47,244	47,312
Wrought Steel, minimum........	63,025	60,370	75,931
Wrought Iron, maximum........	53,809	55,074	61,309
Wrought Steel, maximum........	67,586	66,495	91,591
Wrought Iron, average of all pipes tested	50,002	51,852	54,311
Wrought Steel, average of all pipes tested	65,999	63,057	82,355

The table shows that the steel pipes excelled the wrought iron pipes by the following percentages: Line pipe, 32 per cent.; tubing, 22 per cent.; casing, 52 per cent.

An objection that is sometimes urged against steel pipe is that it corrodes much more rapidly than wrought iron. Of late years this objection has been shown to be based on prejudice rather than fact.

As early as 1895 Professor Howe, in a paper entitled "Relative Corrosion of Wrought Iron and Steel," summed up his analysis of a considerable number of experiments made by himself and other investigators, in the following language: "It is misleading to say either that normal low carbon steel corrodes more or that it corrodes less than wrought iron, since the irrelative corrosion varies with the inclosing medium. I think we have every strong reason to believe that such steel when carefully made, resists corrosion in fresh water as well as wrought iron; in cold sea water, at least nearly as well as wrought iron and in acidulated water better than wrought iron." Five years later Professor Howe published the results of a series of experiments in which he exposed a number of plates of wrought iron, steel, and nickel steel, one-eighth of an inch thick, to the action of sea water, river water, and the weather for two periods of one year each. The results are summed up in the following table:

CORROSIVE TESTS.

	Sea Water.	Fresh Water.	Weather.	Average.
Wrought Iron	100	100	100	100
Soft Steel	114	94	103	103
3 Per Cent. Nickel Steel....	85	80	67	77
24 Per Cent. Nickel Steel....	32	32	30	31

No matter whether we use wrought iron or steel pipe corrosion is a factor that cannot be ignored. Its rapidity of action depends to a very great extent on the chemical properties of the soil in which the pipe is laid. More than thirty years ago the manufacturers of light riveted pipe in California realized that the success of this class of pipe depended upon the application of a satisfactory preservative coating. Judging from riveted pipes that were recently taken up in Oakland after having been in the ground since the early seventies, it was customary in those days to apply the asphalt coating very generously and with great care. Since then manufacturers of riveted pipe, refiners of asphaltum and engineers, have devoted much time and thought to this all-important subject, and at the present day the coating of steel pipe with asphaltum is probably better understood in California than anywhere else in the world.

In view of the importance of the subject the following points are suggested regarding the coating of pipe with asphaltum:

1. The pipe should be thoroughly cleaned. Every particle of rust, and as much of the mill scale as possible, should be removed.

2. The asphalt bath should be brought to a temperature of 300 degrees Fahrenheit. Its proper consistency may be determined by dipping in the mixture a strip of thin steel, and then withdrawing and plunging into cold water. If after this treatment the coating is soft and sticky the mixture contains too large a proportion of the fluxing or liquid grade of asphalt, and if in bending the strip the coating shows a tendency to crack and flake off there is an excess of the solid grade.

3. The pipe should be left in the bath until it has had sufficient time to attain the same temperature as the asphaltum. For the heavy types of welded pipe, it would be advisable to heat each pipe to the same temperature as the bath before immersing.

4. As a thick coating of asphaltum affords more thorough protection than a thin coating, two dippings are recommended, in which case the first coating should be allowed to harden before re-dipping.

5. Pipe should be coated in the vicinity of the laying. Under no circumstances should it be dipped before leaving the mill, except as a precaution against rusting en route, in which case it should be re-dipped at destination. After the pipes receive their final coat the greatest care should be exercised to prevent abrasion, both in distributing along the trench and in laying. As a final precaution every pipe should be rigidly inspected for abrasions, and wherever exposed, the metal should be given two coats of some reputable brand of asphalt paint.

Specifications.

Engineers sometimes prepare elaborate specifications for pipe without stopping to consider if they are practicable. So far as the quality of the material and the details of manufacture are concerned, it is always advisable to conform to the practice of the best pipe mills. All grades of steel, for example, are not equally weldable. Therefore it would be a waste of time to specify steel that could not be welded.

So far as testing the pipe at the mill is concerned the standard hydrostatic tests for the several classes of pipe will answer, unless extraordinary working pressures are contemplated. The standard tests are as follows:

Standard, extra strong and double extra strong pipe, two-inch and smaller, 300 pounds per square inch.

Standard, extra strong and double extra strong pipe, two and a half inch and larger, 500 pounds per square inch.

Line pipe, six-inch and smaller, 1,500 pounds per square inch.

Line pipe, seven-inch to twelve-inch, 800 pounds per square inch.

Tubing, 2,000 pounds per square inch.

Irrigation casing, five and five-eighths inch and smaller, 500 pounds per square inch.

Irrigation casing, larger sizes, 300 pounds per square inch.

Oil well casing, five and five-eighth inch and smaller, 600 pounds per square inch.

Oil well casing, larger sizes, 500 pounds per square inch.

Unless otherwise specified the several classes of pipe are tested at the mill to the above pressures. Arrangements can always be made for special tests when the pipe is to be used under high pressures. In no case should the mill test be less than one and one-half times the proposed static pressure.

Specifications for merchant pipe. The following specifications are sufficient to secure a good quality of merchant pipe at the ruling market price. Pipe to be made of good, ductile metal of uniform quality, and to be straight and smooth. Threads to be clean cut in accordance with manufacturers' standard. Couplings to be well screwed on. Jointers not to exceed 8 per cent. of the total number of lengths. All pipe to be subjected to the standard hydrostatic test before leaving the mill.

Specifications for line pipe. Pipe to be made of steel, of tough, ductile and uniform quality. Each length to be fitted with a full weight line pipe coupling, the ends of which shall be recessed. The threads of the coupling to taper uniformly from both ends to the center. A half-coupling thread protector to be securely screwed on to the exposed end of each length of pipe. None of the pipe to vary more than 5 per cent. above or 5 per cent. below the standard weights. Jointers not to exceed 6 per cent. of the total number of lengths. Each length to be tested at the mill to a specified hydrostatic pressure.

The *New York Times* in an article on post office oddities refers to the manufacture of stamps and tells its readers that the original steel plate bearing a stamp design, although *baked* as hard as a diamond, is never used for actual printing.

FLEXURE SIMPLIFIED.*

JOHN S. MYERS.

Most mechanics and even a few draftsmen, especially those engaged on machine tool work, know very little about the theory of flexure or strength of beams. They may know that the maximum bending moment in a beam uniformly loaded equals $\frac{\text{weight} \times \text{length}}{8}$ and that for a beam with concentrated load in the center, maximum moment equals $\frac{\text{weight} \times \text{length}}{4}$ because they have seen the formula in some book but could not tell you why such is the case; or if they had a problem the book did not cover, could not work it out. Moment of inertia, section modulus, radius of gyration and extreme fiber sound too scientific to them and seem too hard to tackle. As a matter of fact the whole thing is comparatively simple when divested of technical terms and put in a simple form.

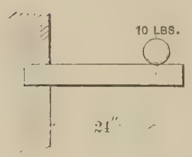

Fig. 1.

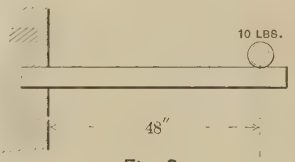

Fig. 2

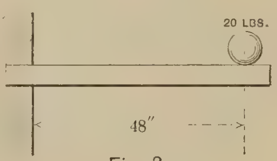

Fig. 3

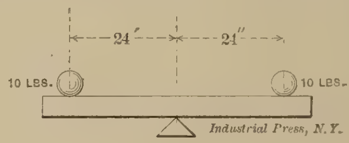

Fig. 4

The first thing we have to consider is moments. The word moment almost explains itself. It means importance, or of account, in ordinary talk, and in mechanics, when applied to a force, it means the importance of the force, with respect to bending; that is, it is a measure of the ability of a force to bend. A force of ten pounds at the end of a beam 24 inches long has a certain definite power to bend the beam. The same force 48 inches or twice as far from the support we at once say has twice the power to bend the beam. Twenty pounds 48 inches away from the support we would say had four times the power to bend the beam, for we have twice the load and twice the distance from the support.

The power of a force to bend is called a bending moment and is nothing more or less than the force multiplied by the distance from it to the point where we wish to determine its power. In Fig. 1, the bending moment at the support is 10 × 24 = 240 inch pounds. In Fig. 2, 10 × 48 = 480 inch pounds. In Fig. 3, 20 × 48 = 960 inch pounds.

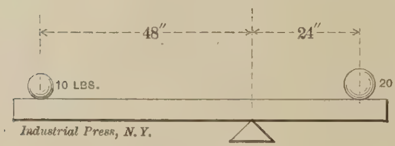

Fig. 5

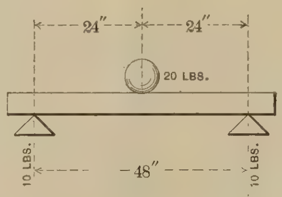

Fig. 6

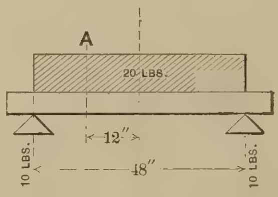

Fig. 7

Now we come to the principle of the *equality of moments.*

In Fig. 4 the beam is evidently balanced, as equal weights are equal distances from the fulcrum or point of support. The moment on the left is 10 × 24 and on the right 10 × 24. There is no tendency to move either way, so we say the beam is in *equilibrium.* In Fig. 5 the moment at the point of support for the force on the left is 10 × 48 = 480 inch pounds, and for the force on the right 20 × 24 = 480 inch pounds. The moments are equal so we see this beam is in equilibrium since the moments express the power of the forces to turn about this point. In Fig. 6 we have 20 pounds in the center and half of this or 10 pounds at each support. This force at the end, which acts upward, is called a *reaction.* The bending moment at the center of the beam is 10 × 24 = 240 inch pounds, just the same as in Fig. 1.

In Fig. 7 we have a reaction of 10 pounds upward at each end also, and the moment of this about the center is 10 × 24 = 240 inch pounds, but half the load on the beam, the center of which is at *A*, acts downward and has a moment in the other direction of 10 × 12 = 120 inch pounds. The net moment at the center then is 240 − 120 = 120 inch pounds. This is what is called the *algebraic sum* of the moments. It is all the moments in one direction minus all the moments in the other direction on one side of the point under consideration, and expresses the power of all the forces to bend the beam at this point. By a similar method we may find the bending moment for any character of loading.

Now the beam must of course be able to resist the bending moment, and the power of a beam to withstand flexure is termed the *resisting moment,* which of course must equal or exceed the bending moment.

We will take the case shown in Fig. 8, where a force of 5,000 pounds acts in the center of a beam 200 inches long. The reactions are of course 2,500 pounds each, and the bending moment 2,500 × 100 = 250,000 inch pounds. All that portion of the beam above the line *y y* is in compression and all that portion below *y y* is in tension and at the center the stress is zero, as indicated by the arrows. This line *y y* is called the *neutral axis.* Now if we divide the entire area of a cross section of the beam up into small parts and multiply the area of each part by the stress per unit of area at that point and then by its lever arm, *x*, we would have the resisting moment of the beam. This would be laborious, however, and it is the maximum stress at the outer edge called the *extreme fiber stress* that we wish to find. If we multiply each of these elementary areas by the square of its distance from the neutral axis *y y* and take their sum we have the quantity called the *moment of inertia* and if we divide this quantity by the distance *C* we get the quantity called the *section modulus.* Section modulus may be said to be the area equivalent to the total area of the section if concentrated at the extreme fiber and multiplied by its lever arm. We readily see that this equivalent area times its lever arm, when multiplied by the stress per unit of area equals the resisting moment of the beam; or in other words, section modulus × stress = resisting moment, which is also equal to the bending moment or $ZS = M$ where Z = Section modulus, S = unit stress and M = bending moment. As we have seen before, $Z = \frac{\text{moment of inertia}}{C}$ usually written $\frac{I}{C}$. The section modulus Z for different shapes has been worked out to simple formulas; for a rectangle like beam in Fig. 7 the formula is $Z = \frac{BD^2}{6}$. Now to find the size beam for conditions in Fig. 8, we take our formula $ZS = M$ or $\frac{M}{S} = Z$ and inserting the values of M and S, allowing say 1,000 pounds per square inch for S, if a pine timber, we have $Z = \frac{250{,}000}{1{,}000} = 250$. But for a rectangle $Z = \frac{BD^2}{6}$, so $\frac{BD^2}{6} = 250$ or $BD^2 = 250 \times 6 = 1{,}500$. Now we can assume some breadth and figure for the depth or assume some depth and figure for the breadth. If we took a beam 10 inches deep, it would have to be $\frac{1{,}500}{10^2} = 15$ inches wide; if we took a beam 12 inches deep it would have to be $\frac{1{,}500}{12^2} = 10.42$ inches, say a 12-inch by 10-inch timber. If we wanted to use an I-beam with a stress of say 16,000 pounds per square inch for dead load, we would get $Z = \frac{M}{S} = \frac{250{,}000}{16{,}000} = 15.63$, and from tables in the handbooks of steel concerns we see that an 8-inch, 23-pound beam or a 9-inch, 21-pound beam would answer the purpose. The foregoing simple application should be enough to start one on the right track and the writer hopes it may be of use to someone struggling for the truth under adverse circumstances.

---

* This simple explanation of the flexure of beams is to assist the younger readers in the use of this month's data sheet.—EDITOR.

DOUBLE-ACTING PUMP.

Editor MACHINERY:

The pump illustrated in your issue of October, 1903, page 90, is a hoary old friend of mine. As your correspondent states that W. H. Wilcox & Co., of London, England, have been exhibiting it lately it might be well to correct the probable impression that it is new.

Thirty years ago I was engaged in steam pump building and patented several improvements; so I was interested in finding the simplest double-acting pump possible. Some time afterward, but more than twenty years ago, I proceeded to build a pump—intended to be the limit of simplicity—as follows:

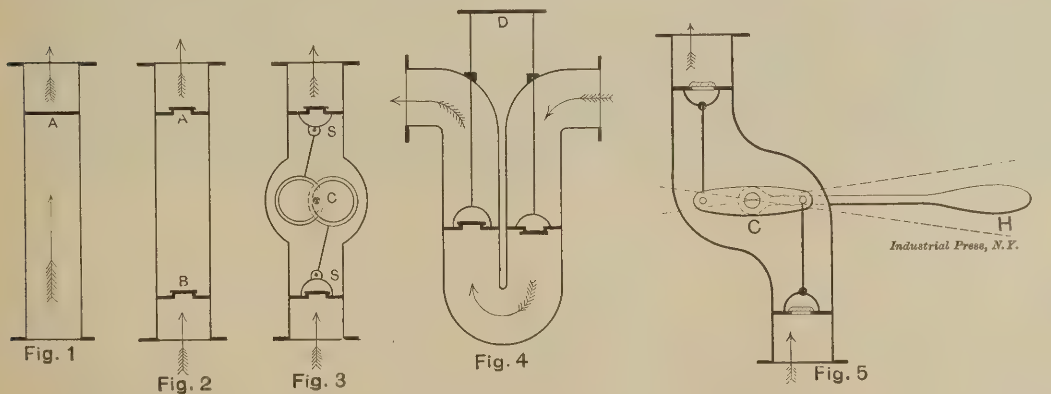

Fig. 1 Fig. 2 Fig. 3 Fig. 4 Fig. 5

Simple Double-acting Pumps.

Let *A* be a piston in a simple piece of pipe, Fig. 1. If *A* is moved upward as per arrows we have a pump, but only till the piston reaches the top end of the pipe. Now, it becomes necessary to take a new hold of the water, but there is nothing to hold up the column while this is being done. I then evolved the arrangement, Fig. 2, putting in two pistons, *A*, *B*, in each of which there is a valve opening upward and imagined that while *A* is going down *B* is coming up, and *vice versa*. In other words, the pistons, *A*, *B*, approach *to* and recede *from* each other alternately and a solid stream is discharged. I then put stirrups on the pistons, as in Fig. 3, and used two opposite eccentrics on center shaft, *C*, connected with the pistons, as shown. This I built and tested and found to work better at high speed than any double pump I ever saw.

At no period of my life did I ever feel so certain that I had the material for a fundamental patent; so my application was at once sent in. It would be safe to say that no enthusiastic inventor ever got a more beautiful reference from Washington, for the office sent to me a complete drawing of my model with two cranks instead of my two eccentrics—patented in 1860 (No. 27,945)! Applying this old claim to Fig. 3 it would read thus: "The shaft, *C*, its two cranks, in combination with the two connecting rods and the valved buckets, *S S*, and their valves—so that a simultaneous reciprocating motion, in contrary directions, may be imparted to the said buckets, *S S*, by the rotation of the shaft, *C*, and so that the two barrels may be in direct line with each other." "Bucket" is the old name for a piston containing a valve. The "Wilcox" drawing is substantially the same as the drawing in this old patent. In 1857 (No. 17,625) a modification appeared as per Fig. 5, shaft *C* having a simple crosshead, as shown. Outside the case was placed the lever, *H*, to be moved through any convenient angle, by hand, as indicated by the dotted lines. This pump, in whatever form, with the "motion" working in the water, is not of much practical value and is only good when bent into a U, as in Fig. 4, and the two pistons operated in the same direction from a crosshead, *D*, common to both. For this successful form see MACHINERY, August, 1899, page 367. But to *all* these forms there is a fundamental objection. Assume that the displacement by one of the pistons, while its valve is seated, is x: then through the other piston, during the same time, $2x$ of water must pass. In other words, when any one of the pistons is taking water through its port (or valve) it is *meeting* a stream of its own velocity in the opposite direction. It is not usually evident at first glance that the action of pump, Fig. 4, is the same as Figs. 3 and 5, yet such is the fact. JAMES ARTHUR.

The Arthur Co., New York.

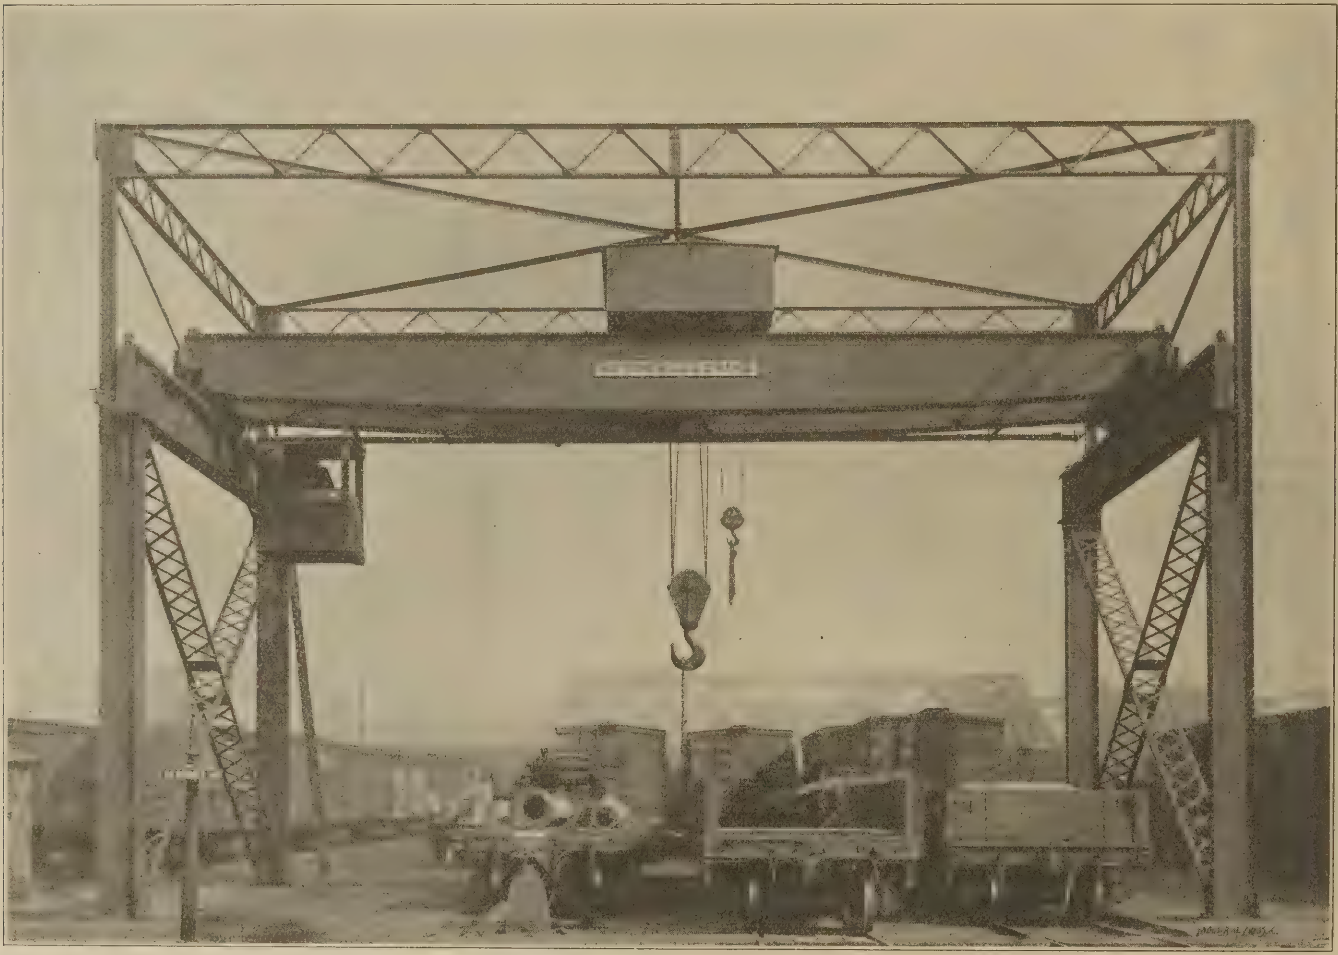
NILES FORTY-TON TRAVELING YARD CRANE.

A cut given on next page shows the latest type of an improved and economical apparatus for the handling of heavy and bulky freight in a railroad yard. The view shows a portion of the yard of the Buffalo & Allegheny Valley Division of the Pennsylvania Railroad Company, at Buffalo, N. Y., and includes a four-motor Niles overhead electric traveling crane, 48 feet span, and a substantial structural steel runway 40 feet long. The crane spans three tracks, and leaves a wide passageway which gives ample approach for teams and trucks on one side of the cars covered by this apparatus. The height of the runway gives the main hook a lift of 24 feet. The motor operating the main hook is 30 horse power.

In addition to the main hook, a quick running auxiliary hook of 5 tons capacity, driven by a 21 horse power motor, is provided for the rapid and efficient handling of light loads, which performs by far the greater part of the service of the crane. The bridge consists of two heavy curved girders, of box section. It is driven longitudinally on the runway by 30 horse power motor located on the front girder which is geared to the truck wheels on either side, the motion being controlled by a foot brake located in the operator's cage which acts directly upon the armature shaft of the motor. A foot bridge is provided the entire length of the span, with customary guard rail. The bridge trucks are of built-up type, securely fastened with the utmost rigidity to the girders, provided with heavy cast steel double flanged truck wheels with treads accurately finished to uniform diameter.

The trolley, traversed on the bridge by a 7½ horse power motor, is the standard type used on overhead cranes, consisting of heavy side frames securely bolted together and kept in perfect alignment by a separator. All the gearing is cut from the solid, and runs encased in oil, which gives the entire mechanism an unusually high mechanical efficiency. Both hoists are provided with mechanical and electric brakes, also circuit breakers and limit switches to prevent overwinding and consequent damage to the crane or its load. The trolley, operator's cage, and bridge drive motors are of the inclosed type, affording suitable protection from the weather. The runway, it will be noticed, is of substantial construction. It consists of four built-up columns carrying runways of riveted plate and channel construction, laterally braced by overhead struts and chords of lattice construction. The speed of the main hook lifting full load is 9 feet per minute; light, 18 feet. Auxiliary hook, full load, 50 feet; light, 100 feet. Trolley travel across bridge, with full load, 80 feet; light, 100 feet. Bridge, full load, 225 feet; light, 275 feet.



Yard Crane in Use by Pennsylvania Railroad at Buffalo.

It will be readily appreciated that an equipment of this character has a much greater capacity than the average pillar or swinging crane which, where any is in use, is usually installed at railroad freight stations. If at any time it is desired to cover increased acreage with the hook, the length of runway is readily increased by adding additional spans. This crane is notable because of the extra height of lift, 24 feet, which enables the loaded hook to clear the top of box cars or other obstructions while performing the functions of its regular service of loading and unloading.

The complete apparatus was manufactured, installed and erected by the crane department of the Niles-Bement-Pond Company, Meadow and Mifflin Streets, Philadelphia, Pa.

* * *

In annealing cold rolled steel, gas is turned into the annealing boxes after they are removed from the furnace. The burning of the gas uses up any air that might come in contact with the steel while cooling. By this method the steel comes out of the boxes in bright condition.—*Sparks from the Anvil.*

HYDRAULIC INSTALLATIONS.

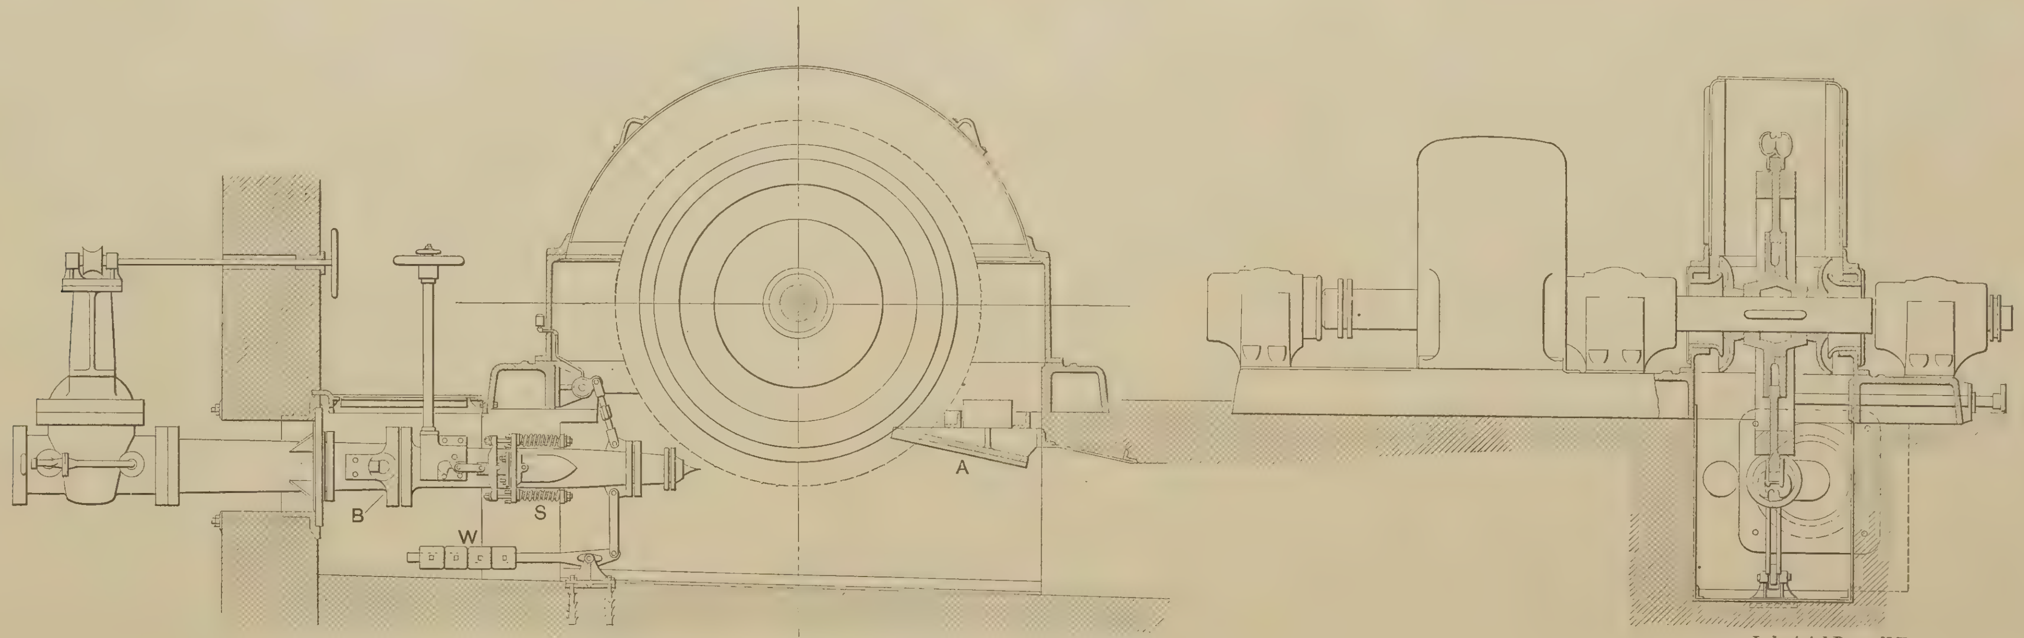
REMARKABLE WATER POWER ON THE PACIFIC COAST.

Recent development in hydraulic practice on the Pacific coast has been in the tendency of the utilization of higher heads. In the minds of a number of engineers the question has arisen as to the wisdom of developing these high heads, utilizing the totality of fall in one station, as against dividing the fall up and passing the water through two or more stations in series, in this way utilizing the same water under lower heads in two or more power plants.

The Edison Electric Company, of Los Angeles, had this problem to consider when it was proposed by them to install their new power plant, which has been known as Mill Creek No. 3 being located in the Mill Creek Canyon, near Redlands, Cal. The effective head on this plant is 1,912 feet. After carefully considering the matter the Edison Company decided that it would be better engineering to utilize the total available head in one power station, although it is the highest or greatest head it has ever been attempted to utilize in this manner. Water falling from a height of 1,900 feet would theoretically have a velocity of flow of over 20,000 feet per minute and it would be necessary for a tangential water wheel to have a peripheral speed of nearly half this velocity; as a matter of fact the wheels now running in this plant have a peripheral speed of between 9,000 and 10,000 feet per minute, or upward of a mile and three-quarters a minute.

The plant to be installed was to consist of four water-wheel generating units of 750 kilowatts each, designed for a 25 per cent. overload, at a turning speed of 430 revolutions per minute. They therefore decided to install at first but two units, the balance of the plant to be placed after tests had been made in the first two wheels. Accordingly they placed an order for one unit with the Pelton Water-Wheel Company, San Francisco, and one with the Abner Doble Company, San Francisco, makers of the ellipsoidal tangential water-wheel.

We are informed by the Abner Doble Company that the balance of the equipment for this station was finally purchased



Industrial Press, N.Y.

Tangential Impulse Wheel for Operating under the Highest Head yet Utilized—1912 feet.

from their firm and they have kindly furnished us with particulars about this and other important installations of the Doble ellipsoidal tangential wheel, together with a blueprint of one of their Mill Creek wheels direct-connected to an electric generator.

The Doble wheel installed at the Mill Creek station showed an efficiency on the preliminary tests of from 80 per cent. to 84 per cent., at loads ranging from one-half load to 25 per cent. overload. The installation is of particular value in confirming the wisdom of the Edison Electric Company in utilizing their total head in a single station as against dividing it up over several stations, as has been done by several other companies. It is demonstrated by the tests at this plant that the efficiency to be secured from tangential wheels under these very high heads is exceedingly favorable, clearly showing that it is safe to utilize the total available power value in one station. These tests make an interesting comparison with the work of one of the famous Swiss builders in the Vouvry plant, where the efficiency was only 56 per cent.

The illustration on this page of one of the Mill Creek wheels shows a 1,300 horse power wheel with needle regulating and deflecting nozzle designed to operate under an effective head of 1,900 feet. The generator base plate is extended to carry a third bearing for the electric unit and the housing of the water-wheel. The water wheel itself has a diameter of 7 feet 8 inches, and one single nozzle is applied, furnishing a stream of 2 inches maximum diameter. The wheel body is of the composite type, a steel disk being clamped between the hub and follower plate, and carrying two heavy cast steel flywheel rings, rigidly bolted to it.

The nozzle is of the deflecting needle regulating type, the regulating needle being operated by hand by means of a hand wheel with worm-gear attachment; whereas the Lombard governor used for regulating the wheel, but not shown on the drawing, deflects the nozzle and turns the stream down into the tail race, partially or entirely away from the buckets, according to the load on the generator. The regulating needle in this case has the purpose to increase the area of jet during periods of peak load, which occur in the evening, when to the normal load considerable load is added on account of lights being switched in.

The power station furnishes the light and power for Redlands and Los Angeles and smaller places between, a considerable part of the power being used to operate centrifugal pumps to irrigate citrus groves in that part of the country.

The engraving shows how the connection is made with the gate valve outside of the power house, the operating spindle going through the wall in such a way that the operator has both the handwheel for the gate and the handwheel for setting the needle within easy reach.

The sectional end elevation at the right corner of the drawing also shows the centrifugal water guards applied to avoid stuffing boxes, which cause unnecessary friction. These water guards serve the double purpose of preventing splash water escaping from the housing, and at the same time ventilate the housing to maintain an easy flow of water in the tail race. The casting shown in the front elevation of the drawing is a baffle plate, through whose opening the buckets pass. The purpose of this baffle plate is to shave off the last particles of discharge water emanating from the buckets.

The needle, by which the size of stream flowing through the nozzle is regulated, has a long stem extending back longitudinally through the body of the nozzle. At the forward end the stem is enlarged and formed into a cone which, by the longitudinal movement of the needle, opens or closes the mouth of the nozzle. The spiral springs, *S*, at the side of the nozzle, are to equalize the varying pressure on the needle cone in the different positions of the needle or at different nozzle openings. The needle stem is provided with a balancing plunger which extends into the pressure chamber of the nozzle body and balances the needle at normal opening.

When the needle is entirely drawn back or the nozzle full open, the pressure on the springs is released as the pressure on the balancing plunger and the forward pressure on the needle bulb are equal. By shutting the nozzle or moving the needle forward in reducing the area of the issuing jet the reaction decreases, whereas the forward pressure remains the same. To make up for this variation, the compression springs are provided, which are fully compressed when the needle is entirely closed and in which case the forward pressure on the bulb is a maximum. On account of this it takes the same power to operate the needle wherever its position might be.

As stated at the beginning, the Mill Creek plant, of which one of the power units is shown in the illustration, is operating under the greatest head of any similar plant in the world, and it will be of interest to add a few facts about the impulse wheels recently built by the Abner Doble Company, for use in connection with the Bay Counties transmission system, which are the largest impulse wheels ever constructed, so far as we are aware. Last summer two wheels were installed at the Nimshaw Power House of the Valley Counties Power Company, a sub-company of the California Gas and Electric Corporation, and feeding into the transmission line of the Bay Counties Power Company. These two machines have now begun operation.

The power house is located in the Butte Creek Canyon, twenty-four miles from Chico. The available total head of water is 1,531 feet, taken down in one pipe line 6,200 feet long, and tapering in three sections, from 30 to 28½ inches diameter. Within the power house the pipe terminates in a Y, each branch of the Y supplying a 3,700 horse power water-wheel, the largest wheels operated as yet by one single jet of water.

The generators are of the Stanley Electric Company's make, the rotary element mounted on one single shaft with the water-wheel; the entire hydro-electric unit runs in two bearings, the rotary element of the generator between the bearings, and the water-wheel overhung. Shaft and disk are nickel steel forgings, made by the Bethlehem Steel Company, the shaft being hollow-forged and oil-tempered, and the buckets are steel castings of the ellipsoidal type. The total weight of the revolving part of each unit is over forty tons; the speed 240 revolutions per minute.

The Abner Doble Company is now building, however, a unit of 7,500 horse power to operate under the same total head of 1,531 feet, for the Bay Counties Power Company, which thus considerably beats their own record. It will be direct-connected to a Stanley Electric Company's alternator, and will run at a speed of 400 revolutions per minute, the entire hydro-electric unit being mounted on two bearings and one single nickel steel shaft. The wheel takes water from a single nozzle.

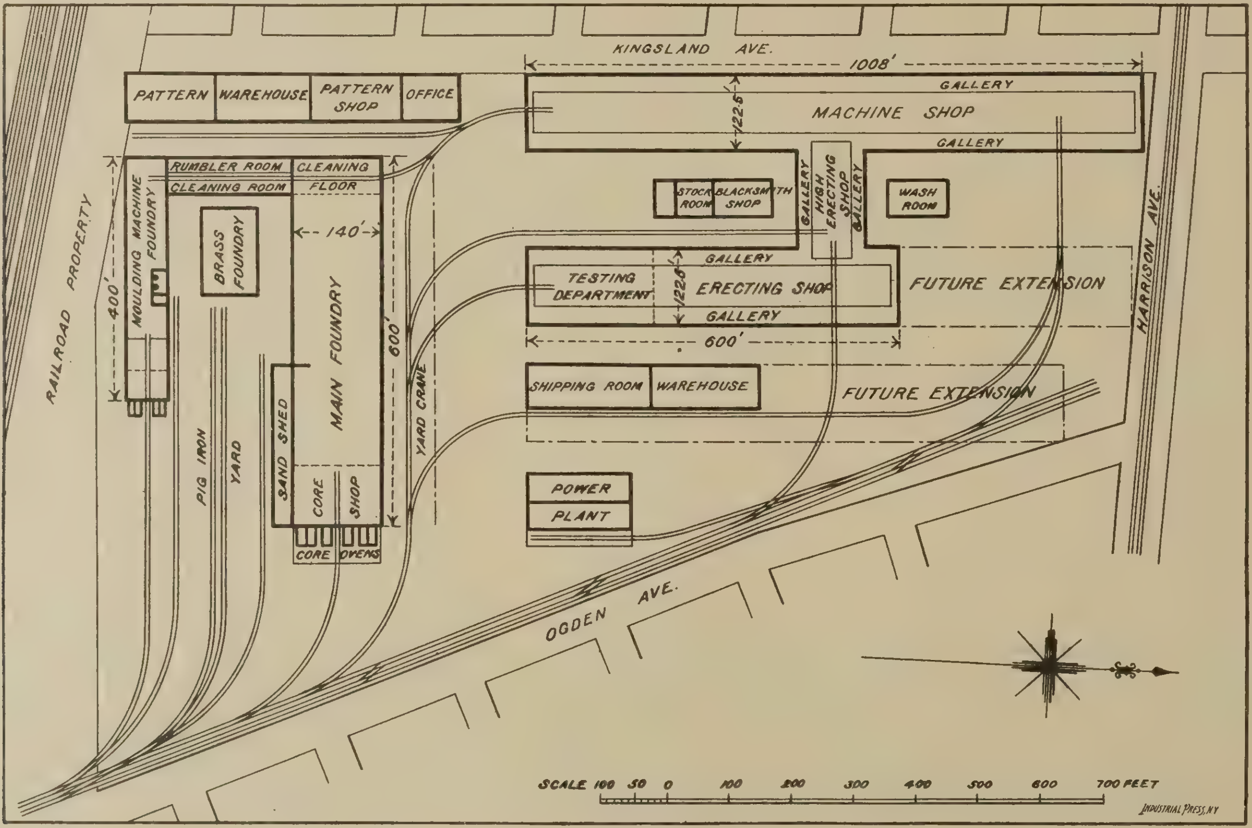
THE NEW WORTHINGTON PLANT.

An extensive pump manufacturing plant, the largest in this country and probably in the world, is now under construction at Harrison, N. J. It is to be occupied by the firm of Henry R. Worthington, who employ about 3,000 men in their present works at South Brooklyn, L. I., and Elizabethport, N. J. The new plant at Harrison covers an area of about 30 acres, facing Harrison avenue, and will employ from 4,000 to 5,000 men. The total cost will be in the neighborhood of $2,000,000.

It consists of a main machine shop with side galleries over 1,006 feet long, an erecting shop 592 feet long and of the same section as the machine shop and a high erecting shop 210 feet in length and four galleries in height in the side bays connecting the two shops. The main foundry is 600 feet in length and there is also a special foundry for small work, 410 feet in length, with a building 200 by 60 feet in size, for cleaning castings, connecting the two. The pattern building is four stories high and 550 feet long, and is divided by fire walls into four sections. The north section will be used for offices and drafting rooms, the adjoining section for the pattern shop and the balance of the structure for pattern storage. The power house, which will be equipped with the best modern boilers, engines and generators, is a building 172 by 102 feet. Five generators are to be installed having a total capacity of 2,500 kilowatts. Electric power distribution is to be employed throughout, and the grounds will be illuminated by electric arc lights. There are many other buildings which will be used for packing, storing and shipping goods, etc. The buildings are so arranged that additions can be built when the work demands it. All will be connected by a complete system of railroad tracks entering the ends of the buildings and placing the works in direct communication with the Delaware, Lackawanna & Western, the Erie and the Pennsylvania railroad systems. The new plant will be devoted entirely to the manufacture of water works machinery, water meters, cooling towers, condensers, feed-water heaters, centrifugal pumps and steam pumps of all kinds. It is expected that at least three of the buildings will be ready for occupancy about January 1, 1904.



Plan of the Worthington Plant of the International Steam Pump Company.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

Beginning with the January, 1904, issue the name of *Feilden's Magazine* will be *The Engineering Review.*

In a paper on foundations read by Mr. George B. Francis before the Boston Society of Civil Engineers, February 18, 1903, some elementary information on permissible loads per unit of area were given as follows: Ledge rock, 36 tons per square foot; hard pan, 8 tons per square foot; gravel, 5 tons per square foot; clean sand, 4 tons per square foot; dry clay, 3 tons per square foot; wet clay, 2 tons per square foot; loam, 1 ton per square foot.

The gross earnings of the railways in the United States for the six months ending June 30, 1903, were the largest in the history of railroading in this country. The increase in gross earnings for this period was over $90,000,000, and of the net earnings, somewhat less than $20,000,000. The increased cost of operation due to higher wages, and of fuel and other supplies, have had the effect of keeping the increase of net earnings down to a little more than twenty per cent. of the increased gross earnings.

The extending use of aluminum for electrical purposes and the wide prospective use for it in the manufacture of thermit, makes the report that a St. Louis man has discovered a pyrochemical process of manufacturing aluminum from clay of considerable interest, especially so as he claims the metal will be greatly cheapened by the new process. The process, discovered by Mr. Schwahn, is claimed to effect the reduction in much shorter time than now required and to reduce the cost from $500 to $100 per ton.

A somewhat novel plan for balancing a loose pulley is described in the *Woodworker.* After the pulley has been bored out ready for use, place it upon a smooth arbor that is solidly supported in place. Wind a cord around the hub, or the rim, according to size of pulley, and give the cord a long, even pull, that unwinds it, giving the pulley the motion due to unwinding process. The inner end of the cord is not tied to the pulley, but left free, except that the cord crosses it to hold the same in place. When the pulley is perfectly balanced it will run a long time without "chattering."

The Ellwood Ivins Tube Works mills at Oak Lane Station, Philadelphia, have succeeded in producing tool steel seamless tubing. The tubing is made in sizes from about 2 inches in diameter down to small sizes of 1-64 inch, in all thicknesses of walls. The tubes are most accurately drawn both as to internal and external diameters, and have a polished surface. So great is the precision that it is claimed that no work is required for fitting the tubes after they are made in sizes ordered. It would seem that this new product in tool steel would eliminate the necessity of boring out solid rods or bars where either short or long hollow articles were required, such as cutting dies, bushings, drills, etc. These steel tubes take a high temper at low heat.—*Iron Age.*

The largest circular saw in the world has just been turned out at the works of Henry Disston & Sons, in Philadelphia, for use in the lumber section of Elk county, Pennsylvania. The saw is 7 feet 4 inches diameter and bears teeth each one of which is 4 inches long. The saw weighs 305 pounds. The purpose for which the mammoth saw was made is of interest. It will be used to cut pine stumps into shingle bolts, thus opening to the market a vast quantity of material which until recently was considered useless. In Elk county, where thirty years ago the forests of white pine were hewn down and turned into lumber, are thousands of acres of great pine stumps as solid as the day the trees were cut. Many of these stumps stand from 5 to 8 feet above ground, so that in the swampy regions of the Elk county plateaus there are millions of feet of choice shingle wood.—*The Woodworker.*

A German casehardening process described in a recent consular report by Consul-General J. O. Hughes, Coburg, Germany, employs phosphorus in connection with the other ingredients of the pack, to impart a greater hardness. The effect of the phosphorus is said to be to weaken the coherence of the surface particles of the iron and to thus facilitate the absorption of carbon. The pieces to be casehardened are packed in cast-iron boxes in the ordinary manner, the cover being tightly closed and luted with clay. The pack consists of bone dust, yellow prussiate of potassium, cyanide of potassium and phosphorus. An example is quoted to show the proportions. To caseharden pieces weighing say, 400 pounds, 300 grains of yellow prussiate, 250 grains of cyanide and 400 grains of phosphorus are mixed with the necessary amount of bone dust to properly and economically harden the work. It is said that the surface hardness obtained by this process is phenomenal.

An accident, illustrating the danger of not having main valve connections carried through to the upper decks of steam vessels, occurred to the *Picqua,* October 10, off the American coast during a heavy storm. The main steam pipe broke off close to the cylinder, filling the engine room with scalding steam and causing the death of two men. For two hours the vessel rolled at the mercy of the seas, the engines having stopped, and the steam still pouring through the broken pipe until the fires were finally extinguished. At last it was possible to enter the engine room and effect a temporary repair of the broken steam pipe, so that the vessel could proceed. Had there been connections to the main steam pipe valves from the upper decks, the danger of the accident would have been greatly minimized and perhaps the lives of the men saved. Connections to all important valves from the upper decks is one of the details that Uncle Sam looks after very carefully in the design of the navy vessels.

In his "Engineering Reminiscences," November *Power,* Mr. Charles J. Porter says that the firm of Smith & Coventry, Manchester, first introduced the plan of using inserted tool holders for lathe and planer work, thus saving the time of the men spent loafing in the blacksmith shop waiting for tools to be dressed. This firm also adopted the plan of grinding the tools to fixed angles, having one boy who did nothing else but collect tools, grind them while held in a suitable fixture, and return them to the men. In the same connection Mr. Porter says that in this shop he picked up the idea of the solid wrench having the sides of the jaws at an angle of 15 degrees with the handle, by which expedient it is possible to turn a hexagon nut in close quarters, as is now well known. Upon his return to the United States in the late "sixties," wrenches made on this plan were furnished with the Porter-Allen engines, and the J. H. Williams Co. soon commenced their manufacture here.

It is well known that water under pressure will leak through joints that appear (and are) perfectly tight with steam pressure. In the language of the pipe-fitter, steam pipe joints have the property of "taking up," that is, small leaks are self-sealing. Prof. Ewing calls attention to the fact that this property applies to superheated steam to a greater degree inasmuch as the presence of water of condensation is impossible, which is not the case with saturated steam. In the cylinder of a saturated steam engine in good condition there is always a certain amount of leakage past the piston and valves, represented almost entirely by the water of condensation which collects in films and slips by the closest fitting surfaces—in small quantities, it is true, but representing a vastly greater volume of steam. But with superheated steam this trouble vanishes since with a large ratio of expansion there is little or no cylinder condensation. This is not stating, however, that a whole troop of other mechanical troubles are not introduced, which are of much greater difficulty and importance.

Several years ago Mr. George Westinghouse, we believe, first called attention to the great increase of distance required for the stopping of high-speed trains after the brakes are applied, over the distance required for stopping trains running at ordinary speeds, say, 35 to 45 miles per hour. The distance required, with the same braking effect, is theoretically as the ratio of the squares of the two speeds. That is, if it requires a distance of 400 feet to bring a train running 40 miles an hour to a dead stop after the airbrakes are first applied, a distance four times as great, or 1,600 feet, would be required, theoretically, for the same train running at a speed of 80 miles an hour. Therefore we are not surprised to learn that in the high-speed tests on the Marienfelde-Zossen experimental railway the car ran fully a mile after the brakes were applied. The maximum speed was, it will be remembered, something over 130 miles per hour.

In dealing with slowly-moving mechanism, it is easy to determine by observation the exact motion of the different elements constituting the machine. At high speed this is less easy, and where cams are made use of for actuating certain parts, it is impossible to find out what happens at high speeds from observations made at low ones, since the inertia effects only become of importance when the speed is great. A method of observing the motions of rapidly-moving parts, such as, for instance, the opening and closing of the exhaust valve motion of a high-speed petrol motor was described by Professor Hospitalier at a recent meeting of the Paris Society of Civil Engineers. In principle the plan consists in illuminating the valve motion in question by flashes of intermittent light. If these flashes occur regularly at every cycle of the motor the valve gear will appear quite stationary, while if the periodicity of the flashes is slightly decreased, the motion will appear to run through its complete cycle, but at a very slow speed, and in so doing every vibration it makes will be clearly observable. An instrument specially designed for researches of the kind in question has been constructed for M. Hospitalier by Messrs. Malicet and Blin, of Paris.

In a paper read by Charles F. Burgess before the American Electrochemical Society at Niagara Falls, N. Y., September 18, 1903, he told how the passive state of iron is successfully used to permit the removal of spelter from the outside of brazed joints. Iron has the peculiar property of going into a passive state when employed as the anode in suitable electrolytes—sodium nitrate and other soluble nitrates being examples. When in the passive state the iron is no longer attacked by the anode products, the iron acting the same as an anode of platinum. This peculiar property has been only recently utilized for removing spelter, the demand for such a process having arisen with the "dip" process of brazing used in bicycle manufacture. In this process the joints of the frames are dipped into a crucible of melted spelter, covered with a suitable flux. The spelter not only enters the joint, but adheres to the exterior of the frame and has to be removed before the frame is enameled. The ordinary process is by laborious filing, but this is now being rapidly superseded by the electrolytic stripping process, the spelter being dissolved off in the bath without affecting the iron or steel frame. The process not only saves considerable labor, but avoids the danger of damaging thin tubing by file scratches, etc.

From the daily consular report No. 1802 we learn of a new armored concrete flooring manufactured in the shape of beams ready for use by three factories in Germany, three in Russia, and one in Italy, operating under the Siegwart patent; also by the Siegwart Beam Company of Lucerne, Switzerland. These beams are made hollow for the sake of lightness and generally have six iron rods ranging in size from .197 to .394 inch diameter, according to the size and span, imbedded in their walls. They have a uniform width of 9.84 inches and are made 3.5, 4.7, 5.9, 7.1, and 8.4 inches high, according to the span and load. The beams are not made singly, but in breadths of about 8 feet, which are cut up into slices before the cement has set, by means of a special machine. The hollow spaces are formed by iron cores so made that they may be contracted by turning a screw, and thus allow their easy removal after the concrete has partially hardened. The concrete is made in the proportion of one part of cement to four parts of coarse sand. In addition to being used for floors the Siegwart beams may be used for terraces, roofs, walls, pavements, etc. Being hollow they prevent excessive radiation of heat, making buildings warm in winter and cool in summer, and the hollow spaces may be used for hot air conduits if so desired.

RECORD FREIGHT RUN.

New York Central officials recently made public the running time of a freight train loaded with export cotton, which it was said holds the freight record between Montreal and New York. The train made the 435 miles between Valleyfield, Quebec, and New York in 16 hours and 20 minutes. Two hundred bales of Egyptian cotton were in store at Valleyfield, a few miles south of Montreal. They had been sold to Liverpool spinners and in order to make delivery it was necessary to get the cotton to New York within seventeen hours. One of the railroad traffic officials in speaking of this run said that it was significant in showing that the Canadian rail and ocean service was wholly inadequate in cases of emergency when certainty of delivery is important. From this it was maintained that the trunk lines are in absolutely no danger of losing their prestige to the Grand Trunk or the Canadian Pacific.—*New York Herald.*

THE MACHINIST MUST BE A SPECIALIST.

The writer was in a railroad repair shop recently when the division superintendent brought in a typewriter to be fixed—said it was out of kilter. The foreman looked at it, struck a key or two, and remarked: "I don't know much about these things." "Why," exclaimed the superintendent, "you have the reputation of being the best mechanic on the road; I thought you were just the man." The foreman turned to the speaker and said: "I am a locomotive repair machinist, and have carefully studied it for fifteen years; if you will bring me any job on a locomotive that I cannot do that any other mechanic can, I will resign, but life is too short for a man to spread himself out so thin as to attempt to be familiar with all classes of machinery. There are men who make a specialty of typewriters, as I do of locomotives. They can repair that machine in half the time, for half the money, and twice as well as I can. I would be as foolish to attempt to put new letters on that machine as the maker of typewriters would be to put a new tire on a locomotive."—*Railway and Locomotive Engineering.*

THE BAND SAW IS AN ENGLISH INVENTION.

The well-known English author of several books on wood-working machinery, Mr. M. Powis Bale, of London, takes issue with the *Timber Trades Journal* of the same city regarding the invention of the band saw, which was attributed by that publication to a Frenchman. He says:

"I notice that the invention of the band saw is attributed to M. Perin, of Paris. This is an error, as it was really the invention of an Englishman—one William Newberry, who, in 1808, patented a machine for sawing wood, in which an endless band or ribbon saw strung over two wheels was used. Owing to the difficulty, however, of obtaining saw blades that would withstand the strain put on them, the machine remained in abeyance for many years, till M. Perin, about 1855, introduced a much improved machine on which he used specially-tempered saw blades of French manufacture, and thus made the machine a practical commercial success. The early history of wood-working machinery is extremely interesting, and I would draw your attention to the marvelous patent specifications of Sir Samuel Bentham in 1791 and 1793, as they are truly remarkable examples of inventive genius, and fully illustrate the old adage, 'There is nothing new under the sun.' In these specifications the principles involved in many of the most important wood-working machines at present in use are claimed and set forth in the clearest and tersest manner, including planing machines with rotary cutters to cut on several sides of the wood at once, veneer cutting machine, horizontal saws, molding and recessing machine, bevel sawing machine, saw sharpening machine, tenon cutting by means of saws, and many kinds of rotary and boring tools. Well may the disappointed inventor say, 'Those beastly ancients have cribbed all our best ideas.'"

ELASTICITY OF CAST IRON PISTON RINGS.

A somewhat elaborate paper on cast iron for piston rings was read by Mr. C. H. Wingfield before the British Association, September 16, in which he referred to what we infer is a generally well-known fact, and that is, that cast iron is not initially elastic, but becomes so only after it has received a permanent set. That is, any ordinary piece of cast iron when placed under a bending stress for the first time, does not return to its original shape when the load is removed, but suffers a permanent change of form. After the permanent set has been given it, however, cast iron is perfectly elastic within limits. Mr. Wingfield made experiments on piston packing of the class having an inner and outer ring, the outer being turned to same diameter as the cylinder bore and the inner ring turned to a larger diameter than the bore of the outer ring. These inner rings were made 5.236 to 5.728 inches diameter, and had sections cut out so that they could be pushed into a ring gage 5.039 inches diameter, to determine the amount of permanent set and the "follow" (reduction in diameter) of the ring. He was surprised to find that a ring 5.236 inches diameter having a section 1½ inches cut out, could be bent until the ends met without fracture and that they would spring back to within ⅜ inch of their original position an indefinite number of times without taking any further permanent set. He found that some time was required of the rings pushed within the ring gage before the maximum permanent set was acquired. For example, the follow in the case of a ring 5.433 inches diameter was .396 inch before being pressed into the ring; after being in the ring one minute, it was .291 inch; after fifteen minutes, .287; after forty minutes, .280 inch; and after forty-eight hours, .275 inch.

In this connection it may be mentioned as a matter of interest and possibly of news to some, that cast-iron packing rings often show a wonderful increase of flexibility (not elasticity) with use. The editor has repeatedly tested certain old cast-iron packing rings used in locomotive cylinders, say 20 inches diameter, by placing a foot on one end and pulling the other end of the ring upward in a direction parallel to its axis, to the level of his shoulder—he is not a short man—before it fractured. In such cases the observers would almost invariably declare that the ring must be made of wrought iron so great was its flexibility, but such was not the case in any instance, as was easily discerned from appearance of the fractures.

MOUSE POWER.

In these days of 12,000-horse power stationary steam engines, 100,000-horse power central stations, and 1,000,000-horse power Niagara development (near prospective), it is somewhat difficult to appreciate the scarcity less than one hundred years ago and the shifts made to gain that which more than anything else has made present civilization possible—power. The following remarkable item published by the *Scotsmen* and copied by the *Tradesman*, to whom we are indebted, may be an exaggeration, but it undoubtedly records one of the schemes seriously contemplated for operating machinery:

"About the year 1820 this gentleman actually erected a small mill at Dunfermline for the manufacture of thread—a mill worked entirely by mice. It was while visiting Perth prison in 1812 that Mr. Hatton first conceived this remarkable idea of utilizing mice power. In an old pamphlet of the time, 'The Curiosity Coffee Room,' he gave an account of the way in which the idea dawned on him. 'In the summer of the year 1812,' he wrote, 'I had occasion to be in Perth, and, when inspecting the toys and trinkets that were manufactured by the French prisoners in the depot there, my attention was involuntarily attracted by a little toy house with a wheel in the gable of it that was running rapidly round, impelled by the insignificant gravity of a common house mouse. For a shilling, I purchased house, mouse and wheel. Inclosing it in a handkerchief, on my journey homeward I was compelled to contemplate its favorite amusement. But how to apply half-ounce power, which is the weight of a mouse, to a useful purpose was a difficulty. At length the manufacturing of sewing thread seemed the most practicable.' Mr. Hatton had one mouse that ran the amazing distance of eighteen miles a day, but he proved than an ordinary mouse could run ten and one-half miles on an average. A half-penny's worth of oatmeal was sufficient for its support for thirty-five days, during which it ran 736 miles. He had actually two mice constantly employed in the making of sewing thread for more than a year. The mouse thread mill was so constructed that the common house mouse was enabled to make atonement to society for past offenses by twisting, twining and reeling from 100 to 120 threads a day, Sundays not excepted. To perform this task, the little pedestrian had to run ten and one-half miles, and this journey it performed with ease every day. A half-penny's worth of oatmeal served one of these thread mill culprits for the long period of five weeks. In that time it made 3,350 threads of twenty-five inches, and as a penny was paid to women for every hank made in the ordinary way, the mouse, at that rate, earned 5 pence a day, or 7 shillings and 6 pence a year. Taking 6 pence off for board and allowing 1 shilling for machinery, there was a clear yearly profit from each mouse of 6 shillings. Mr. Hatton firmly intended to apply for the loan of the old empty cathedral in Dunfermline, which would have held, he calculated, 10,000 mouse mills, sufficient room being left for keepers and some hundreds of spectators. Death, however, overtook the inventor before his marvelous project could be carried out."

EXPERIMENTS TO DETERMINE THE AIR FRICTION OF DISKS.

Abstract of Paper read by William Odell before the British Association at Southport, September, 1903. Electrical Review (London), September 25, 1903, p. 490.

The experiments were made with the object of finding a convenient method of determining the power wasted by air friction or windage of flywheels, armatures, etc. They were made with paper disks mounted on the shaft of an electric motor. The excitation being kept constant, the torque was proportional to the current. Thus the extra current required to keep up the speed after the disk was fixed on the shaft, gave the power absorbed by air friction.

There was found to be an angular speed for each disk above which the torque was accurately proportional to about 2.5 power of the speed. This critical speed appeared to vary inversely as the square of the diameter. Below it the law followed was of a lower degree; but owing to the multiplication of errors of measurement no definite conclusion as to its exact nature was arrived at.

As the three disks originally tried gave uncertain results as to the effects of size, a much larger one, nearly 4 feet in diameter, was also tried; and as a result of all the experiments it was concluded that the torque varies as about the 5.5 power of the diameter.

To give an idea of the amount of power thus absorbed, it may be stated that a disk of 47 inches required 1-10 horse power to keep up a constant speed of 500 revolutions per minute, and that if the above law holds, a 9-foot disk would absorb 10 horse power at the same speed.

STANDARDIZING MACHINE TOOL PARTS.

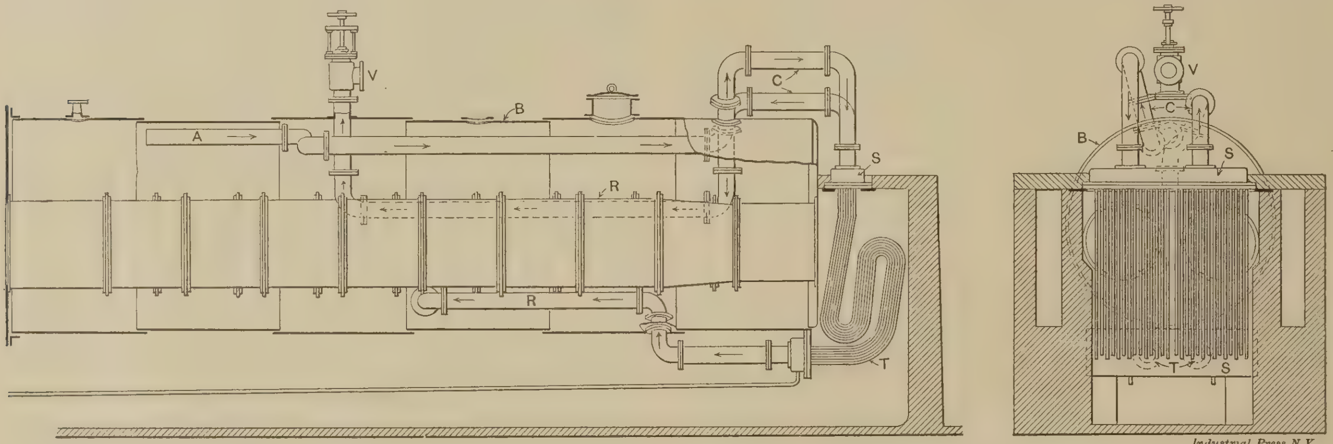
Extract from Paper read by Mr. William Lodge before the New York Meeting of the National Machine Tool Builders' Association, November 10, 1903.

It would be to the interest of this association, if it could possibly be brought about, that some standard be adopted. Why may not all manufacturers of machine tools have the same size of general bearings, the same size of nose for the lathe spindles for the different sizes of lathes, so that our customers may find it easy to transfer faceplates, chucks, and tools from one machine to another, irrespective of who may have been the manufacturer. If this matter can be brought about we shall be the first country to have adopted a uniformity. This would be a most important matter, not only to ourselves but to the men to whom we sell, and it would, at least, have the effect in foreign countries of securing preference for American tools, because of their interchangeability at certain points and because of their uniformity in weight and power. I do not advocate uniformity in the design of the machines throughout, and I know it is utterly impossible to secure uniformity in the quality of the work put into the machines but it will be of great assistance to incorporate the features mentioned wherever possible. If the salesmen for the different houses were attempting to get trade in either Europe, Asia or Africa, and the statement could be made that chucks and tools could be interchanged from one machine to another, no matter who the maker was, it would be bound to result in a preference for American goods. As we are all likely to have to make new designs, it would be well if it were possible to bring about this interchangeability. Would it not also be well to establish uniform widths and diameters for countershaft pulleys and for the countershaft itself, because these vary so much as to appear ridiculous at times?

APPLICATION OF AIR BRAKES TO THE TRUCKS OF LOCOMOTIVES ON THE STATE RAILWAY OF BELGIUM.

Bulletin of the Railway Congress, June, 1903, p. 589.

The management of the State railways of Belgium have realized the advantages to be obtained by the application of brake-shoes to the wheels of bogie trucks on locomotives. Heretofore, shoes operated by the Westinghouse brake have only been applied to the driving wheels of locomotives. An arrangement designed by the motive power department has just been tested on a four-coupled engine. Several months of service have shown that this supplementary braking on the locomotives makes it possible to secure a very material reduction in the distances needed in which to stop trains. Further tests are in progress in order to determine the time advantage that can thus be obtained at different speeds upon the several lines of the State railways. G. L. F.



Industrial Press, N.Y.

Elevation and End View of a Boiler Fitted with McPhail & Simpsons Superheater.

SUPERHEATED STEAM FOR STEAM ENGINES.

Cassier's Magazine, November, 1903, p. 18.

The weight of steam used per indicated horse power is materially less when the steam is superheated than when saturated steam of the same pressure is used. If the consumption be taken as 100 for saturated steam, it will be roughly as given in the following table, when superheated. In other words, each 50 deg. of superheat in a reciprocating engine reduces the former consumption by about 10 per cent., and by 5 per cent. in the case of a turbine, which is in inverse proportion to the volume of the steam or to the absolute temperature. This must be taken only as a rough approximation, but it nevertheless, agrees tolerably well with the results of experiment.

Superheat at the Engine.	Consumption.	
	Turbine.	Reciprocating Engine.
...	100	100
50° F.	95	90
100° F.	90	81
150° F.	86	73
200° F.	81	66
250° F.	77	60
300° F.	73	53
350° F.	69	48
400° F.	66	44

This economy is largely due to the fact that the temperature of superheated steam is considerably above its saturation or condensing point; consequently when it enters a cylinder cooler than itself and its temperature is thereby reduced, the usual cylinder condensation does not take place until the temperature is reduced to that of saturation. Cylinder condensation is, therefore, largely reduced, and if the superheat be sufficiently great, the condensation may be entirely overcome.

The decreased steam consumption is due also to the fact that the volume of the steam is increased by the superheating in amount almost proportional to the absolute temperatures before and after superheating. Since its capacity for doing work at any given pressure varies almost directly as its volume, it follows that a given weight of steam has a greater capacity for doing work when occupying a greater volume than before; consequently a smaller weight of steam is required to do a given amount of work. A minor advantage, apart from the question of economy, is that the steam supplied to the engine is perfectly dry when it is superheated, and the dangers of priming are thus avoided. Now that so many water-tube boilers are used which nearly always prime badly when forced, the question of getting dry steam, especially with high speed engines, is becoming one of very great importance.

The disadvantages of highly superheated steam are that the steam not only supplies no water of condensation to lubricate the rubbing surfaces of the valves and cylinders, but it decomposes many of the oils that are fed into the cylinder for lubricating purposes; hence the valve faces, cylinders, and pistons are liable to become badly scored; also, the gland packing not infrequently is burnt or melted out.

It must, however, be remembered that these are troubles which arise only when high degrees of superheat are adopted. Thus, in order to get some of the benefit to be derived from superheating without experiencing the troubles mentioned above, it is necessary, under ordinary circumstances for power purposes, to use only very moderate degrees of superheat, say 100 degs. F. This, however, is a difficult matter to accomplish, unless a special regulator or modifier be used to keep the superheat within any given limits. With many of the superheaters in common use, it will vary a hundred degrees or more in a very few minutes unless it be very carefully watched.

When considering the disadvantages of superheating, the fact must not be overlooked that in a great many cases the superheater tubes have been known to burn out. The burning away of the superheater tubes has occurred in most cases where flooding arrangements have been used, as a deal of scum and scale is carried into the tubes with the water, and if the flooding is frequently indulged in, the tubes, in time, get choked up, with the inevitable result that they burn out, thereby making the wear and tear an important item, as compared with the reduced coal bill. Again, it must not be forgotten that superheaters which are not furnished with a device for regulating the temperature become a source of trouble and expense if neglected.

The McPhail & Simpsons superheater, says the writer, Mr. John Goodman, has been designed with the express purpose of overcoming most of the disadvantages enumerated above, primarily by producing superheated steam at a controlled and constant temperature, and, further, by utilizing more of the heat of the escaping gases than can be accomplished by ordinary economizers and feed heaters.

The apparatus in one style consists of superheater tubes *T* connected together by top and bottom boxes *S*, which are divided into two compartments; connections to and from the superheater *C*; radiating pipes in the water space of the boiler *R*; and anti-priming pipe *A*. The steam passes from the anti-priming pipe *A* to the connecting pipes *C*, and thence through the first compartment of the top box and through the first nest of superheater tubes to the first compartment of the bottom box and into the radiating pipes *R*, which are placed in the water space of the boiler below the fire flues. It then passes out of the boiler again into the second compartment of the bottom box and up through the second nest of superheater tubes to the second compartment of the top box, and, by connections *C*, into the radiating pipes *R*, placed in the water space above the fire flues, and leaving the boiler at the stop valve. It will be observed that the steam is superheated twice and carried into the boiler twice, where it gives up a part of its surcharged heat each time to the water in the boiler, thereby assisting evaporation, the steam leaving the stop valve at a controlled and constant temperature. This apparatus is constructed of steel throughout. The superheater tubes are of cold, solid-drawn steel. The tube-plate is of rolled mild steel, 1¾ inches thick, and the boxes are of rolled mild steel plate, dished.

MONEY VALUE OF TRAINING.

Abstract of Paper read by Mr. James M. Dodge before the Williamsom Trade School of Philadelphia, March 1903.
From St. Nicholas Magazine.

When the trade guilds were in active existence in England and this country up to 1850 they gave thorough instruction to apprentices in the various crafts. A shoemaker's apprentice, besides learning how to make boots and shoes, might also learn to tan skins, make thread and wax, carve his lasts, build his own furniture, and, in fact, produce from the raw material everything required for the prosecution of his calling. But with the decline of the guilds, due to the introduction of labor-saving machinery, the opportunities for learning a trade dwindled away. Generally speaking, there are now few opportunities for a young man to acquire the trade of a machinist in the shops of this country. In the first place the establishments are frequently so large that an individual is entirely lost sight of. If he does the special line of work assigned him, he is allowed to remain in one place indefinitely. Frequently the training of years in one shop will not enable a man to get employment at good wages in another. The trade unions have not filled the place of the guilds in this respect; they pay no attention to the training of apprentices or otherwise recognize them, beyond limiting so far as possible the number that shall be employed. The attitude of the trade unions to apprentices is purely "negative."

In years gone by the apprentice was trained in a large range of duty incident to the work of a machinist, in a broad sense; but there is no longer in the machinist trade true apprenticeship. We believe that a month in a good trade school is worth a year in a large shop, so far as the matter of training in first principles is concerned. Of trade schools locally we have some splendid examples—the Drexel Institute, the Williamson Trade School, the manual training school, and others. But scattered over the country are schools of this character which undoubtedly will grow more rapidly than any educational institutions of the past.

It has been said that a three years' course in a trade school, in which an average of but a few hours a day is devoted to actual manual work, can in no way compare with three years' time spent in actual work in a shop. This is felt to be a popular error. In shop work a man may spend months in repetition of the same task, to no ultimate advantage to the worker. Instead of his skill being quickened it is dulled. He very quickly acquires the skill which is unconscious in its operation, and, like the old lady with her knitting needle, he can talk to a fellow-workman or think and dream about far distant places and matter without in any way lessening the rate of production. In fact, sometimes his pace might be actually quickened by some mental emotion having an exciting effect upon his nervous organization, in the same way that the old lady, in chatting with her friends, will knit fast or slow in harmony with the dullness or animation of the conversation. It is quite obvious that repetitive routine work is not desirable for a young man of natural ambition and aptitude. In the trade school he escapes routine, but is instructed in the underlying principles of his work, and does enough manual labor to familiarize himself with the various tools required and tend to prove the correctness of the theories in which he has been instructed.

The trade school training is one decidedly tending toward individualism. Its boys, as a rule, do not come from the wealthier classes. There is earnestness of purpose, and the records show that the percentage of failure to pass satisfactorily through the course is exceedingly small. In opposition to this, it not infrequently happens in our larger universities of learning that less than one-half of those entering the freshman classes graduate. Not more than 5 per cent. of the boys entering the trade schools fail to complete the course satisfactorily, and the tasks set are no less exacting than those in our large colleges and universities. This may be attributed to the fact that no boy enters a trade school without a positive determination to complete the course and be thankful for the opportunity. None are forced to go through the ambition of their parents, because, as a rule, the decision to send a boy to one of the trade schools is a serious sacrifice on the part of his family. In the trade school the boy is impressed with the idea that his first day there is the beginning of his career. In our larger institutions the day after commencement is looked upon as the beginning of the career. This is a very important distinction. Again, in entering the trade school a boy has already made up his mind what his life work is to be. In the majority of cases, boys entering our universities have no clearly defined idea of their future work after graduation. As a result, the trade school boy can directly apply the training he has received toward increasing his value to his employer and himself.

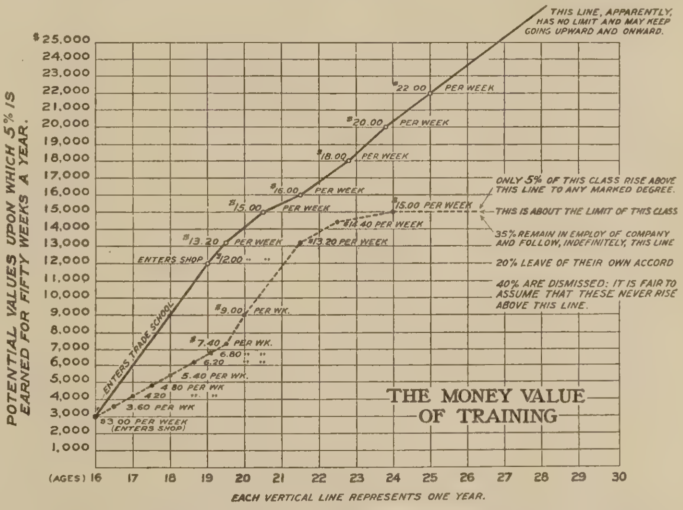


Diagram giving Curves showing the Comparative Value of Trade-school and Shop-trained Boys. Curves Plotted from Records of two Groups of twenty-four Boys each.

Now for a comparison of values of the trade school boy and the shop trained boy. The boy of sixteen who is tired of going to the day school thinks he will learn a trade. His father does not oppose his leaving school perhaps because he thinks, from his own experience, that the boy has enough "schooling." The boy naturally selects some trade because he sees all about him the relatively affluent position of the men working at trades and those who are simply laborers. Say he obtains employment in a machine shop where he will receive about $3 per week, this being, we will say, $150 per year, or 5 per cent. on $3,000. The dotted curve in the diagram shows his probable money value up to 26 years, beyond which age only about 5 per cent. increase their earning capacity. The full line shows the probable earning capacity of the trade school boy, and its upward tendency apparently has no limit. This diagram was plotted from two groups of twenty-four boys each, or forty-eight in all, one-half entering the trade school and the others going directly into the shop.

The untrained boy in three years has increased his earning power from $3 per week to $6.80, and the Williamson School boy in traversing the line between his entrance and graduation crosses the $6.80 line after he has been in the school a year and three months. In other words, he has gained almost two years on the boy who entered the shop with the idea that school training was an unnecessary waste of time. It is quite evident, therefore, that time has been lost, and not gained, by entering the shop without training. Roughly, this holds true indefinitely. While the two lines run along parallel or substantially so, say for the next four or five years, the time element is always in favor of the trained boy, and that in a very few years he is leaving his less fortunate brother well to the rear.

From the age of 20 to 21½, or for 18 months, if the untrained boy continues to do his work well, it will be seen, by reference to the chart, that his line has continued running more toward the vertical than it did from the time he was 16 until he was 19½. Now the experience which he received during the formative period is beginning to make itself very manifest. He becomes more useful as an all-around man, and his rate is increased to $13.20 per week. Carried back to the left, we find that his potential value is working upward toward $14,000. A year later, or taking the age 22½, his wage has been increased to $14.40 per week. Again we see his potential value has gone up beyond $14,000. For the next 18 months he continues in substantially the same line, and at 24 years of age is earning $15 per week, and his potential value is $15,000. In other words, he has increased his potential value $12,000, and draws the interest on his investment in instalments once a week, and is earning 5 per cent. on his accumulated value.

We find that only 5 per cent. of this class rise above this line to any marked degree. Thirty-five per cent. remain in the employ of the company and follow the line indefinitely. Twenty per cent. leave of their own accord, but with good records behind them (so that probably the same statistics would apply to them also—that is, 5 per cent. of them may rise above the line and 35 per cent. of them follow the line in other establishments). Forty per cent. are dismissed, and it is fair to assume that these never rise above the line. They are not dismissed at the age of 26, but fall by the wayside, unable to keep pace with the march of progress.

We will now turn to the group who have entered the trade school. Starting again at the potential value of $3,000 for the boys of 16 years of age, we will follow the course of an individual, representing the average of his companions. The first noticeable thing is that for three years, starting from the age of 16 and terminating on the line representing 19 years, he is in school; and instead of having his wage-rate dotted along at intervals of 6 months, as in the case of the boy entering a shop without the trade school training, we find no rates at all, and we feel justified in making this line perfectly straight, with the first money entry made upon it at the time of his graduation, at the age of 19, and entering upon his employment. We now find a most interesting state of affairs. He is employed at the rate of $12 per week, this representing a potential value of $12,000, or an increase *during his school term* of $9,000, or an average of $3,000 per annum. During the same term the untrained boy has reached a potential of $7,000 at the same age; in other words, the trained boy has a $5,000 start at the same age. Again, the untrained boy's line crosses the $12,000 potential line at a point which indicates that he is 21 years of age. In other words, the trained boy has $5,000 advantage at the same age, and has two years running start on the boy who has not had the same training. Now, what does he do in the next two years? To follow along his career, it will be noted that in six months his rate has been increased to $13.20 per week. One year later, or at the age of 20½, he has reached $15 per week. The untrained man is now 24 years old and earning the same wage, but his line of progress is running more nearly parallel with the horizontal line than that of the trained man. Six months later, at the age of 21½, they part company quite decidedly, the untrained man's line running off horizontally to the right, whereas the line of the trained man is progressing onward and upward, at substantially the same angle it has shown since the time of his entrance to the trade school. Why is it possible for these two men thus to part company? It is because the untrained man can increase his rate only by remaining as a working machinist in a shop. The trained man has substantially mastered all that the untrained man has, so far as his actual labor is concerned, but he has within him other possibilities. He can now apply in a combined manner his theoretical and his practical training, becoming a leading man, possibly a foreman or a draftsman. It is now that this, his better knowledge, coupled with his intellectual improvement, makes itself most manifest. His rate at the age of 21½ is $16 per week; his potential value $16,000. Fourteen months later we find him earning $18 per week; ten months later $20 per week; and in another year, or at the age of 25, he is earning $22 per week—a rate practically unattainable by the untrained man. Five per cent. of the untrained—those having decided genius and a faculty of improving their minds and increasing their theoretical knowledge, courage enough to take courses in the correspondence schools or obtain instruction in the evenings—rise to his class, and it is not impossible that in very rare instances would do as well through their future life. A trained man at 25 years of age has a potential value of $22,000, or in nine years he has increased his value $19,000, or at the rate of $2,100 per annum, as compared with $1,300 per annum for the untrained man, and with this manifest additional advantage over the untrained man—that his line has no limitation, so far as we can see.

THEORETICAL EFFICIENCY OF WORM GEARING AND TESTS OF SAME.

Page's Magazine, November, 1903, p. 428.

Worm gearing differs from most other forms—belting, spur gearing, etc., in that it requires very accurate design and manufacture to be efficient. It has always been more or less under a cloud on account of bad examples of the gear which have been set to work. Several firms, however, amongst whom may be mentioned the Oerlikon Company have consistently stood by the gear, and by turning out good work have helped materially to win for it the position it now holds as one of the best mediums for electric motor driving. One of the distinct advantages of the gear is its *noiselessness*, and this undoubtedly has a money value. As there still exists a certain amount of mistrust as to the efficiency, it may be of interest to give some figures obtained by the Oerlikon Company.

TABLE GIVING THEORETICAL EFFICIENCY OF WORM GEARING.

Coefficient of Friction.	ANGLE OF INCLINATION.								
	5 deg.	10 deg.	15 deg	20 deg.	25 deg.	30 deg.	35 deg.	40 deg	45 deg
0.01	89.7	94.5	96.1	97.0	97.4	97.7	97.9	98.0	98.0
0.02	81.3	89.5	92.6	94.1	95.0	95.5	95.9	96.0	96.1
0.03	74.3	85.0	89.2	91.4	92.7	93.4	93.9	94.1	94.2
0.04	68.4	80.9	86.1	88.8	90.4	91.4	92.0	92.2	92.3
0.05	63.4	77.2	83.1	86.3	88.2	89.4	90.1	90.4	90.5
0.06	59.0	73.8	80.4	84.0	86.1	87.5	88.2	88.6	88.7
0.07	55.2	70.7	77.8	81.7	84.1	85.6	86.4	86.9	86.9
0.08	51.9	67.8	75.4	79.6	82.2	83.8	84.7	85.2	85.2
0.09	48.9	65.2	73.1	77.6	80.3	82.0	83.0	83.5	83.5
0.10	46.3	62.7	70.9	75.6	78.5	80.3	81.4	81.9	81.8

The efficiency increases with the angle of inclination up to a certain point, and with the smallness of the coefficient of friction, and knowing these two factors it is possible to calculate the theoretical efficiency as shown in the table. Experience shows that for larger angles of inclination than 25 degrees to 30 degrees the efficiency increases very little, especially if the coefficient of friction is small, and this fact is of importance in practice, because, for reasons of gear ratio and conditions of a constructive nature an angle greater than 30 degrees cannot be employed. The coefficient of friction increases with the load and diminishes to a certain extent with increase of speed. Besides the friction between the worm and the wheel teeth there is also the friction of the spindle bearings and the ball bearings for taking the axial thrust. To obtain the best results, there must be very careful choice of dimensions of teeth, of the stress between them, and the angle of inclination. Also the most accurate workmanship in which the hardening of the worms without any consequent retouching, forms an important part. To show what can be done, the following are the results of a test with an Oerlikon worm gear for a colliery winding engine: The motor gave 30 brake horse power to 40 brake horse power at 780 revolutions. The normal load was 25 brake horse power, but at starting it can develop 40 brake horse power. The worm gear ratio is 13.6 to 1, the helicoidal bronze wheel having 68 teeth on a pitch circle of 7.283 inches and the worm 5 threads. The power required at no load for the whole of the gear was 520 watts, corresponding to 2.8 per cent. of the normal. The efficiency at one-third normal load gave 90 per cent., at full load 94½, and at 50 per cent. overload 93 per cent. The efficiency of the *worm and wheel alone* is higher, and knowing the no load power, it calculates out at 97½ per cent. According to the above table of theoretical efficiencies this gives the coefficient of friction as 0.01. To obtain a reduction of 13.6 to 1 with spur gear would have necessitated two pinions and two wheels with their spindles and bearings, and if the bearing friction was taken into consideration the efficiency of such gearing would certainly not have reached the above-mentioned figure of 94½ per cent. at full load.

LOCOMOTIVE INJECTOR OPERATED BY EXHAUST STEAM

Fielden's Magazine, November, 1903, p. 422.

In locomotive feed-water injection it is highly desirable that the temperature of delivery be the highest degree attainable at which the injector will work without breaking. If this heat can be abstracted from the exhaust without increasing the back pressure it is apparent that an economy will result. While the ordinary type of high-pressure steam injector will not work satisfactorily when the supply water in the tender is even moderately warm, the exhaust steam injector made by Davies & Metcalfe, Manchester, it is claimed, in connection with the supplementary apparatus, will deliver water to the boiler at a temperature of 270 degrees F. Thus, while it is not feasible to utilize the heat of the exhaust to warm the supply water with the ordinary injector to any extent, it is possible with the exhaust steam injector to use a considerable portion of it and to deliver the water in a large volume at so high a temperature that it cannot have a bad effect upon the plates or tubes.

British Locomotive Exhaust Steam Injector.

The exhaust pipe, *A*, is tapped near its base for the steam supply. A grease extractor, *B*, is provided to remove the oil and water of condensation. From thence the steam passes into the exhaust injector, *C*, which, of course, is of the non-lifting type, being located beneath the foot-plate. But because of its weak forcing power it is necessary to provide the supplementary injector, *D*, to take the water from the exhaust injector—which it does at a temperature of 200 degrees and a pressure of about 70 pounds—and deliver it to the boiler, which it does at a temperature of 270 degrees as stated. A wing valve, *E*, is provided in the exhaust pipe between the oil separator and the first injector which may be closed, and a live steam valve opened to work the injector when the locomotive is standing idle.

It is stated that the firm making these injectors have applied a large number of them to locomotives on various English railways, and that they are working successfully.

ELECTRICITY IN MANUFACTURING PLANTS.

Abstract of Paper by Walter M. McFarland before the Society of Naval Architects and Marine Engineers.

In considering the relative merits of alternating and direct-current for motor driving, it is the writer's opinion that if the induction motor had been the first to enter the field there probably would have been no room for argument, because its merits are so great that there would have been little incentive to develop anything else. It happened, however, that although alternating current was the first, as it is the natural product of any machine without special commutating devices, it was some time before a commercially practicable alternating current motor appeared, and the direct current motor, being first in the field and being undoubtedly meritorious, acquired the vogue which always comes to that with which people are familiar.

Mechanically the induction motor appeals at once to every practical man as the better device. The coils of wire are entirely stationary, while the rotating part consists of disks of sheet steel enclosed by massive composition end rings, which latter are connected by stout bars of copper bedded in slots in the steel sheets. The direct current motor, on the contrary, has its coils movable as well as stationary, and, while these do not often give trouble, they are not so simple and mechanical as the rotating part of an induction motor. The direct current motor has an additional feature which is entirely absent in the alternating current motor—the commutator and brush holder. These are the parts requiring most attention and the ones most liable to give trouble, although the modern methods of design and manufacture have reduced this to a minimum. The efficiency of the induction motor is fully equal to that of the direct current motor and indeed is slightly better over most of its range of capacity.

Thus far it might seem that everything is so greatly in favor of the induction motor that there could be no room for choice; but this type has one defect, namely, it is a constant speed motor, and many of the foremost advocates of individual tool driving want a motor whose speed can be varied through a wide range. While it is entirely possible to make an induction motor whose speed can be varied, the extreme simplicity of the first type is lost on account of the slip rings, which are used to enable the variable speed to be obtained by throwing resistance into the circuit. These, while not so liable to derangement as the commutator of a direct current machine, do add a slight additional complication. Before going on to explain some of the different methods by which variable speed is obtained with direct current motors, it may be mentioned that in the New York Shipbuilding Company and also in the steam engineering plant at the Brooklyn Navy Yard, the simplest type of induction motor is used, and the variable speed is obtained by means of belts and cone pulleys. In the opinion of the writer this method is entirely satisfactory and gives an adequate range of speeds with extreme simplicity.

It may be well to mention, in speaking of direct current motors, that apart from crane service, the type of motor almost universally used in industrial plants is the shunt motor, so called because the field circuit is a shunt from that of the armature. The shunt motor is inherently self-regulating, and within moderate limits the speed remains constant without regard to the load coming upon it. One of the simplest methods of varying the speed is by varying the field strength, which can be done by introducing a suitable rheostat in the field circuit, and as only a small portion of the current goes through this circuit anyhow, the loss is immaterial. The speed can also be varied by introducing resistance in the armature circuit to cut down the E. M. F. acting upon the armature, but this is objectionable on account of the large amount of energy wasted as heat in the resistance.

Another method which has been used with decided success and simplicity is the three-wire system from a single generator in connection with field regulation, which enables the speed of the motor to be varied sufficiently to meet all practical purposes. The three-wire system is obtained by utilizing a special generator somewhat resembling a rotary converter; that is, in addition to the brushes and commutator furnishing direct current, leads are brought out from the armature winding to two or more slip rings placed upon the armature shaft. From these slip rings alternating current is taken, and if this is passed through an auto-transformer, and a lead is tapped from the middle of the transformer coil, this lead will always have a potential midway between that of the terminals on the direct side of the machine, thus securing at the motor two voltages, one equal to twice the other. By field regulation the speed can be varied through a ratio of about one to three, so that with this variation combined with the two voltages of the three-wire system we get a range of six speeds, which, in general, will be amply sufficient.

Another system, known as the multi-voltage system, has also been used to some extent with direct current motors, consisting of a number of circuits working at different voltages. Suppose that, commencing with a negative wire, the voltage rises to 60 at the second wire, 140 at the third, and 250 at the fourth, thus giving intervals of 60, 80 and 110 volts. It is obvious that we can get any of the three voltages by the intervals, and by varying the wires we can get in all six voltages. If the field of the motor is constantly excited at, say, 250 volts, the several voltages applied to the armature will give as many different speeds, and the gaps between may be filled in by slightly varying the field excitation. The objection to this system is the complication of the generating apparatus and of the wiring.

Still another system is that called after the name of its inventor, the Ward-Leonard system, which depends upon supplying a current of varying voltage to the motor by varying the field strength of the generator, the field of the motor being constantly excited from an independent constant potential circuit. This is the system employed for turret turning on board naval vessels, where it has worked very successfully, and it was described in detail some years ago in a paper before the Society, so that we need not go into it further here. It will be seen that the objection to this system is its enormous complication when attempting to apply it to so large a number of motors as would be found in a manufacturing establishment.

An advantage of the induction motor is that from its construction there is no danger from a short circuit, because the bars in the rotating part are purposely short-circuited. Further, this motor will stand being brought to a full stop for a moment with the full current upon it without any resulting damage, while such an occurrence with a direct current motor would certainly burn out the insulation, if not doing still greater damage. As a result of this it is not necessary to fit circuit breakers or fuses to take care of these motors. In the small sizes the motor can be started up by simply closing the circuit by means of an ordinary switch, and in the larger sizes practically the same thing is done, as a two-throw switch is used in connection with an auto-starter, which is simply a small transformer arranged to give half the line voltage in starting up. The object is not so much the protection of the motor itself as to avoid the demand for a large amount of current from the generating system, as the starting current without the transformer would be somewhat more than twice full-load current. In the case of the direct current motor it is, of course, necessary to start through the rheostat, so that the full voltage only comes on when the motor is up to speed.

In regard to individual and group driving some engineers go so far as to say that they would have a motor for each tool, even if it involved going to sizes as small as one-quarter horse power, but the writer is inclined to believe that the judgment of more conservative engineers is favorable to individual driving where the power required will be, say, from five to ten horse power and upwards, and for group driving where the individual tools would require less than those amounts. In any large plant there are numerous small tools, such as drill presses, screw-cutting machines, light lathes, etc., which are in any case located together, and where it is perfectly easy to drive them as a group. The average power required for such a group will be quite uniform, and when they are group driven a moderate sized motor, with its relatively high efficiency, can be used with a fairly steady load, thus contributing to the efficiency of the general system, as well as of the particular group, and materially reducing the first cost of the installation.

ACETONE AS AN ABSORBENT OF ACETYLENE GAS UNDER PRESSURE.

Extract from Paper read by Mr. E. G. Fisher before the International Acetylene Association at Chicago.

In 1896 Messrs. Claude and Hess, two French engineers, conceived the idea of utilizing some liquid as a solvent of acetylene, and after many experiments discovered that acetone (a limpid, mobile liquid, with an agreeable odor and burning taste, produced by the destructive distillation of acetates, and procured on a large scale from the aqueous liquid obtained in the dry distillation of wood) has the property of absorbing many times its volume of acetylene gas. This property varies greatly with the pressure and temperature under which the acetylene is applied; the acetone will again release the gas absorbed under pressure, when the pressure is removed. Acetylene dissolved in acetone is inexplosive, as has been shown by Messrs. Berthelot and Vielle, French chemists. It is an inert liquid, so that if an explosion be intentionally produced in the compressed gas outside or above the solution, the solution would not be affected thereby. Thus, if a red-hot wire were inserted into a tank containing acetylene dissolved in acetone, under a pressure of 240 pounds per square inch, the small quantity of gas that exists above the liquid would explode, but the liquid would not be influenced in the least. This was a long stride in the direction of safely transporting acetylene, but absolute safety is demanded in a gas-lighting system, especially for transportation, and it was Edward Fouche, another Frenchman, who conceived the idea of packing the gas cylinders with an absorbent or porous material, thereby filling the entire air space—except, of course, the small cells in the porous brick or asbestos—then introducing sufficient acetone into the tank to moisten the cell walls of the porous brick or asbestos. This has been proved to make an absolutely safe structure for storing and transporting acetylene in small or large quantities.

Acetylene gas absorbed in acetone is now being safely and efficiently used for railway car lighting, having decided advantages over the Pintsch gas system both in efficiency and in manufacture. The ability to transport acetylene safely while under heavy pressure gives the world the use of an illuminant unequaled in brilliancy by any save the electric arc lamp.

ADJUSTABLE DIE HEAD AND METHOD FOR MAKING THREADERS FOR USE IN SAME.

JOSEPH M. STABEL.

Economical thread cutting and the production of the tools for accomplishing the same, form a very important item in many factories, especially where several hundred sizes of threads are used, so that to make a solid tap for each size would be very expensive. The tools and method here described, while by no means inexpensive in the first cost, will, when once brought into use on such work, produce a great saving over the cost of making solid tools for each size of thread, and the cutting tools, or threaders, when worn out may be renewed at a very small expense. Another advantage of this method is that found in the fact that many shops use quite an assortment of different styles of threads, and to keep each one standard, not only as to size, but as to its form, is often a difficult matter. With this system a master hob is demanded for each style of thread, such as, V, Whitworth, square, 29-degree, 45-degree, and U. S. Standard. Such a hob will, with with proper care, last a lifetime, and will insure all of the different styles being kept to their proper form, which is a very essential point in thread cutting.

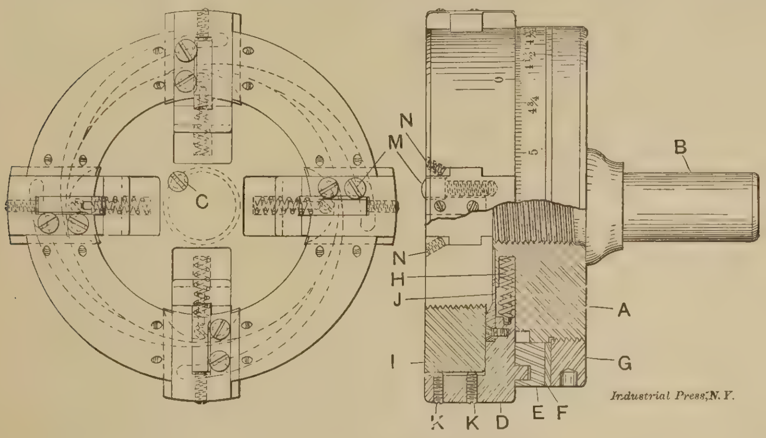

Fig. 1. Combined Adjustable Die and Holder.

Fig. 1 illustrates what is termed an adjustable die and holder combined, and its sphere of usefulness can be appreciated, as it has an adjustment of one and one quarter inches and its threaders are very simple to construct, thereby making them inexpensive to renew. They may easily be made of high-speed steel, which has proved far superior to the regular tool steels when it is properly hardened. The body, *A*, is made from a piece of forged steel, onto which the shank, *B*, is screwed, being locked into place by the screw, *C*, one-half of which is in each piece. The shank is made of low-carbon steel and is hardened. The four jaws, *DD*, are made of machine steel, casehardened, and are a good fit in the body, *A*. Gibs and gib screws, *N*, are utilized to compensate for wear. On the lower part of each jaw is a projection which engages a slot in the cam ring, *E*. The construction of both jaw and cam ring will be more clearly seen by reference to the details shown in Fig. 2. The threaders, *I*, *I*, fit into these jaws and are held by the screws, *MM*, while adjusting screws at the back of the threaders allow for resetting after they have been rehobbed. The springs, *H*, serve to always hold the jaws against the top of the cam groove, thus insuring accuracy. To protect these springs and the inner part of the slot from dirt or chips, when the jaws are set at their largest diameter, the pieces marked *J* are used, being held fast in a slot milled into the jaw, by means of a screw located at the bottom of the threader slot. They are fitted into the body, *A*, so that they will move in and out with the jaw, and are flush with the bottom of the body.

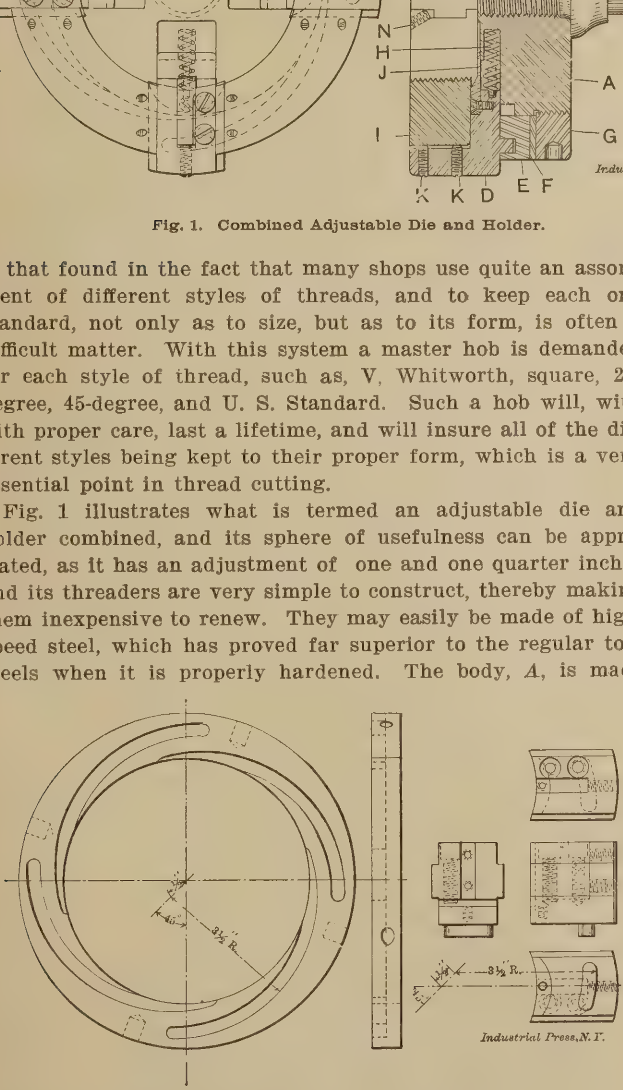

Fig. 2. Detail of Cam Ring and Jaws.

The cam ring *E*, from which the 1¼-inch adjustment is obtained, has four cam grooves, the milling of which presented some little difficulty, but was finally accomplished by use of the special plate and arbor shown in Fig. 3. The shank of this arbor was made to fit the dividing head of the milling machine, and the projecting head was turned to a sliding fit in the plate *B*, and tapped on the end to receive a bolt by which the plate was clamped in position. This plate served as an arbor for milling the cam rings. As will be seen from Fig. 2, these cam grooves are struck from a center which is one-half inch off from the center of the ring, and with a radius of 3½ inches to the further side of the groove. One side of the milling plate, *B*, is turned to fit the cam ring and is concentric with the plate, and on the other side there is a similar projection which is one-half inch eccentric and holds the rings while the grooves are being milled. The plate is first placed on the arbor with its concentric side outward, and to this the cam ring is secured by three screws fitting into the plate. With a graduating tool in the milling machine spindle, and the arbor placed in the dividing head, four equally spaced lines are graduated on the inside of the ring. The ring and plate are then removed from the arbor, the ring taken off and the plate replaced with its eccentric side outward. A line is graduated on the plate so that it will bisect the eccentric boss. The cam ring is then replaced on this side, with one of the four graduations in line with the zero line on the plate, being secured with the three screws as before. The milling machine table is first raised so that the center of the spindle is in line with the center of the dividing head, and is then lowered just 3.344 inches, which amount, with a 5-16 inch cutter, gives a 3½ inch radius on the largest diameter of the cam groove. After the first groove is milled, the ring is released and revolved around on the plate to its next graduation for the second groove, which, with the third and fourth, are all milled in the same manner as the first.

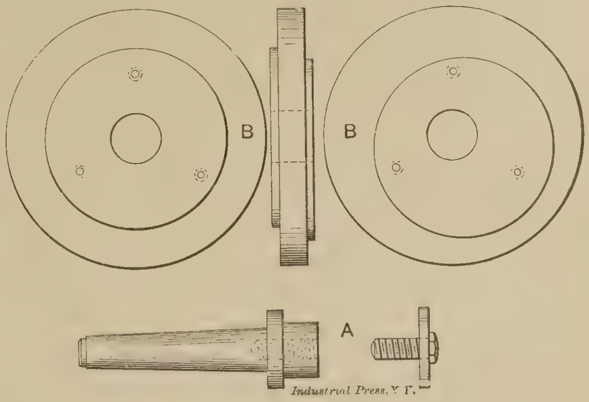

Fig. 3. Arbor and Plate for Milling Cam Ring.

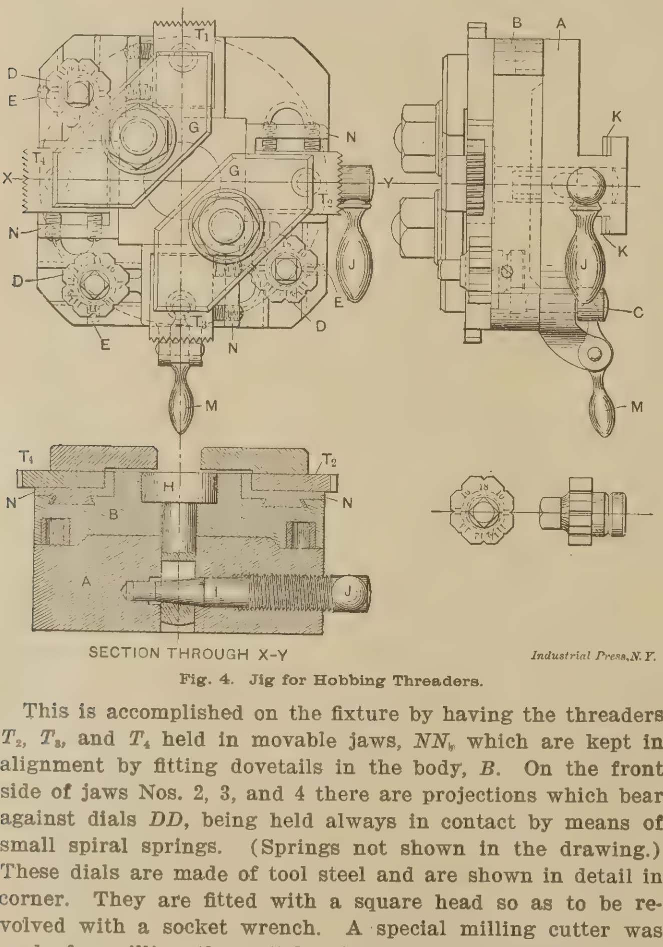
The threaded ring, *G*, Fig. 1, serves to lock the cam ring in position by pressing against the washer, *F*, which is kept from revolving with the ring by a small key set into the body, *A*, and fitting a spline in the washer. It is well when replacing threaders to always adjust them so that the diameter threaded by them will correspond with the graduation which is upon the outer diameter of the cam ring.

The method adopted for making the threaders necessitated the fixture shown in Fig. 4, which was made for use on a lathe with a hob placed between the lathe centers. This hob should be made a trifle larger in diameter than the largest size that is to be cut with the threaders, as a set of threaders that is used on work 4 inches in diameter will not work properly when hobbed with a 3½ inch hob, since the heel of the thread would drag. One hob of a certain pitch will answer for hobbing all threads of the same pitch, provided it is in all cases larger in diameter than the work that the threaders are to act upon.

The body of the fixture is made in two parts, *A* and *B*, the part *A* fitting the tool-post T-slot in the lathe carriage, and being held securely by the two taper keys *KK*, each being placed in position from the opposite sides of the carriage. In the front side of *A* is a hardened and lapped bushing carrying the index pin *C*, which enters four similar bushings equally spaced in the part *B*. By rotating the part *B* and letting the pin *C* engage with each of the bushings successively, the threaders, which are fastened to the top of the part *B*, are brought into position for hobbing. As there are four threaders in the die it is necessary to have them located on the fixture at different distances from the center line; as, for example, in hobbing a threader for a ten-pitch thread, threader No. 2 would be located .025 inch off from the center line, which equals $\frac{\text{Pitch}}{4}$, threader No. 3 would be .050 off, or $\frac{\text{Pitch}}{2}$ and threader No. 4 would be .075, or three times that of No. 2.



Industrial Press, N.Y.

Fig. 4. Jig for Hobbing Threaders.

This is accomplished on the fixture by having the threaders T_2, T_3, and T_4 held in movable jaws, *NN*, which are kept in alignment by fitting dovetails in the body, *B*. On the front side of jaws Nos. 2, 3, and 4 there are projections which bear against dials *DD*, being held always in contact by means of small spiral springs. (Springs not shown in the drawing.) These dials are made of tool steel and are shown in detail in corner. They are fitted with a square head so as to be revolved with a socket wrench. A special milling cutter was made for milling these dials. It had a 90-degree projection upon it, and the slot which it formed in the dial was employed for locating the jaws by means of a similar projection on them.

NOTE.—Subtract figures of table to obtain difference of dial steps.

Table showing Difference of Settings for Milling Dials.

As will be seen, the dial is divided into eight parts, each being marked with the pitch of the threader which it is to locate. The milling of the dials was accomplished by raising the table of the milling machine the proper amount for each division, the table placed below the detail showing the difference that must be made on each dial, with the corresponding number of threads per inch. The figures are stamped upon the dials before they are milled, so as to avoid any mistake. The dials are held in position in the fixture by means of a small screw, *E*, with a 90-degree point, which fits a slot in the shank of the dial. When the threaders have been located in position they are held securely by the two clamps *GG*.

The cross sectional view of the fixture shows the device that is employed for locking the parts *A* and *B* together. In the central stud, *H*, is an elongated hole through which passes the tapered pin *I*, and when this pin is turned by the handle *J*, it bears against the bottom of the hole in the stud and clamps it firmly. To operate this fixture we first unscrew the handle *J*, and thereby withdraw the taper end of the pin partly out of the hole in the stud, so that it loosens up the part *B*. The index pin *C* is then withdrawn by pulling up on the handle *M*, and the head is revolved a quarter of a turn. A spring attached to this handle causes it to spring into the bushing as soon as it is brought over it.

Another method for accomplishing the threading of the chasers without the aid of so elaborate a fixture as that just described consists in placing the hob on the lathe centers as before, and having a faceplate arranged with as many slots as there are threaders in the die head, care being taken that the slots are equally spaced. A simple fixture is placed on the lathe carriage to hold the threaders in position, and the threaders are numbered as they are cut, the slots on the faceplate having corresponding numbers. After threader No. 1 has been hobbed, the hob is released from the centers and revolved so that its driver will engage slot No. 2 on the faceplate. No. 2 threader is then placed in the same position as was occupied by No. 1 and is hobbed in the same manner. Nos. 3 and 4 are likewise hobbed, using the driving slots corresponding in number. In both of these methods it is understood that the lathe is geared to cut the same number of threads as there are upon the hob.

* * *

A drawback to the general use of nickel steel is the high price of nickel, which is now about 35 cents a pound. This in effect adds $10 to $12 a ton for each per cent. of nickel used, but as the nickel can all be recovered from the scrap, part of the extra cost may be regarded as an investment to be eventually recovered. As interest the user gets wonderful durability under severe stresses, which is especially apparent in locomotive and car axles. The average of forty tests on nickel-steel axles made for the Pittsburg, Bessemer & Lake Erie R. R., which, by the way, has four thousand nickel-steel car axles in use, showed that 67 blows of a drop weighing 1,640 pounds, and falling a distance of 44 feet, were required to break a nickel-steel 5 x 9 inch car axle having a diameter of 5⅜ inches in the middle. These axles contain carbon, 0.26 per cent.; manganese, 0.75 per cent.; and nickel, 3.25 per cent. The deflection after the first blow was 5.2 inches. The Pennsylvania R. R. standard requirements for 5 x 9 inch axles are 5 blows of 1 640-pound drop from a height of 43 feet and a maximum deflection in the center of 5.5 inches.

* * *

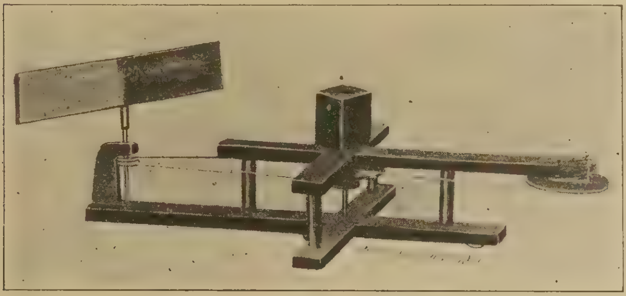
An interesting statement bearing on the future of great cities was embodied in an address recently made by Prof. H. B. Smith of the Worcester Polytechnic Institute, speaking of electrical transmission of power. He said that in San Francisco a few years ago the cost of electric current for power and light was 15 cents for one horse power per hour, while to-day the published price is almost exactly one-seventh of this amount, and it is possible to deliver at the factory on the coast, from the melting snows and glaciers of the Rockies, power for the machinery at a smaller cost than that at which it is possible to produce that power by steam, even though the fuel were to be delivered at the factory boiler without cost to the power producer. It has been estimated that the quantity of carbonic acid annually exhaled by the population of New York city is about 450,000 tons, and that this amount is less than three per cent. of that produced by the fuel combustion of that city; so we may expect that, with the removal of this great source of contamination of the atmosphere, even the air of our greater cities will be practically as pure as that of the country.

LETTERS UPON PRACTICAL SUBJECTS.

SOMETHING FOR THE HOLIDAYS.

Editor MACHINERY:

I am sending herewith photograph of a revolving Christmas tree holder, which you may find appropriate for your December number of the paper. I used the device last Christmas and it worked very satisfactorily. The frame carries a central, vertical rotating spindle, which supports a block for holding the base of the tree. At the right is a clock movement for furnishing the power and at the left a fly governor for regulating the motion of the tree and clock movement. I fitted the device with an old alarm clock movement, taking all the wheels out except the ones attached to the spring axle and to the main axle, which geared together. The wooden pulley below the movement was attached to the main axle of the works, and a cord led from this pulley to a small pulley on the central spindle supporting the tree. A large pulley, also, on this spindle drives the governor shaft by means of a cord, as shown.



Apparatus for Revolving Christmas Trees.

In making a mechanism like this, it would be well to have the governor wing a little lower down so the lower branches of the tree will clear it. The one that I have made will turn a medium-sized Christmas tree for from 20 to 25 minutes before it is necessary to rewind the clock spring. It is possible that some of your readers, who intend to celebrate Christmas by means of a tree for the younger members of the family, would like to make a revolving Christmas tree holder like this one.

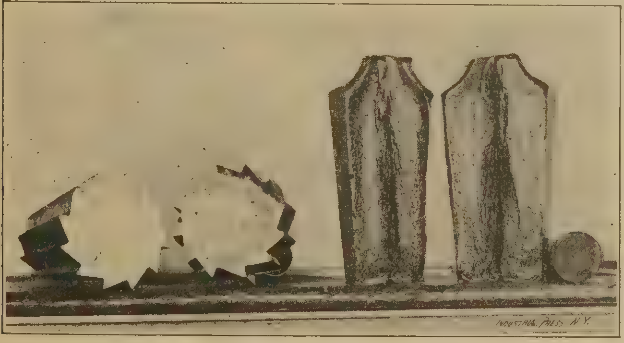
MAX SCHILLING.

St. Paul, Minn.

WHAT CAUSED THEM TO BREAK?

Editor MACHINERY:

The accompanying photograph illustrates two reamers that broke in hardening and it is hoped that they will call forth some opinions as to the cause of their doing so. They were made of the very best of tool steel purchased from one of the leading steel manufacturers especially for this purpose.



Reamers Broken in Hardening.

The dimensions were as follows: Length of taper 7 inches, length of parallel shank 6 inches, largest diameter 4½ inches, smallest diameter 3½ inches.

The reamer at the right was made first and this split lengthwise and in a few hours the shank broke off. The toolsmith was so confident that he could temper another successfully that a second one was made and this broke crosswise at about one inch from the large end, as shown at the left of the cut. A third one was then made with a taper hole throughout its entire length, two inches in diameter at the large end and having the same taper as the blades of the reamer, a shank being made later to fit it. This one came out of the hardening in good condition and is now in use.

It may be said that the smith was a very reliable man, of wide experience in this line of work, with which he is usually successful. The reamers were heated slowly and evenly in a charcoal fire and dipped in warm water—in fact, they received exactly the same treatment as has been given to other reamers by the same man with excellent results. Now I would like to hear from some of the readers of MACHINERY as to what they think was responsible for the breaking; whether the trouble was with the steel, the toolmaker or the smith. I have a theory of my own which may be submitted later.

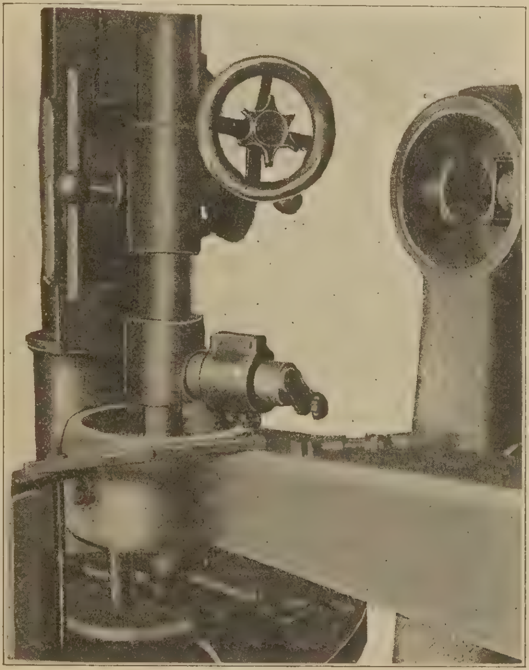
M. H. WESTBROOK.

Port Huron, Mich.

LARGE FACING WITH AN UPRIGHT DRILL.

Editor MACHINERY:

While we are all interested in well equipped shops, and special machines are being put into use for facilitating work, it is doubtful if the time will ever come when it will not be necessary, at times, to use machines for work which was not intended for them. The accompanying photograph shows a job of this nature which was done in a 27-inch Barnes upright drill. A motor field, integral with the column of the machine, is being bored and turned where the hood carrying the other bearing fits on. The hole for the front bearing case is 4¼ inches in diameter, as is the bore of the steel pole pieces, and the surface on which the tool is shown at work in the photograph is 11 inches in diameter. The tool is 5-16 inch square and is held directly in a socket provided for it in the sleeve which slides upon the radial arm. This arm forms one piece with the hub that is clamped on the end of the drill spindle. The boring bar is shrunk in this hub and has a bearing in the drill table.



Facing Motor Columns on an Upright Drill.

The writer believes that some attempts at large diameter work in the drill press are failures because the tang of a taper shank bar is depended upon to drive the cut. In the arrangement shown here this is not used but all driving is done by the outside of the enlarged end of the spindle. The feeding of the tool radially is done by hand as the surface is but ⅞ inch wide and there would be no advantage in having a power feed, although a star feed could easily be provided.

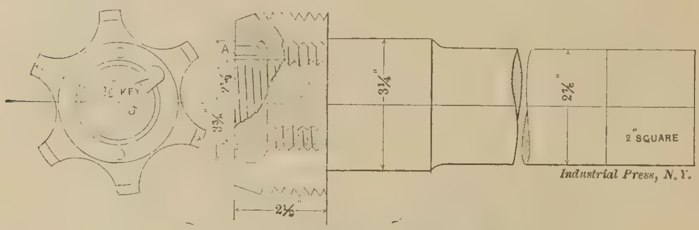
Another peculiarity of this job is that the work is held firmly onto the drill table by pouring babbitt around two projections on the casting and into two slots in the drill table. The close proximity of the drill press to the babbitt bench renders this a good way of holding the pieces. Two light clamps help to secure the work, and that it is held as solidly as if it were one piece with the machine need not be doubted. About fifty motors have been machined in this way and it has not been found difficult to do a true job in a very fair time. CORNEIL RIDDERHOF.

Grand Rapids, Mich.

DETAIL OF LARGE SHELL TAP.

Editor MACHINERY:

The writer noted with interest the account in the October number of MACHINERY of H. H. E.'s accident in hardening a large tap. The accompanying sketch shows the form of tap that is used at the Cramp Shipbuilding Co. for taps of the size described by H. H. E.; no tap over 4 inches in diameter ever being made from the solid. Taps of this design have been made in sizes up to 6¼ inches in diameter, four threads, and have given very good results. The shank of these taps is made of mild steel and can be of any length that is convenient. The tap proper, or shell tap, is held to the shank by a spanner nut, *A*, which fits the end of the shank and a key is used to keep the shell from turning on the shank. The sketch shows the dimensions which would apply to a 5-inch tap. Other sizes would be in proportion and several sizes of tap shells may be made to be used on the same shank.



Industrial Press, N. Y.

Large Shell Tap.

While there is much that is to be said about taps a great deal depends upon the quality of the steel that is used for making them. Although they will sometimes crack and break with the most careful treatment, if good stock is used good results will usually be obtained. F. HARRISON.

Philadelphia, Pa.

SPIRAL GEAR-CUTTING MACHINES.

Editor MACHINERY:

I am able to furnish some of the information desired concerning the spiral gear-cutting machine illustrated in your issue of November.

The reason that the machine is not made in this country is that I hold a patent upon it. I am not making it myself because I am not a machine-tool builder, and cannot induce any manufacturer to take it up for me. The patent will probably run out its term unused.

It is only fair to intending purchasers to record my claim that the Biernatzki & Co. machine which you illustrate is a direct infringement upon my patent, and that anyone who purchases one without a permit from me is liable to be called to account by my lawyer. The machine, as made by this firm, is patented in this country by Phauter, and a most cursory examination of his patent of January, 1900, will show that his invention is fully included in mine and covered by my claims.

My patent is disputed by several concerns who imagine that it is cheaper to steal my invention than to purchase it, but it is to be noticed that every one of these concerns has adopted the futile device of secrecy. They have the machines working in locked rooms, out of sight, and imagine them out of reach. When the patent runs out these machines will blossom forth as brand new. Not one of these infringers will discuss the matter of validity, for the simple reason that they have no argument to offer. I am preparing a suit against one of them which will test the matter. Intending infringers and importers of infringing machines will do well to wait the decision of the court in this test case.

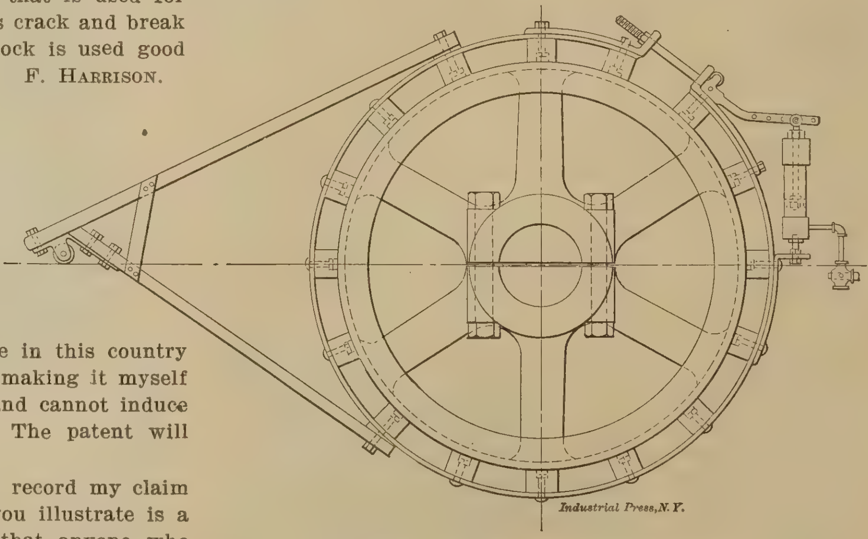
That the invention is practical is proven by the uniform success of the machine when properly made. I do not doubt that it will appear under names of Smith or Jones, or otherwise, as soon as my patent is out of the way, and that it will be the future method of cutting spur and spiral gearing in regular manufacture. It is not very well adapted to the jobbing trade, but for turning out gears in rows by the hundred it is the coming thing. The machine is described in my Treatise on Gear Wheels. GEO. B. GRANT.

A QUICK-ACTING ATTACHMENT FOR THE PRONY BRAKE.

Editor MACHINERY:

The office of the Prony brake in connection with the testing of dynamos, motors, steam and gas engines is to hold a load on a band wheel used in connection with the brake band. The load is maintained constant by the use of a wrench or hand wheel with which the band is tightened or loosened as the case may require. This method is, however, by all means too slow for obtaining good results when variations of the load are often from 0 to 125 per cent. overload and take place so rapidly that hand regulation would be impossible. The accompanying sketch shows a brake which is fitted with a quick-acting attachment that makes it suitable for this kind of testing.

A small cylinder, having a diameter of about three inches, is fastened to one-half of the brake band and to the upper end of the piston rod is connected a short lever which supports a cam on the end toward the band. Power, which may be either steam, hydraulic, or compressed air, is supplied to the cylinder by a ⅜-inch pipe entering on the lower side of the piston. When pressure is admitted to the cylinder the piston is forced upward and consequently imparts an upward motion to the short lever on the end of the piston rod. This causes the cam on the end of the lever to close the band and to hold the load at any desired point, this being regulated by the amount of pressure that is admitted to the cylinder. In order to make this application complete and at all times under control of the engineer, a ⅜-inch plug cock of ordinary style has been placed in the supply pipe line at whatever point is the most convenient for operation. This cock has a 5-16-inch hole drilled through one of its sides and a similar one drilled half way through the plug, thus forming an outlet on the cylinder side of the cock for release of the pressure in the cylinder. Thus it will be seen that closing the cock to pressure opens it to release and the pressure in the cylinder immediately falls. In using this arrangement from 1 to 500 horse power can be instantly applied by simply moving the lever on top of the cock, and release is as easily obtained.



Industrial Press, N. Y.

Prony Brake with Quick-acting Attachment.

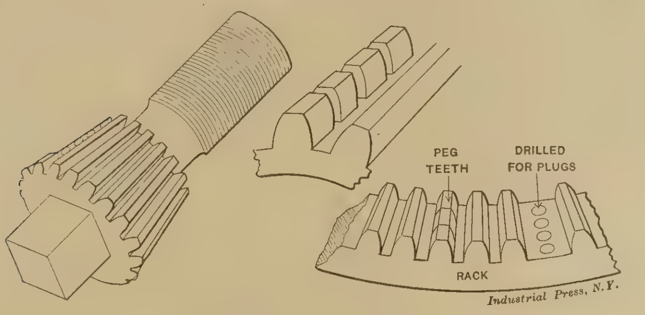
Oswego, N. Y. JAMES H. TAYLOR.

THE TOOLMAKER IN THE SMALL SHOP.

Editor MACHINERY:

Among the many odd jobs that come to the toolmaker in the small shop is the taking out of broken taps and setscrews from various pieces of work. Of course it is careless on the part of the workman, or so the toolmaker thinks, forgetting that he broke a small tap himself in the very last job he made, but it has to be fixed just the same, and so he goes at it.

If it is a tap or a hardened setscrew the first operation is to draw the temper so it can be drilled easily, and the best manner of doing this depends on the kind of a piece it was broken off in. When it's a small tap in a big piece of work that you don't want to heat all over, the temper can sometimes be drawn with a blow-pipe, playing the flame directly on the broken piece. It is better, however, to get it as soft as possible so as not to make the drilling out hard or to increase the tendency of the drill to run into the softer metal, in this case, the work.



Repairing a Geared Chuck.

In the case of a setscrew you can sometimes drill out so close as to leave nothing but the thread in the holes, and this can then be easily removed. This cannot often be done, however, as it is difficult to keep the drill running true enough to avoid cutting away the thread on one side or the other. It is decidedly safer to use a drill that will leave about a sixteenth of an inch on a side. Then, unless the setscrew is a particularly tight fit, a square punch can be driven into the hole firmly enough to unscrew it with. If, as is usually the case, the setscrew was broken from setting it up too tight on a shaft, this pressure will be relieved when the drill reaches the end of the screw, even if it does not drill through into the shaft. The square punch usually takes them out, but at times it is necessary to split the shell which remains, with small cape chisels. A careful man can usually get them out without much damage to the tapped hole. Where damage cannot be avoided it is often necessary to tap the hole out with a larger tap. I believe this practice is largely responsible for some of the odd sizes we find in some shops.

Practically the same treatment is needed in the case of a broken tap, but more care is generally required. A small hole is necessary owing to the grooves cut into the sides, and this makes it harder to remove the broken piece, as there is such a small chance of getting a good grip with a punch driven into the hole. It is a mean job at best, and a man who has had the pleasure of drilling a tap out of a piece of work will be almost unduly cautious for some time to come.

Another job that isn't altogether pleasant, though preferable to the drilling out of taps, is that of playing at dental surgery with the teeth of geared chucks or other gear teeth. The universal chuck is perhaps more largely used in brass work than any other line, and the brass chips find their way into the internal regions of the aforesaid chuck with great rapidity. Then they wedge into the teeth and in an unguarded moment the operator gives a little extra pull, snap! go a few teeth of either the pinion or rack (usually the former) and the chuck is on the repair list again.

The toolmaker takes it apart, locates the damaged teeth, and goes to work by drilling a row of holes fairly close together, as shown by the illustrations. The width of the teeth at the base determines the diameter of the holes, and he files or chips the broken tooth to a fairly level base before drilling. Then he takes steel wire rods—either Bessemer or drill rods—and drives into the holes, leaving a little extra length to file off for a finish. The next step is to file up the sides as nearly like the teeth in the pinion or rack as possible, although at best it is enough to make a regular gear man shudder. But they do the work and the false teeth almost never break, even when made from Bessemer rods.

Putting the chuck together again so it will run true isn't such an easy matter unless you've been there before. The quickest and surest way is to first put it together without the rack. Put it on the lathe where it belongs and, using it as an independent chuck, true up a mandrel or other round piece in it. Leaving this tight in the jaws, take off the back, put the rack in place and put together again. It will generally be found to run true after this, although there may be slack enough in one pinion to throw that out a little. If so, this particular pinion probably needs to be turned one tooth in one direction or the other to make it right. One thing is certain, if it ran true before you commenced your dental operations, it can be made to again. In many ways the universal chuck for anything larger than a drill chuck, is a delusion and a snare. As any mechanic who has handled them knows, it is a miracle when they run true for any length of time and they are weak as compared with an independent chuck.

It is also true that much of the trouble with chucks of this class comes from improper handling. If you attempt to tighten a piece of work from one screw, as you might do in a three-jawed independent chuck, you are very apt to have trouble. Either the teeth will break out or the work will not be firmly held.

The man who has had experience of this kind, tightens up on one screw until he grips the piece, then he turns the lathe and tightens each screw separately, perhaps two or three times. This uses the rack simply to bring the jaws to the work and tightens by each screw as it should.

Repairs can also be avoided by cleaning universal chucks occasionally—not to wipe out the oil, as they are generally kept dry on brass work, so the chips will not stick, but to clean out the little chips and brass dust. These pack into the teeth and cause trouble. For cleaning, just clamp a piece into the jaws, take off the back, get out the dirt and put back the rack and other parts removed. This keeps the jaws just where they were and saves any readjusting.

FRED. H. COLVIN.

SOME MORE MICROMETER MEASURING INSTRUMENTS.

Editor MACHINERY:

That micrometer lathe stop which was shown by Mr. Cantelo in the July number of MACHINERY is certainly a good one, but the writer takes the liberty of suggesting an improvement in its construction. Without doubt this is one of the most accurate and universal tools in use, but the description referred to showed an instrument that is limited in its use to work where only a stationary height is required. It is, however, often necessary to use the stop at different heights, to accommodate different lathes; then again, we wish to use it on the right-hand side as well as the left. The form of holder shown in Fig. 1 can be used either right or left, and for various heights and, by simply taking out the screw, *A*, the micrometer may be removed and used in any other form of holder desired.

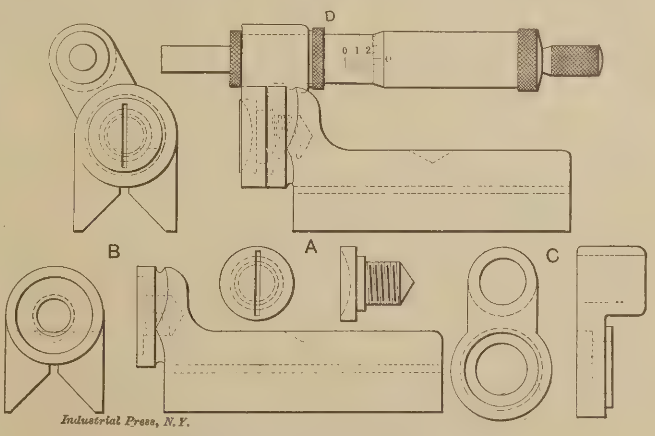


Fig. 1. Micrometer Lathe Stop.

Both assembled view and details of the holder are shown in the figure so that it can be easily constructed by any one desiring to do so. The micrometer and barrel may be procured from any of the manufacturers of measuring instruments. The swivel *C* is bored out so that the axis of the micrometer screw will be parallel to the body of the holder

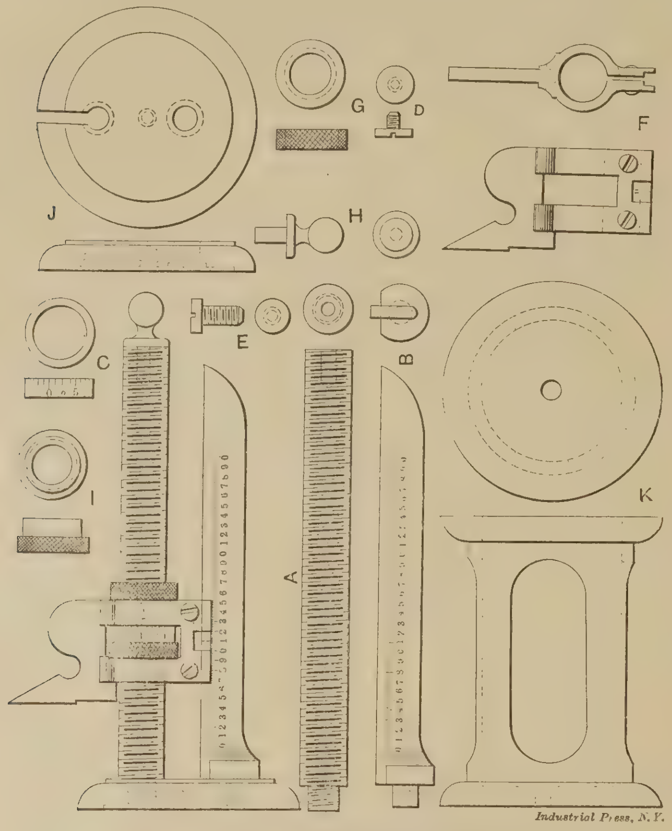

Fig. 2. Micrometer Surface and Height Gage.

when it is in place. The swivel is made of tool steel and is fastened to the holder by the screw *A*. It is hardened and lapped to a true bearing surface on the sides and bottom and so adjusted that it will turn to either side and remain in desired position without moving the screw. The holder *B* is milled through its entire length with a 45-degree cutter so that it will fit along the ways of the lathe, and the bottom is lapped to a true surface. For a neat appearance it should be color hardened. On top of the holder the point of a drill is entered a short ways to form a recess for the *C* clamp. A knurled ring *D* is driven onto the micrometer sleeve so that it can be turned around to bring the graduations uppermost when the position of the barrel is changed.

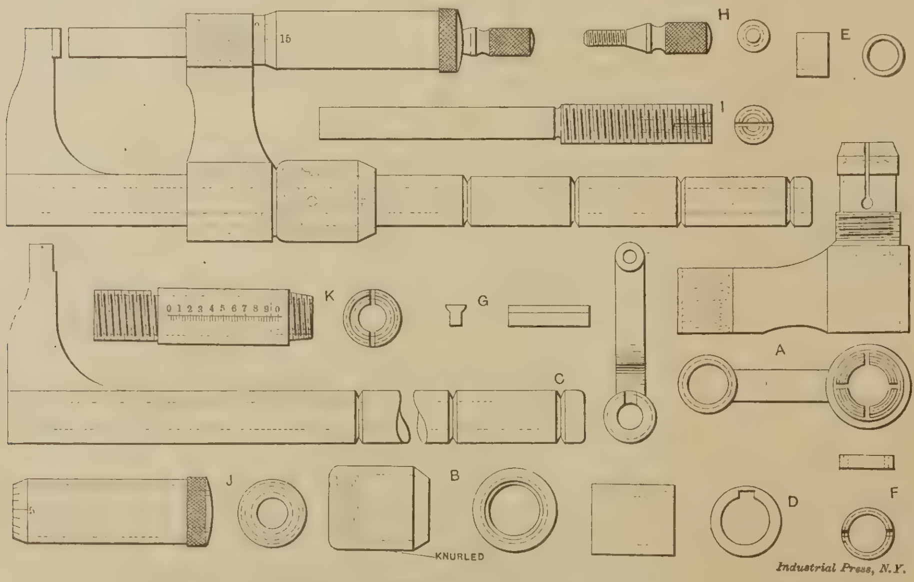

Fig. 3. Five-inch Bar Micrometer.

Fig. 2 shows a form of surface gage that has proved very handy and can be used also as a height gage for measuring distances from shoulders to the base. If accurately made it is equal, and often preferable, to the vernier or slide caliper now so generally used with an attachment to the sliding jaw. One of its advantages over the vernier is the readiness with which the graduations are discerned, and it is as easy to manipulate as the ordinary micrometer. The part *B*, which forms the main body of the instrument, is made of tool steel and one end is fitted into the base where it is held in position by the screw *D*. The other end is milled to a thickness of ⅛ inch and has graduations of .025 inch for a distance of three inches. The screw *A* is the most essential part of the tool and its construction requires great accuracy. Its diameter is ½ inch and it is cut with 20 threads per inch. On the upper end of the screw is driven the ball *H* for the sake of giving a neat appearance. The top of the thread is turned off .01 inch to allow the scriber *F* to slide freely on the screw. The barrel *I* is used for raising and lowering the slide but instead of having the graduations placed directly upon it they are made upon the sleeve *C*, which fits over a shoulder on the barrel. This allows for more easy means of adjustment than would be possible were the graduations placed on the barrel itself. The sleeve is graduated with fifty divisions each equaling a movement of the scriber of .001 inch. This sleeve may be turned by means of a small spanner wrench so as to bring the zero line into correct position to compensate for wear. A knurled locking nut is also provided for holding the scriber in any fixed position. The scriber itself is hardened and lapped to a finished surface, the tail end being slotted and provided with two screws to compensate for wear. On the scriber is placed the zero mark which shows at a glance the measurement that is being taken. The block *K* is three inches in height and is so constructed that by placing the gage on its top the range of the gage is increased to six inches. The screw *E* is used for fastening the gage to the top of the block. The center of the block is drilled out and slots cut through the sides in order to make it light and neat in appearance.

Fig. 3 shows a very simple and light five-inch micrometer that can be quickly set to exact position from one to five inches. The round beam is graduated by a series of angular grooves, 1 inch apart, which are of such a form and depth that the clamping fingers at the end of part *A* spring in, allowing one inch adjustment of the beam to be quickly and positively made. The sleeve *K* is of tool steel, being counterbored from the forward end for all but one-half inch of its length. For this half inch it is threaded on the inside and acts as a micrometer nut. The outside of the same end is threaded to receive the adjusting nut *F*, and two slots are cut in the sleeve, at 90 degrees with the graduations, so that these, by a movement of the nut *F*, provide a means for compensating for wear. The bushing *E* is hardened and lapped, and fitted tightly in the forward counterbore of this sleeve where it acts as a guide for the front end of the micrometer screw. The barrel *J* is the same as that of a regular micrometer and is graduated in .025 inch divisions.

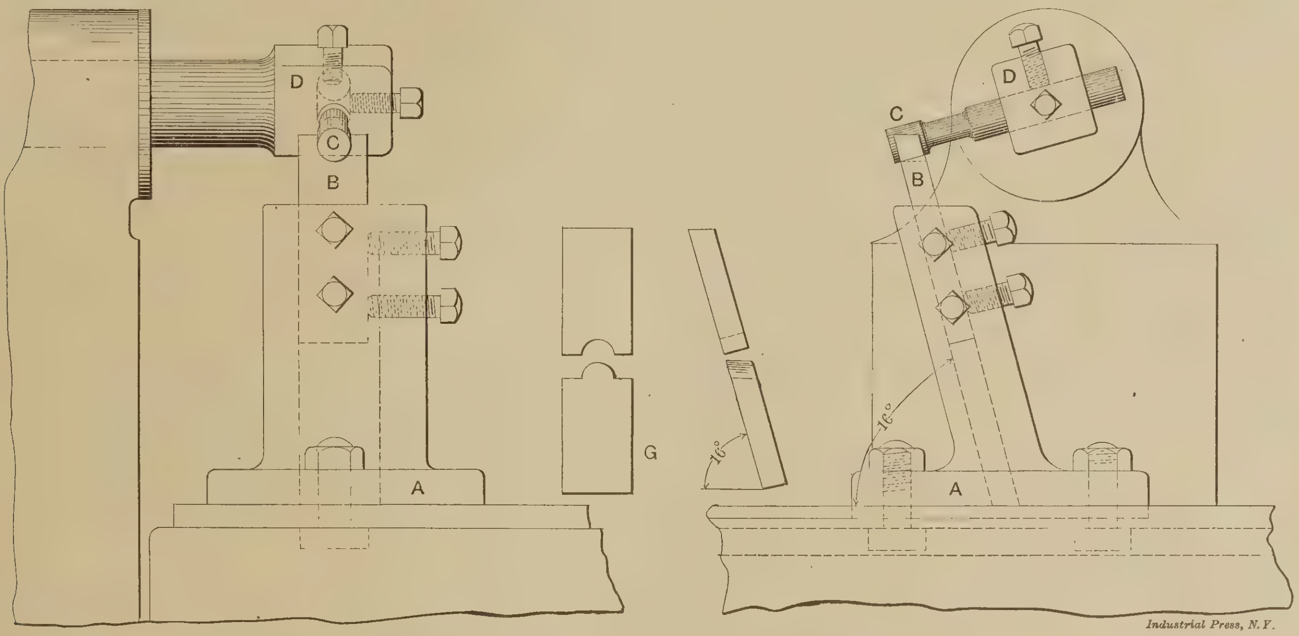
The most essential part of the tool is the threaded screw *I*, over the end of which fits the barrel *J*. The end is tapped out to receive the speeder *H*. which serves to hold the barrel in position. The thread is 5-16 inch in diameter and threaded 40 pitch, while the unthreaded part is hardened, ground and lapped. To adjust the instrument, loosen the speeder *H* and turn the barrel until the proper adjustment is obtained; lock the barrel by again tightening the speeder. The beam *C* has a ¼-inch hole drilled throughout its entire length in order to make it light. Small 90-degree grooves are cut into it at intervals of 1 inch, and a ⅛-inch slot is milled through one side to within 1¼ inch of the forward end. The back end of part *A* forms a spring-tempered split chuck, which grips the beam and holds it in position, while the exterior is threaded to receive the knurled cap *B* by which the chuck is tightened firmly to the beam. From the front end, toward the split chuck, the body is counterbored ⅝ inch and the bushing *D* driven in tight. This bushing has a key *G* fitted into it which slides in the slot of the beam and prevents the arm from turning. The projecting arm is bored and tapped to receive the sleeve, *K*. This gage has proved one of the writer's handiest tools but it must be carefully and accurately made to be of value.

New Haven, Conn. A. L. Monrad.

MAKING A CONCAVE FORMING TOOL.

Editor Machinery:

The accompanying drawing illustrates a method of making a concave forming tool such as is used for backing off convex milling cutters. This tool is required to have the same shape for its entire depth so that it may be ground and reground without changing its original form.



Industrial Press, N.Y.

Shaping a Concave Forming Tool in the Milling Machine.

In the sketch, *B* represents the tool which is held in the holder *A* at an angle of 16 degrees with the table of the machine, this inclination giving to the tool the proper cutting clearance. The first thing to be done, after placing the tool in the holder, is to mill off the top of the tool so that it will be parallel with the table of the machine. A semicircle of the desired radius is then drawn on the back of the tool and with any cutter that is at hand, it is milled nearly to the mark, care being taken not to go below it. For finishing the cutter a plug, *C*, is made, the end being hardened and ground in a surface grinder. This plug is held in a special holder, *D*, which fits the spindle of the milling machine, and when it is set so that its axis is perpendicular to the tool the spindle of the machine is firmly locked. Some machines are now being built with provision for locking the spindle, but if not so made the same result may be accomplished by driving wedges under the cone pulley. Now by moving the platen of the machine backward and forward by hand the plug can be made to cut a perfect semicircle in the tool.

It is good practice to plane a little below half of the diameter of the plug, thus allowing some stock to be ground off after the tool is hardened. In hardening, these tools usually come out very satisfactorily, but if any distortion takes place it will be from the sides and may be readily remedied by a little stoning.

By using the concave tool for a planing tool, as shown in the sketch at *G*, a convex tool may be formed, but in doing so care should be taken that both tools stand at an angle of 16 degrees with the bed of the machine. This shape of tool would be used for backing off a concave cutter.

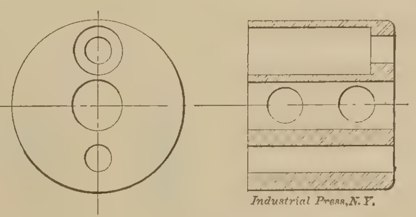
Providence, R. I. J. J. Lynskey.

A TIME-SAVING DRILL JIG.

Editor Machinery:

The drill jig which is here illustrated and described had considerable influence in establishing the cost of production, and maintaining the uniformity of the piece shown in Fig. 1, and although there is nothing remarkable in its construction, it embodies one or two points of interest since it is rigid and simple and is designed to withstand the severe handling that a tool of this kind usually receives from unskilled workmen, and at the same time it is capable of producing very satisfactory results. The pieces are first turned in the lathe to the proper size and length and the hole through the center is drilled at the same time. The object of the jig is to drill the side holes and the two end holes, which are diametrically opposite, one of them being stopped off at ⅛ inch from the bottom and continued through with a smaller size of drill.

This jig, which is shown in Fig. 2, consists of an L-shaped casting, *A*, which is supported on its bottom or side by the steel legs, *BB*, the faces of which are hardened and lapped true. A hole is drilled straight through the jig from top to bottom and into the top of this hole is forced the bushing, *C*, of tool steel, having a No. 19 and a ¼-inch hole, also a guide for one end of the work projecting at the center on the lower side. This is forced into the jig from the inside until the shoulder bears firmly against the upper arm of the jig. This combined bushing and guide was made in a single piece instead of inserting drill bushings and a guide piece separately, because the variation allowed for the holes was greater than any that was likely to be incurred in the hardening of the piece.



Industrial Press, N.Y.

Fig. 1. One of the Pieces to be Drilled.

Fitted tightly in the hole in the base of the jig is the sleeve, *D*, which carries a traversing piece, *E*, with a guide point on one end directly opposite and like the one in the upper bushing. These guides fit the hole in the work which is advanced or withdrawn by means of the screw, *F*, which is fastened to the piece *E* by the pin, *G*, introduced in such a location that the side rests in a round groove on the upper end of the screw, attaching it thereto and at the same time permitting it to rotate freely. The end of a small pin, *H*, enters a spline in the side of *E* and checks any tendency that it may have to turn when the screw is being turned. A knurled head is pinned and riveted on the end of *F*, as shown in the cut.

A strip of machine steel, *J*, of sufficient length to extend from top to bottom of the jig, is seated in a square milled channel and fastened by screws and dowel pins. The side holes were carefully located in this strip and two hardened and ground bushings for No. 4 drills were pressed in.

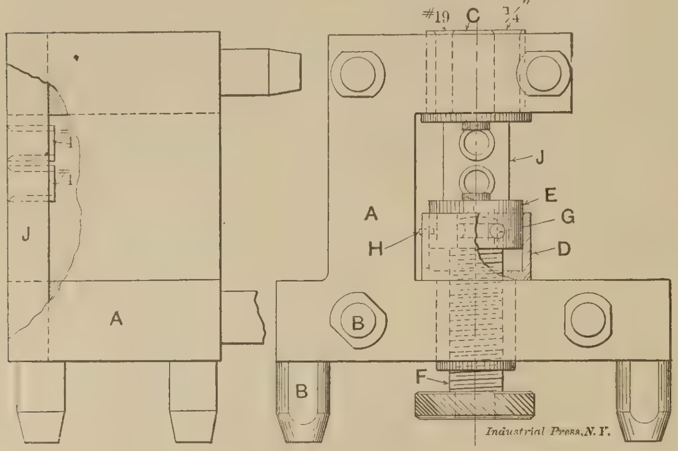


Fig. 2. Jig for Drilling Pieces shown in Fig. 1.

When in use the work is slipped on the upper guide point and, when the piece *E* is advanced by the hand screw, it is held firmly in place, being properly located in relation to the bushings by the center hole. The piece is then drilled as in ordinary jig drilling, the finished piece being removed by simply loosening up the hand screw. The piece, *E*, with the exception of the guide on its end, is left soft for the point of the drills to enter the necessary depth for clearance.

Worcester, Mass. C. H. Rowe.

THE TOOLS FOR MAKING BOX CORNER FASTENERS.

Editor Machinery:

Many of the readers of Machinery are doubtless familiar with the crinkled metallic fasteners that are used for strengthening the sides of boxes after they have been put together, as is shown in Fig. 1, which is a corner of a box into which one of these fasteners has been driven. These articles are used in large quantities and are sold very cheaply as they are produced in one operation by the means of dies to which the stock is fed automatically. As the manner in which they are made is suggestive for other work of a similar nature, a description of the tools used may be of interest.

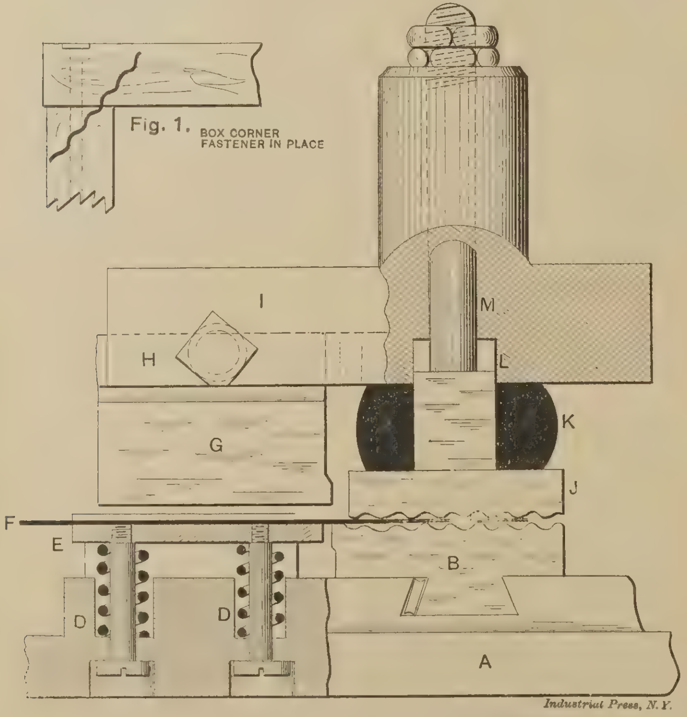

Fig. 2. Punch and Die for Box Corner Fasteners.

In Fig. 2 is shown a front view of the punch and die as they appear when in the press. As will be seen the tools are constructed so as to allow of feeding the metal in strips and producing the finished article in a single operation. In the die, *A* is the die block, which contains the spring pad *E* along which the metal is fed, and the combined cutting off and forming die, *B*. Fig. 3 shows a plan of the punch looked at from below. The punch consists of the usual cast-iron holder, *I*, the cutting off punch, *G*, and the forming punch, *J*. It will be noticed that the cutting off punch is let into a dovetailed channel in the face of the punch holder and fastened in position by the large setscrew, *H*. This allows for the adjustment of the cutting off punch when its face and that of the die *B* are ground. The forming punch *J* is furnished with a stem, *M*, which fits a reamed hole running through the stem of the holder, while the punch proper locates in the channel *L* cut in the face of the holder. *K* is a piece of hard spring rubber placed between the face of the holder and the back of the punch. The punches, *G* and *J*, were hardened and drawn to a dark straw temper while the die *B* was drawn to a light straw.

When the tools are in use they occupy the position shown in Fig. 2. The strip of metal is fed along the face of the spring guide way, *E*, the feed being automatically adjusted to project a certain length of strip across the face of the die at each stroke. As the punch descends this portion of the strip that is to be formed is cut off by the punch *G* and the section is held on the face of the die by the punch, *J*, which remains stationary while the cutting off punch and the spring guide may continue to descend, the rubber compressing meanwhile, until the punch *J* bottoms in the punch holder, when it presses the strip into the desired form. As the press is inclined the finished piece slides off from the face of the die as soon as the punch has risen sufficiently to release it. By the use of these dies the articles are produced very rapidly and cheaply. Metal Worker.

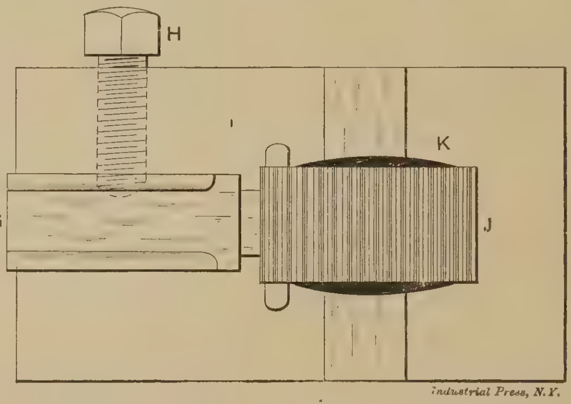

Fig. 3. Plan of Cutting and Forming Punch (from below.)

* * *

Some beautifully smooth examples of planer work are daily produced at the works of the G. A. Gray Co., Cincinnati, O., especially such parts as have to be scraped and fitted. An interesting kink in this connection may be mentioned. As everyone knows who has had experience in scraping planer work, there may be a great difference between the scraping required on two pieces that appear to casual inspection of the eye to be equally smooth. But the moment a scraper cut is taken over the surfaces, the difference is detected. One may show that little work is required; the other will at once disclose that the surface is a succession of "hills and dales," the working down of which requires a lot of time and labor. When the scraping department is on piecework the men naturally object strenuously to the latter class of planer work. To prevent this trouble in the Gray works, each planer hand is required to place a "telltale" on each planer job that is to be scraped. He does this by taking a few strokes with a broad scraper across the work; if it shows up satisfactorily he removes the job from the platen, but if not another finishing cut must be taken. The telltale is in effect an inspection mark of satisfactory planing.

DESIGNATION OF STANDARD MACHINE PARTS.

The accompanying cuts, Figs. 1 and 2, show sample pages from a book of blueprints used by the King Machine Tool Co., of Cincinnati, Ohio, for designating standard machine parts, such as studs, screws, etc., and which is used in their shop and drawing room practice, and for ordering same from the firms making or dealing in such supplies. The method of designating different screw sizes is of interest and will perhaps be new to many of our readers, although it has been used for some time by a number of concerns, having originated, we are informed, several years ago with the Garvin Machine Co., of New York.

Fig. 1. Specimen Page for Hexagon Head Cap Screws.

A page of the book, which is simply bound with split staples and marginally indexed, gives the drawing of one style of screw with the principal dimensions designated by *A*, *B*, *C*, *D*, etc.; the name, as "hexagon head cap" in Fig. 1; the style, being "*H*" in this case; and a table of sizes regularly kept in stock. It will be noticed that in the body of the table in this particular case, there are 200 squares, only a few of which have numbers marked therein. These are the sizes regularly used. In this instance the first size regularly used is designated by the number 27. It is a hexagon cap screw ⅜ inch diameter and 2 inches long under the head. The head is ⅜ inch high, 21-32 inch longest diameter, 9-16 inch across flats. All this information is condensed into the symbol "H27." The number is gotten by counting the number of squares, beginning at the upper left-hand corner and going to the right on each horizontal row, successively downward. Thus it will be found that a ½-inch screw, 1¼ inch long under the head, is designated by the 64th square and its symbol, therefore, is H64. Again, if a ⅝-inch screw is wanted 2¼ inches under the head instead of 2 inches (which is H27) it would be designated as H28, and so on. Fig. 2 shows a page given to oval or French head cap screws. In this case the first size regularly used is 3-16 inch diameter and ¾ inch long under the edge of the head; its symbol is G18. In this case it will be seen that the width of the screw-driver slot is also given.

Fig. 2. Specimen Page for French Head Cap Screws.

As already stated, this system is used for ordering stock. Each firm supplying the company with such parts is furnished with a copy of the blueprint book and orders are filled by referring to same. The time required for making out orders is shortened, and the chances for mistakes are lessened. Of course the simplicity of the system on drawings and its advantages in the shop and stockroom are obvious.

ITEMS OF MECHANICAL INTEREST.

METALLURGY OF IRON—RAILWAY CROSSING PLANERS—GASOLINE HOISTING ENGINE—REPAIRING AUTOMOBILE TIRES.

Alloys that melt at temperatures considerably less than that of boiling water, are found very useful for some purposes, especially for taking casts from delicate objects like fabrics, fruits, animal bodies, insects, etc. But it is asserted that all such alloys must contain cadmium if the objects are to be preserved from injury. A German authority states that such an alloy is Woods metal which consists of tin, two parts; lead, four parts; bismuth, seven to eight parts; and cadmium, one to two parts. This alloy melts at 151 to 162 degrees F. Another alloy, known as Lipowitz's metal—consisting of tin, four parts; lead, eight parts; bismuth, fifteen parts; and cadmium, three parts—softens at 121 degrees F. and becomes perfectly liquid at about 151 degrees.

GRAPHICAL ILLUSTRATION OF THE METALLURGY OF IRON.

The diagram herewith illustrates graphically the metallurgy of iron from the mine to the market and affords an interesting means of tracing out the different processes and showing the kind of steel or iron which each process produces.

Thus we see that the ore may, by the direct process, be changed at once to wrought iron in which form it is placed upon the market. The ore may go to the direct blast furnace or, if volatile substances are contained in the ore, it is first roasted, by which method these substances are removed and the ore made ready for the blast furnace. In the blast furnace the ore is changed to pig iron of various grades which may be placed directly upon the market or it may be then treated by any one of several processes. If treated by the Bessemer process the pig iron is changed to ingot iron, in which form it is placed upon the market. If treated by the open-hearth process it is also changed to ingot iron. If, however, the pig iron is sent to the foundry it is made into cast iron and placed upon the market in the form of castings. In the puddling furnace the pig iron is changed to marketable wrought iron or it may be treated by the cementation process, in which it is changed to blister steel, from which, by the crucible process, we obtain tool steel.

DUPLEX PLANING MACHINE FOR RAILWAY CROSSINGS

The machine shown in the accompanying illustration was constructed at the Ancoats Works, Manchester, England, and was designed for planing and finishing railway crossings to a point, and at various angles, from rails of heaviest sections after they were put together at the required angles. There are two transverse foundation beds arranged to radiate from fixed centers on the front foundation bed. These beds may be set at the various angles by means of screw and ratchet lever and they are then securely bolted to the transverse beds. Each longitudinal bed is provided with a table to support the rail while it is being planed and is also fitted with a saddle or carriage. These saddles have upright angle brackets cast on the upper face and to these are fitted swivel tool boxes arranged with compound slides, self-acting in the vertical and angular cuts. The horizontal adjustment is by hand and spring clapper. Each saddle is driven independently and fitted with adjustable stops for various lengths of stroke. Each bed is provided with a separate set of driving gears with single belt and tight and loose pulleys, and the arrangement of the gears is such as to give a quick-return motion to the saddle of 3 to 1.

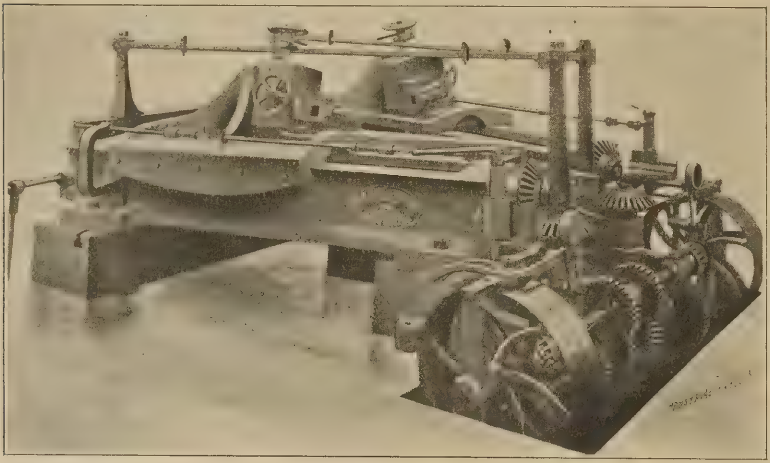

Fig. 2. Duplex Planing Machine for Railway Crossings.

F. C. P.

THE EFFECT OF SUBMERGING COAL.

Considerable attention has been bestowed upon the comparatively recent discovery that coal submerged under sea water does not lose its calorific power so rapidly as when exposed to the air. Indeed, Mr. Macauley, who announced the discovery about one year ago, now states that in some cases there is an actual gain in heat-producing power, but this, as we understand it, does not apply to a unit of weight compared before and after submersion. That is to say, a hundredweight of coal submerged for a certain length of time loses by oxidation very slowly, but it does lose a certain percentage of the softer parts by the process of solution. Thus, the remaining portions may show a gain in calorific power because the proportion of ash and non-combustible matter has been proportionately reduced. This might be an important item in the use of coal for fast steamers, where it is desirable to reduce the actual weight of coal carried to the lowest possible figure, to say nothing of avoiding the loss by oxidation, which is inevitable where coal is stored for some time in the open air, especially in warm weather.

THE USE OF CALCIUM CARBIDE IN SUBMARINE BOATS.

It is generally known that calcium carbide forms acetylene gas rapidly when immersed in water, and, if confined, considerable pressure can be generated in this manner. In the December, 1902, issue mention was made of the suggested use of calcium carbide in a cylinder above a piston for producing heavy pressures, as required for baling cotton, hay, straw, etc. By its use, it was pointed out, such apparatus would be greatly simplified, the pumps and motive power required for a hydraulic press being made unnecessary. This property of calcium carbide has been utilized in Germany in another direction, which also makes the use of pumps unnecessary, and that is for raising and lowering submarine boats. The rapid formation of actylene gas presents a convenient method of increasing or decreasing the displacement of such a vessel as is necessary when it is to be raised or sunk. The boat is supplied with a gas generator connected to the water reservoirs, which act as ballast. The introduction of a carbide cartridge into the generator produces gas which, admitted by a valve to the water reservoirs, displaces the water and lightens the craft so that it rises; releasing the gas so that the water fills the reservoirs, of course, causes it to sink. The apparatus is simple, compact and requires no pumps.

A GASOLINE HOISTING ENGINE.

One of the latest applications of the gasoline engine is its use for hoisting machinery, as illustrated in Fig. 3, which shows a gasoline hoisting engine of recent design. The motive power is supplied by a horizontal gasoline engine of standard type, having directly connected to the crank shaft, by a single gear reduction, a winch shaft which carries a hoisting drum that is made in various sizes to suit the requirements. This drum is controlled, as in the ordinary steam winch, by a friction clutch and brake under the immediate command of the operator. In raising the load the clutch is thrown in; while in lowering, it is disengaged and the speed of the drum is controlled by the friction brake. The speed of the engine may be varied while in operation, and all levers and regulators are operated from one position.

Upon the outer end of the drum shaft is placed a secondary drum or "nigger head," and the outer end of the crank shaft carries a pulley so that the engine may be used for power purposes if desired. When it is so used the hoisting mechanism is disconnected and stands idle. The gasoline tank and the batteries for operating the sparking mechanism are placed in the base of the engine, so that the whole forms a single unit which can be transported as easily as the ordinary steam winch alone, and the need of boilers and feed tanks is obviated. This winch is built by the Columbus Machine Co., Columbus, Ohio.

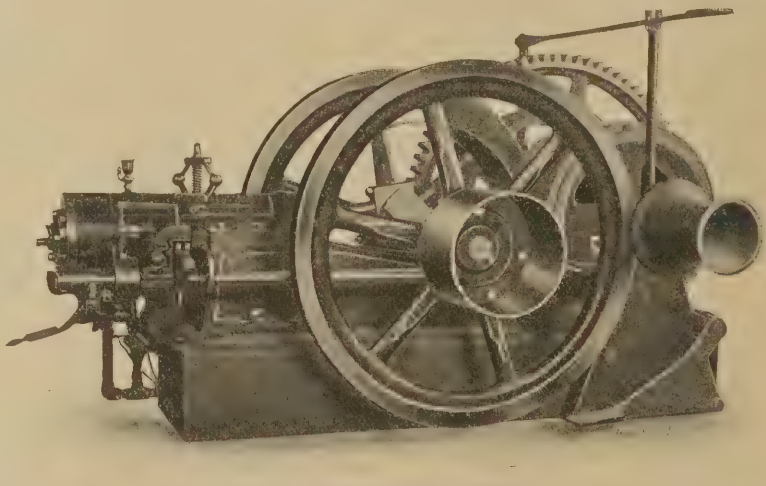

Fig. 3. Gasoline Hoisting Engine.

NEW METHOD OF TIRE REPAIR.

A novel method of repairing automobile inner tube tires has been brought out recently by a European firm of tire makers, which is designed to avoid the troubles incident to the ordinary method of repairing punctures in inner tubes. When patches are applied with cement it appears that they will invariably loosen when run at high speed, and thus cause the deflation of the tire. The only way heretofore to make such a repair reliable has been to vulcanize the patch on the inner tube. The new method makes use of a rubber rivet, *A*, having a hollow stem. This rivet is pushed through the puncture, using a blunt punch for the operation as shown at *B*. After the rivet is in position, a shot such as used in shot-guns of about the size known as B or BB, is pushed through the stem until it reaches the bottom where, of course, it enlarges the stem to a considerably larger diameter than it is in the neck where compressed by the walls of the punctured tube. For large punctures it may be necessary to use a steel ball such as used in bicycle bearings. The result is that the rivet cannot become dislocated when in use without tearing off the stem or greatly enlarging the hole. Of course the under side of the rivet head is treated with rubber cement before being placed in position.

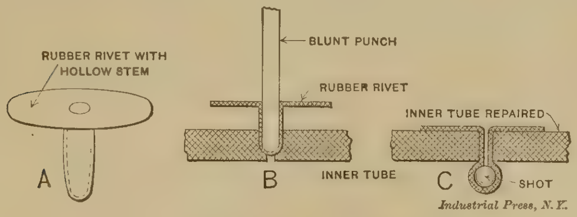

Fig. 4. Repairing an Automobile Tire.

OLD GEAR CUTTER—HISTORY JOHN STEPTOE SHAPER CO.

In the new shop of the John Steptoe Shaper Co., Cincinnati, Ohio, there is an old gear cutter that seems oddly out of place among the other modern machine tools, but is only kept as a relic, its work now being done by a modern automatic machine.

This cutter is of the type built along in the forties and fifties by the Putnam Machine Co., of Fitchburg, Mass., but whether they were the makers of this particular machine is not evident since there is no maker's name on it. The index plate is fixed upon the vertical work spindle on which were mounted the blanks to be cut, which might be both spur and bevel, since the machine was originally adapted for both. The index plate is about three feet in diameter and contains fully 18,000 holes, all of which were probably laid out, and drilled without the aid of a jig. The outer row contains 500 holes and there are 51 circles in all. The number of holes and the arrangement differ somewhat from the old Putnam gear cutter of the same type illustrated in the October, 1897, issue of MACHINERY. That machine had 468 holes in the outer circle and 52 circles, making a total of 15,690 holes. As stated, the machine is retained as much for its association with the past as any other reason, the John Steptoe Shaper Co. being the oldest machine tool builders west of the Allegheny Mountains. In this connection it may be of general interest to give a short history of the concern which was written at our request:

"The history of the company begins when, in the year 1845 John Steptoe was running a small machine shop in this city, it being at that time the only shop west of the Allegheny Mountains building machine tools. Shortly after starting his shop, Mr. Steptoe took into partnership Mr. McFarland, at the time a patternmaker, and formed the firm of Steptoe, McFarland & Co., and manufactured machines of every description. At first the firm employed but three men, but the business steadily increased and, in 1860, Mr. Nottingham, a foundryman, was admitted to partnership, and Steptoe, McFarland & Co. increased their force and established their own foundry. It would not be out of place here to say that The John Steptoe Shaper Co. still have calls for repair parts for machines built at this time, which means that these machines are still considered worth repairing after forty or fifty years of service. In 1870 the partnership was dissolved and, as the demand for shapers was steadily increasing, Mr. Steptoe, operating under the name of John Steptoe & Co., went into the manufacture of this style of tool exclusively, and produced about fifty machines the first year.

"The business was carried on as above until February 25, 1888, when John Steptoe died. At his death the business came into the hands of George Oetting and Adam Lauther, who had been associated with Mr. Steptoe for some years previous. These parties carried on the business under the same name and on the same lines at the old place, until in the fall of 1902, they found their quarters too small for the steadily increasing business and erected a modern two-story factory on Colerain Ave., in the heart of the machine tool district of Cincinnati

"On January 1, 1903, the business was incorporated as The John Steptoe Shaper Company, and continued the manufacture of shapers exclusively; the management being in the hands of George Oetting as president, and Adam Lauther as secretary and treasurer, and a board of directors. This continued until August, 1903, when Messrs. Oetting and Lauther decided to retire from active participation in the business and disposed of a part of their interests to Messrs. A. L. Rich and O. H. Broxterman of The A. L. Rich Company, and Mr. Alexander Dom, formerly superintendent of the metal department of the Globe-Wernicke Co. for many years. These gentlemen took over the active management with Mr. Dom as president and Mr. Broxterman as secretary and treasurer, and the output to-day is from 500 to 600 shapers annually, ranging from 14 inches to 34 inches stroke. Each machine is manufactured from a complete set of jigs and templates and this system of manufacture, established by many years of experience has led to the training of specialists who produce a maximum amount of work in a minimum amount of time."

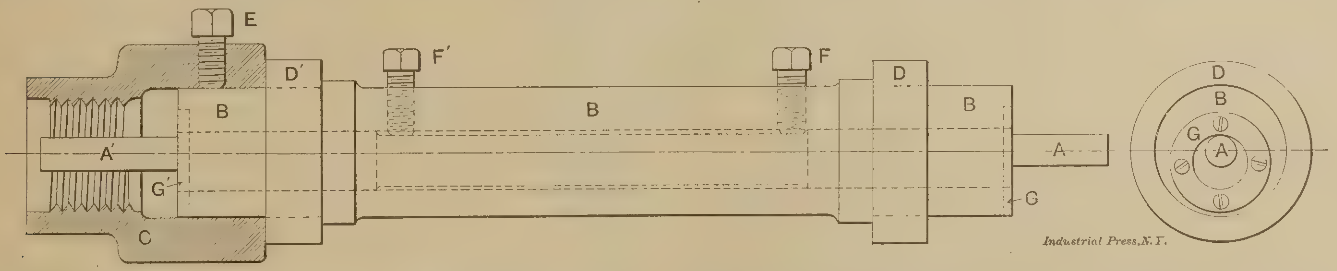
We may add that this concern having been in the machine tool business so long, might naturally be thought to have had an important influence on that industry in Cincinnati, and such is the case. Many of the members of the machine tool concerns in that city worked at Steptoe's and some served their apprenticeships there. In an old-time book still in the office of the company may be found the following prominent names: Mr. William Lodge, of the Lodge & Shipley Machine Tool Co.; Messrs. A. L. Smith and James Mills, of Smith & Mills; Messrs. Ed. Gang, William Barker, Thomas Chard, William Oesterlein and others whose product is well known wherever machine tools are used. Mr. Mills was Steptoe's foreman for over twenty years before going into business for himself.

* * *

CONTRIBUTED NOTES AND SHOP KINKS.

JIG FOR TURNING BACK GEAR SHAFTS.

C. A. Shafer sends a sketch of a fixture that is used for turning the eccentric ends of back gear shafts. These shafts are first turned and ground straight and are then placed in the fixture for turning the ends *AA'*. *B* represents the jig proper and *C* is a chuck, screwed onto the nose of the spindle, by which the jig is driven. *DD'* are hardened tool steel collars pressed onto the ends of the jig and ground to run in the steady rest. The setscrews, *FF'* hold the shaft in the jig and the screw *E* holds the jig in the chuck.

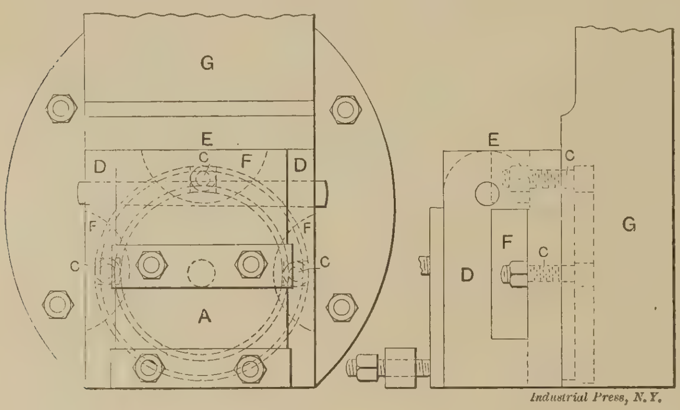


In use, the shaft is placed in the jig as shown, the collar *D* being supported in the steady rest, and the end *A* is turned to the required size, the eccentricity of the jig causing it to be turned eccentric with the main portion of the shaft. The entire jig with shaft in place is then removed from the chuck and turned end for end so that the collar *D'* runs in the steady rest, and the end *A'* is turned in the same manner as *A*.

GG' are tool steel washers inserted in the ends of the jig for the purpose of forming length gages. The end view shows the relatively eccentric positions of the different parts of the jig.

AN IMPROVED FORM OF PLANER APRON.

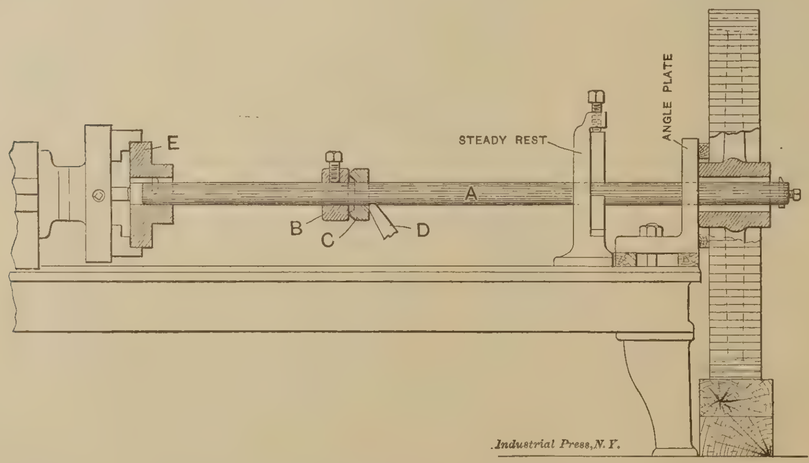
A. D. K. sends a sketch illustrating a form of planer apron which he has found to have considerable advantage over that which is ordinarily furnished. This form is in use by the company with which he is connected and has been furnished, to their specifications, by several of the leading manufacturers of planers. The apron box *D* is cut straight at *E*, doing away with the usual fan-shaped piece with two screws to hold the box in position. On the three sides *F F F* are slots large enough for permitting a wrench to grip the nuts of the bolts *C C C* which travel in a circular T-slot cut in the head *G*. The block *A* is hinged in the box *D* in the usual manner. This style of apron is very stiff and can be swung completely around, which will be found very handy when cutting angles of over 45 degrees and also for jobs of undercutting, such as the guides on the under side of a lathe bed, which can be done without any special fixtures or tools.



Industrial Press, N.Y.

BORING A 42-INCH GEAR ON A 16-INCH LATHE.

A. Putnam sends a sketch of the method by which he was able to bore out the hub of a 42-inch cast gear when the largest machine available was a 16-inch engine lathe. This is a sample of the kind of jobs that are sometimes encountered in remote districts—in this case a Western mining locality—and is a good illustration of the ways and means that some of our ingenious mechanics have to scheme to perform work that would completely phase a machinist of the modern school.



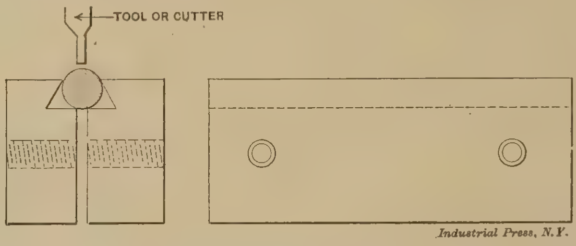
Industrial Press, N.Y.

The casting was bolted to the end of the lathe by means of an angle plate so that its center would be on a line with the center of the lathe, the weight of the casting being borne by means of blocking on the shop floor. The boring bar, *A*, was supported in the steady rest as near to the gear as the angle plate would allow, and as the cuts were light the spring of the bar was not sufficient to prevent obtaining satisfactory results. In the faceplate chuck was placed a shaft coupling, *E*, that chanced to be at hand, bored to the same diameter as the bar, which was a piece of cold-rolled shafting. In the end of this bar was driven a hardened pin which fitted a keyway in the coupling and thus furnished a drive for the bar. In the other end of the bar a boring tool was inserted in the usual manner.

A collar *B* was firmly fastened on to the bar at about the center of its length and against this bore a loose collar, *C*, having its edge turned down to reduce the friction. Against this second collar was placed a round pointed piece of steel, *D*, which was carried in the tool post, so that as the carriage was fed along by the regular lathe feed the boring bar was fed through the gear casting.

SPECIAL VISE JAWS FOR PLANING KEYWAYS.

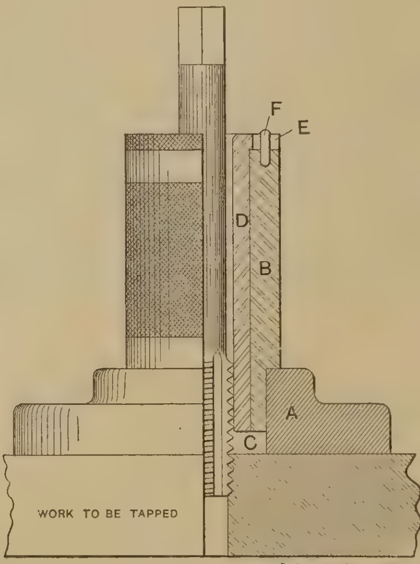
The accompanying sketch, contributed by "A. P.," shows a pair of special vise jaws for use on the shaper or milling machine for holding small, round stock so that it will lie parallel with the vise when planing or milling keyways. The sides of the dovetail should make an angle of about 60 degrees with the bottom, and the thickness and height of the jaws will be regulated by the vise with which they are to be used.



Industrial Press, N.Y.

A TAPPING JIG.

R. A. Lachmann contributes a sketch and description of a combination jig and bushing for tapping holes perfectly true without the necessity of using a square for starting the tap. This jig consists of a base, *A*, made of mild steel or cast iron, the bottom being of any shape that is suited for use on the pieces that are to be tapped. Into this base is fitted the standard, *B*, leaving a clearance space between its end and the face of the base, as at *C*, in order to allow space for burrs thrown out by the tap. Fitting this standard are a set of bushings, *D*, made of suitable sizes for guiding the different sizes of drills that are to be used. These are a good sliding fit in the standard and are all slotted at *E* so as to fit over a small pin, *F*, which prevents them from turning when in use. Any number of bushings may be made for use with a single base, but two or more bases, one for large and one for small sizes, should be provided so as to be better suited to the size of the work. If this jig is held down firmly onto the face of the work it will insure the tap starting straight, and when it is once started the jig may be removed. This arrangement makes it possible to tap holes perfectly straight with but little care and also prevents breakage of taps, especially when using the smaller sizes.



Industrial Press, N.Y.

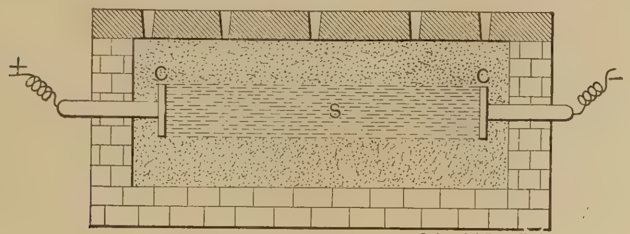
HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

10. A. H. L.: Will you please explain the construction and use of electrical furnaces?

A. An electric furnace, as the name implies, is one in which the heat is produced by the electric current. The general principle involves the formation of an arc between carbon electrodes, and the substance to be treated is exposed to the heat thus produced. Electrical furnaces are used mainly for metallurgical purposes such as the reduction of aluminum and silicon. The sketch shows, diagrammatically, the general arrangement of electrical furnaces which are, of course, more or less modified to suit the conditions. The space in which the reduction takes place is that between the carbon plates, *C C*, which are connected to the electric terminals as shown. In this space is placed the substance to be treated, *S*, while the space above, below and around the sides is packed with powdered carbon or other non-conducting substance. The walls are of fire brick and the cover of fire clay provided with vent holes.



Industrial Press, N.Y.

11. G. A. H.—Kindly tell a reader of MACHINERY how to drill holes in glass.

A.—You do not state what size holes you desire to drill. The best method for drilling holes of medium size is by means of the sand blast and for small holes by the use of a black diamond drill. The black diamond can also be employed for large holes, if several cutting points be inserted in the end of a tube, the tube used as a trepan. As neither of these methods may be convenient for you to adopt, you may have to resort to the old plan of using a very hard drill, lubricated with turpentine. When the drill is about to break through the glass, turn the glass over and drill through from the other side, meeting the first hole. Or if it is not convenient to turn the glass over, clamp a piece of cast iron against the glass, where the hole is to come through, and drill through the glass into the iron. If the iron fits the glass closely the drill will not chip the edge of the hole to any extent in breaking through. It is a good plan to put a sheet of paper between the iron and glass, as this will tend to compensate for any irregularities in the surface of the glass and make better contact with the iron. For holes of medium size you can use a brass or copper tube for drilling, with some abrasive like carborundum or emery to do the cutting. Guide the tube by means of a bushing, so it will run true and stand square with the face of the glass, and rotate the tube at high speed. Allow the abrasive to work under the edge of the tube, and lubricate with water.

12. S. H. S. asks for information regarding the components of the different brands of self-hardening steels and also for an explanation of the Harvey and Krupp processes for hardening steel plate.

A.—1. Most of the self-hardening and high-speed steels are composed of practically the same components, but the percentages of each, and the manner in which they are combined, form trade secrets, which are carefully guarded by the manufacturers. In "Iron, Steel and other Alloys," by Henry M. Howe, the composition of the good self-hardening steels of the present time is given as between the following limits:

Carbon	0.40 to 2.19 per cent.
Chromium	0.00 to 6.00 per cent.
Tungsten	3.44 to 24.00 per cent.
Silicon	0.21 to 3.00 per cent.

The present tendency appears in the direction of replacing the chromium, of steels for high-speed cutting tools, with from 1.25 to 4 per cent. of manganese. 2. Regarding the two processes of hardening plate we quote from the same work: Much of the heavy armor in use is made of nickel steel initially containing so little carbon that it cannot be hardened and remains very ductile even after cooling. The face of these plates is given the intense hardness necessary by being converted into high-carbon steel and then hardened by sudden cooling. Harvey carburized the impact face to a depth of about an inch by heating the plate for about a week to a temperature of 1,200 degrees C. (2,192 degrees F.) with that face strongly pressed against a bed of charcoal. The Krupp process carburizes the impact face by exposing it to illuminating gas at a high temperature. This is decomposed by the heat and deposits on the face of the plate a layer of fine carbon which is absorbed by the steel, as in the cementation process. In either case the face thus carburized is cooled suddenly from a red heat by spraying with iced brine. An intensely hard surface results, decreasing gradually from the face inwards.

13. A. H. G. writes: I desire to make a special study of power and its application, with a view of some day operating and owning power plants. Would it be a good plan to work where I could study and get well enough acquainted with steam engines, their construction, etc., to obtain an engineer's license, and thus get into some power plant? What do you advise as the best course to pursue, both practically and educationally?

A. It is difficult to advise you without knowing what your experience (if any) has been as a machinist, what your technical education has been, and how many years you feel that you can devote to preparation. On general principles, about the best preparation can be obtained in an engine building shop, provided a man is fortunate enough to secure work on the erecting floor and later is able to go out to assist or superintend the erection of engines. If this is not feasible, the next best course to pursue is to at once secure work in an engine room. In any case one should secure all the technical education possible, either by evening or day study; and if you can afford time it would, of course, be desirable to take at least a two-years' technical course at some good school before starting in with the machine shop or engine room experience. A number of schools have good two-year courses that would familiarize one with the various types of steam engines and the principles of steam and its use. There are a great many good books on steam and the steam engine, and many which are not good. For elementary works we can recommend Low's "Power Catechism," price $2.00; Ripper's "Steam," price $1.00; Peabody's "Steam Engine Indicator," $1.50; Spangler, Green & Marshall's "Elements of Steam Engineering," $3.00. For more advanced books, Jamieson's work on the steam engine, price $2.50; Meyer's "Steam Power Plants," $2.00; Peabody & Miller's "Steam Boilers," $4.00. You should also study books on electricity, and we can recommend the following: Swoop's "Lessons in Practical Electricity," $2.00, and Rosenberg's "Electrical Engineering," $1.50, which are excellent elementary works. For advanced books on this subject, Selden's "Dynamo-Electric Machinery," price $2.50, which takes up direct-current; and Selden & Mason's "Alternating-Current Machines," price $2.50.

The Lorenz globoid worm gear, made in Berlin, Germany, is attracting some attention in Europe because of its good efficiency and wearing qualities. From the meager description at hand it appears to be a modification of the Hindley hour-glass type, or perhaps an improvement of same in the matter of manufacture. In the making of the globoid worm gear proper, the worm is first cut by means of a cutting tool swinging in a circle, while the worm also turns about its axis. Lorenz has inverted this process and first forms the wheel teeth with a simple cutting tool, afterward cutting the worm so as to fit the wheel teeth as closely as possible.

* * *

In the August issue of MACHINERY the address of Reinecker Bros., builders of the German worm-milling machine there illustrated, was wrongly given as Coblenz, Germany. It should have been given Gablenz, which is a suburb of Chemnitz, Saxony.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

OESTERLEIN UNIVERSAL DIVIDING HEAD.

Figs. 1 and 2 illustrate a new universal dividing head, for standard and differential indexing, that has just been placed on the market by the Oesterlein Machine Co., Cincinnati, Ohio. This head is arranged to make all divisions from 1 to 380, with the spindle in any position from horizontal to vertical. The differential indexing is obtained by connecting the index plate *A* and rotating it, in a certain ratio, with the crankshaft *B*. This shaft is connected to the spindle by worm gearing and consequently both spindle and index plate revolve in the same or opposite directions in accordance with the divisions that are to be obtained. The principle of differential indexing has recently been thoroughly explained in these columns and its application to this particular head is illustrated in Fig. 2, which shows the arrangement of gearing when set for making 107 divisions.

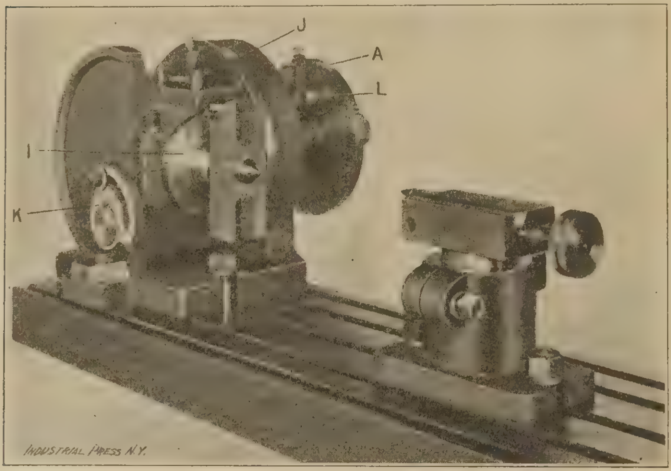


Fig. 1. Oesterlein Universal Dividing Head.

The swivel head is fitted into the frame with taper shank and is held in position by the clamping plate *C* and nuts. For quick spacing a dividing plate *I*, having 24 divisions, is fitted to the front of the spindle, the index pin is operated by the crank *J*, and the whole is enclosed and protected from dirt. When this is in use the worm is disengaged from the spindle by means of an eccentric bushing *K* which can be reengaged by pushing against a stop without adjusting. The crankshaft *B* has secured to its outer part a worm *D* which engages a worm wheel on a shaft running in the bracket *E*. The index plate *A* rides loose on the crankshaft and is connected by proper gearing, for spiral cutting with the table screw and for differential indexing with the wormwheel spindle. The index plate is graduated on its face for the purpose of setting the sector to the desired position by degrees in place of counting the number of holes, a table being furnished for this purpose. For standard indexing requiring delicate adjustment of the spindle, the index plate can be rotated by means of the thumbscrew *L*, placed back of the plate. When the head is used for standard dividing, the bracket *E* may be readily removed. The front end of the spindle is threaded and has a taper hole corresponding to that of the machine spindle. The head swings 11 inches and can be locked without throwing it out of adjustment. The tailstock has a vertical adjustment of 2 inches.

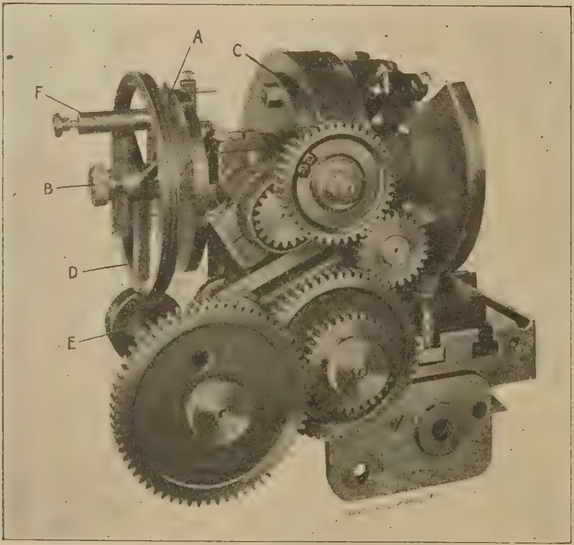

Fig. 2. Oesterlein Dividing Head set for 107 Divisions.

SPECIAL AUTOMATIC MILLING MACHINE.

The half-tone, Fig. 1, illustrates a very interesting machine built by the Newton Machine Tool Works, Philadelphia, Pa., which is a new departure in the milling machine line and is designed to adapt itself to a very peculiar operation. In the work to be milled the cut is very light at the start but increases gradually until near the finish and when the end is reached the cut is very heavy. The machine is also required to stop its feed at an exact point. The milling cutters used on the work are about 6 inches in diameter, and when they reach the finish about one-half of the cutter is in the cut.

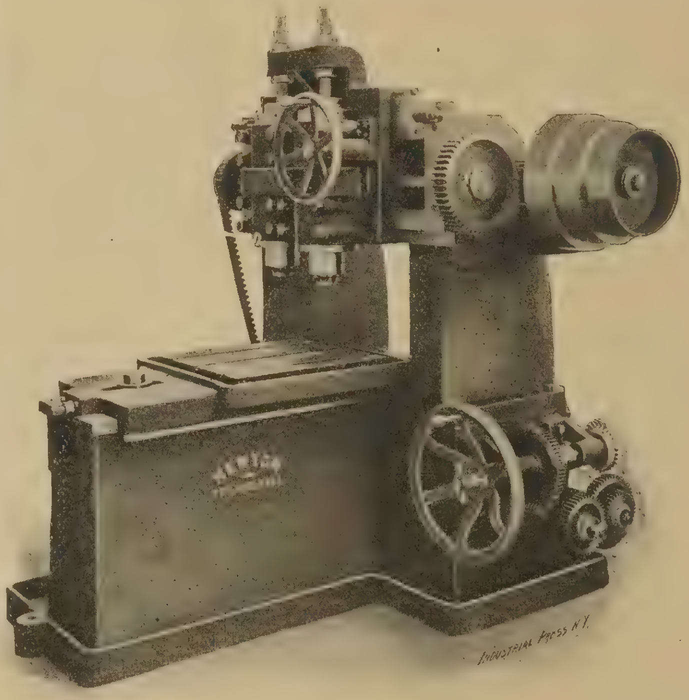

Fig. 1. Newton Special Automatic Milling Machine.

The difficulties of making any automatic trip stop that will operate at an exact point will be readily appreciated, and it is quite a complication of feeds that would be required to produce the result desired, that is starting off with a fast feed and gradually reducing until finally coming to a dead stop at the finish. So the machine was designed to employ a crank feed by which the required results are very satisfactorily accomplished.

Primarily this machine is a heavy vertical spindle miller having two spindles, both of which are mounted on one saddle and have an adjustment vertically for convenience in setting to the work. The ends of the spindles are threaded so that cutters can be fitted to the nose, but only one spindle is in operation at a time, as one is used for the roughing cutter and one for the finishing. When the head is over against one of the stops the roughing cutter is in the center, and when the roughing cut is completed, the saddle, carrying both spindles, is moved across the rail by hand wheel to the other stop, which brings the finishing cutter in exactly the same position.

The feed of the machine, which is more clearly illustrated in the drawing, Fig. 2, is through a silent chain drive and two sets of gearing with a shove pin to give a quick change of feed from the roughing to the finishing cut. Driven through a train of gearing is a large wormwheel which acts as a crank, carrying the connecting rod which is coupled to a crosshead on the front of the carriage, this crosshead having a screw on the front end, for convenience in adjusting carriage and connecting rod. It will be seen that this feed must necessarily be at its fastest when the crankplate is on one quarter of a turn, (the position shown in the drawing) and this will gradually decrease until it gets to the turning point when it starts to reverse, thus producing the result which is necessary on the work. The length of feed is varied by shifting the crankpin across the face of the crankplate, a screw and nut connection being provided for this purpose. As the material to be milled is steel the entire machine is set in a pan to provide for the heavy lubrication that is necessary on this work.

FELLOWS GEAR SHAPER WITH ELECTRIC MOTOR DRIVE.

The accompanying photograph illustrates the Fellows gear shaper as it has recently been arranged for individual motor drive. The only change necessary was the casting of a plate to span the pillow blocks of the regular driving gear to afford a support for the motor, and the substitution of a sprocket wheel for the cone pulley used with belt drive. With these alterations a standard form has been evolved as shown in the illustration. A 5 horse power, semi-inclosed type motor manufactured by the Crocker-Wheeler Co., Ampere, N. J., supplies the power, transmitting it, with a reduction in speed, through a Renold silent chain to the spindle which normally holds the cone-pulley. The speed is further reduced through either of the two regular gear combinations which are used alternately, making two speeds possible mechanically. In addition the motor is supplied with current on the Crocker-Wheeler four-wire multiple voltage system giving it six independent speeds, and with the use of resistance twelve intermediate ones. The upper ten of the motor's eighteen speeds constitute its working range, within which, through the faster gear combination it drives the ram at from 45 to 94 strokes per minute, or with the slower gear combination, 20 to 43. The lower eight available motor speeds may be used to extend the range down to six strokes per minute, though 20 is the minimum in ordinary practice. The machine is capable of cutting external gears up to 36 inches in pitch diameter by 5 inches face and internal gears 28 inches in pitch diameter by 3 inches face, allowing any diametral pitch up to four.

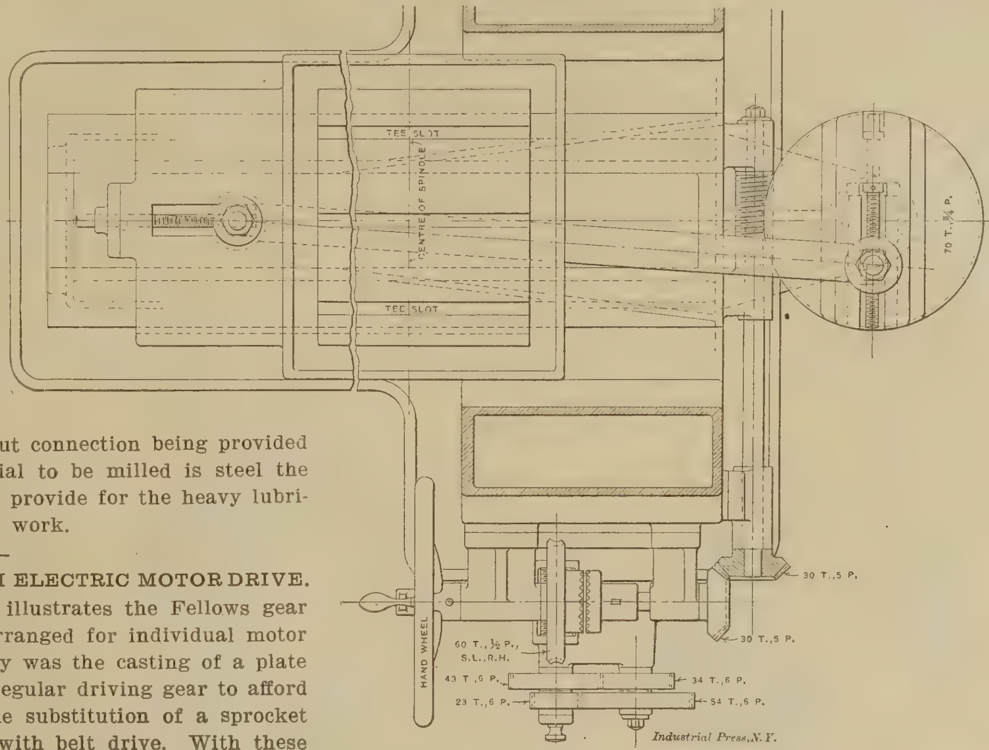

Fig. 2. Detail of Feed for Special Automatic Milling Machine.

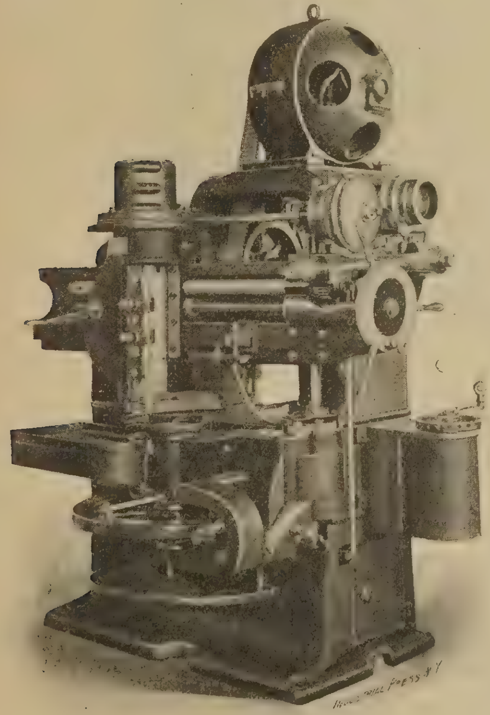
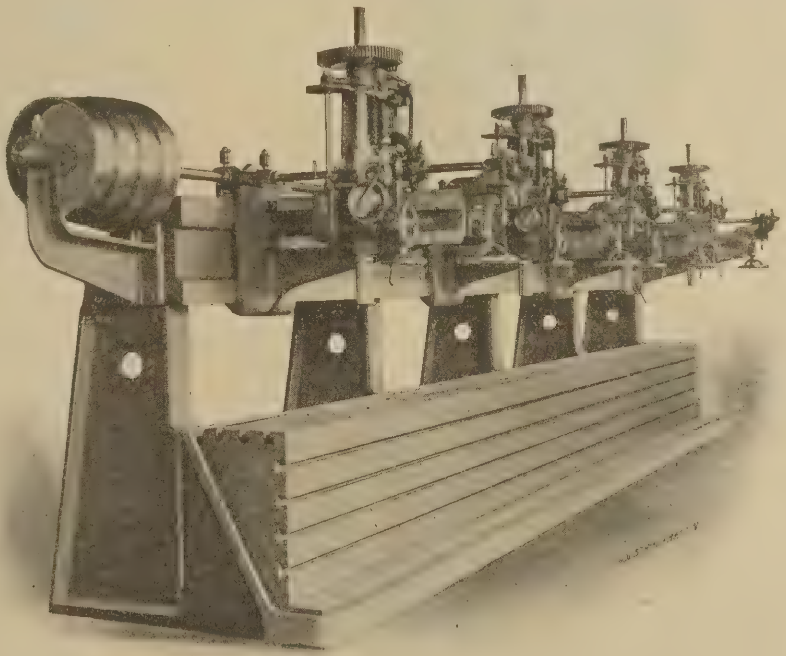


Fellows Gear Shaper with Motor Drive.

LOCOMOTIVE FRAME DRILL.

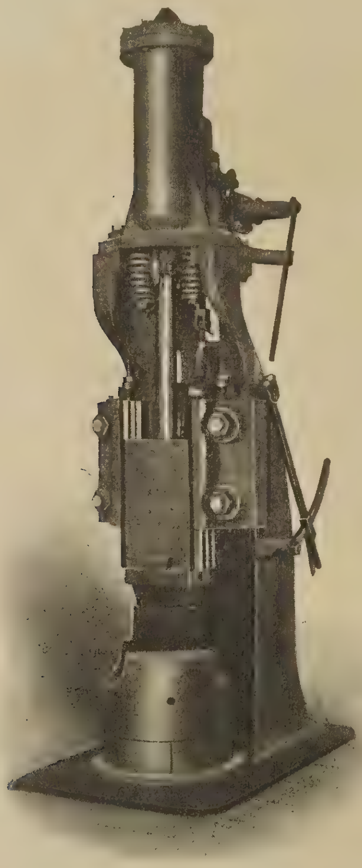
The four-spindle drill shown in the accompanying halftone has been designed and built by the Bickford Drill & Tool Co., Cincinnati, Ohio, from specifications submitted by the Locomotive and Machine Co., Montreal, Canada. This machine is used for drilling, reaming and tapping the sides and edges of locomotives frames up to 27 feet 3 inches between holes.



Four-spindle Locomotive Frame Drill.

The arms are made in pipe section and are adjustable on the rail by either hand or power. One of these is made to rotate through an angle of 30 degrees. The spindles have eight changes of speed ranging in geometrical progression from 49 to 120 revolutions per minute and are provided with both hand and power feed, quick advance and return, safety stop, automatic trip, dial depth gage, and hand lever reverse. The back gears are located on the head, bringing the power directly to the work and may be engaged, disengaged, or thrown out of service while the machine is running, the operator not having to reach the shifter in order to stop the spindle.

The depth gage answers a double purpose since, in addition to its use by the operator for reading all depths from zero—thus obviating the necessity of scaling or calipering—it supplies a convenient means for setting the automatic trip, the graduations showing exactly where each dog should be set in order to disengage the feed at the desired points. The automatic trip operates at as many different points as there are depths to be drilled at one setting of the work and in addition it leaves the spindle free, after any intermediate tripping to be advanced, raised, or traversed its full length without disturbing the setting of the dogs. It also throws out the feed when the spindle reaches its limit of movement.



Eight Hundred pound Double-acting Steam Hammer.

The feeding mechanism furnishes eight rates of feed ranging in geometrical progression from .007 to .064 inch per revolution of the spindle, all of which are instantly available without shifting a belt or operating under a feed of unnecessary fineness. The tapping mechanisms are located on the head and are fitted with friction clutches operated by levers the handles of which extend around under the arms within convenient reach of the operator. The spindles have a vertical adjustment of 17 inches and operate over an area of 2 feet 4 inches wide by 27 feet 3 inches long. The table has a width of 18 inches and is 29 feet in length. This machine weighs 49,000 pounds and is driven by a 5-inch high-speed double belt.

EIGHT HUNDRED POUND DOUBLE-ACTING STEAM HAMMER.

The new double-acting steam hammer which is illustrated herewith has recently been placed upon the market by the Bethlehem Foundry & Machine Co., South Bethlehem, Pa. The piston rod and head of this hammer are made from one solid steel forging and the ram is a steel casting, running on V-shaped guides which are adjusted for wear. The piston head can be raised above the top of the cylinder without removing the rod from the ram, permitting an examination or replacing of the rings. The piston is steam cushioned on top to prevent it from striking the cylinder head. The valve motion is automatic and of simple construction, employing a balanced valve of the piston type which moves very easily. It is controlled by a single hand lever by means of which the operator can strike single blows of any desired force from the lightest to the full capacity of the hammer, or cause the hammer to strike a succession of blows automatically. The steam supply is controlled by a balanced throttle valve by means of a hand lever. The steam cylinder of this hammer is 8¼ inches in diameter and the stroke 24 inches. The falling parts alone weigh 800 pounds while the weight of the hammer complete is 14,000 pounds.

BULLARD BORING AND TURNING MILL.

Fig. 1 of the accompanying illustrations shows a new form of boring and turning mill that has just been brought out by the Bullard Machine Tool Co., Bridgeport, Conn. This machine regularly has one fixed turret head and one swivel head, although two swivel heads can be supplied if required. The machine is driven from the side so as to permit the application of a constant or variable speed motor at any time that it may be desirable. The cross rail heads are operated by power, which is obtained by driving the vertical feed rods at a high constant speed from the overhead shaft, and at a variable speed through an independent feed box on the bed at the lower end of the rods. A lever which is movable in both directions from its normal position, operates a clutch mechanism in the bevel gears of the overhead bracket, giving the vertical rods a movement in either direction as desired, and driving the cross rail heads through the regular feed brackets on the back of the rail. When this lever is in its normal position the overhead clutches are disengaged and the feed works of the lower brackets are automatically engaged with the vertical rods. This makes it impossible for the quick traverse to become engaged at the same time as the feed works, and obviates the necessity for the operator to disengage the feed works before operating the quick traverse.

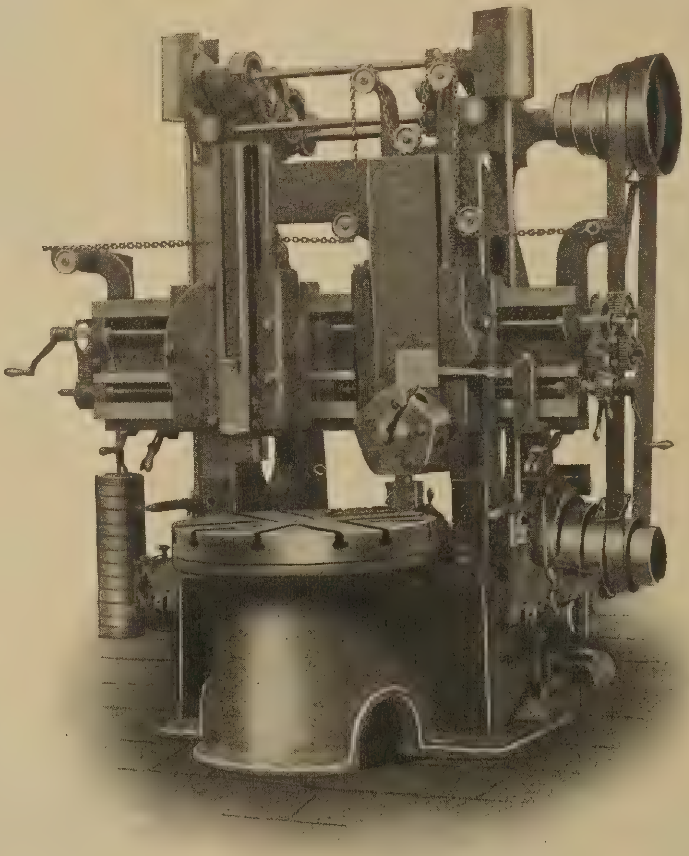


Fig. 1. Bullard 42-inch Boring and Turning Mill.

The feeds are positive, having ten changes ranging from

1-32 to ¾ inch horizontally, and from 1-50 to ½ inch in angular and vertical directions. In the cross rail bracket on each head the feed is engaged and disengaged by a toggle friction, operated by a hand lever, which not only provides a quick means of engaging and disengaging the feed but also answers for a safety device to prevent accidents in case of the heads being run together, either by the quick traverse or by the feed mechanisms. The right-hand head is provided with screw cutting gears that are entirely independent of the feed gears, so that it is possible to bore out a hole with as fine feed as required and then, without changing any gears, immediately chase the hole with any thread for which the machine is geared. The turret head is arranged to cut all standard threads from 2½ to 12 per inch.

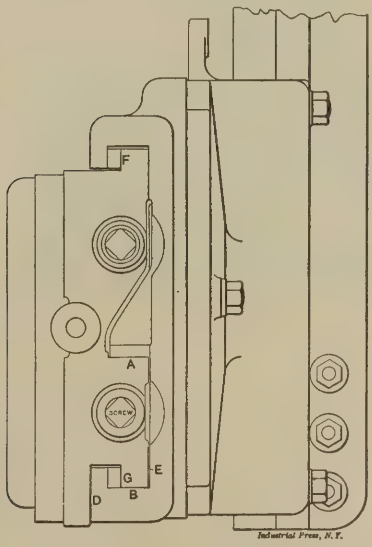

Fig. 2. Cross Rail of Bullard Boring Mill.

The design of the cross rail, shown in Fig. 2, shows the method employed for maintaining the alignment regardless of the severity of the duty required of the machine. The length of the bearing surfaces on the rail has been increased and the width narrowed, the horizontal alignment being obtained on surfaces *A* and *B* with the screw located as near central as possible. The saddle is gibbed back against the rail, receiving its thrust on the surface *D*, and does not bear on the surface *E* but is gibbed between surfaces *F* and *G*. It is of the square-locked type having no loose joints, taper steel gibs being used for taking up the adjustment. This same type of bearing is also employed for maintaining the alignment of the cross rail with the right hand upright, the left hand upright merely acting as a support.

The belt shifter enables the operator to shift the belt from one step to another without injuring his hands even when the machine is running at full speed. A foot brake is applied directly to the large step of the lower cone pulley and brings the table to a stop at any desired point. The counterweighting of the head is accomplished by passing the chain back of the center, where it will be out of the way of any tackle that is used for loading work on the table, and as the turret tools are likely to vary considerably in weight, small weights are employed for increasing or decreasing the counterweight.

The table spindle is of the regular type, the vertical thrust being taken on the angular bearing, which is 24 inches in diameter, and is entirely immersed in oil. The table has parallel slots for the reception of the Bullard spiral jaw chuck but a combination chuck can be fitted if required. The total weight of this machine is 14,300 pounds net.

SPRINGFIELD AXLE BORING LATHE.

Owing to the ever present liability of steel forgings to contain concealed flaws or "pipes" the plan has been adopted by the Pennsylvania Railroad of boring a two-inch hole completely through the center of all locomotive axles, thus affording a means of examination whereby any existing flaws may be detected. Such practice will be seen to present a considerable problem in deep hole drilling, as it must of necessity be accomplished in the least possible time. For this purpose, as well as for general bar and spindle boring, the Springfield Machine Tool Co., Springfield, Ohio, have designed and built the boring lathe illustrated in the half-tone herewith.

This machine has a capacity for boring holes from 1 to 4 inches in diameter, in bars up to 11 inches in diameter, and of any length up to 84 inches. The spindle is a large cast-iron shell having a three-jaw universal scroll chuck secured to a flange that is cast integral with the spindle. This construction will be clearly seen by reference to Fig. 2, which is a partial section through the spindle and driving cone. The bar to be bored is held in the chuck and, passing through the spindle, is supported at the other end by adjustable screws furnished for the purpose. The driving cone is mounted on an auxiliary shaft, placed above the spindle, to which it is connected by means of a pinion which engages with a gear cut into rear flange of chuck. Back gears are provided which, in connection with two speeds obtained from the countershaft, give sixteen boring speeds arranged in geometrical progression.

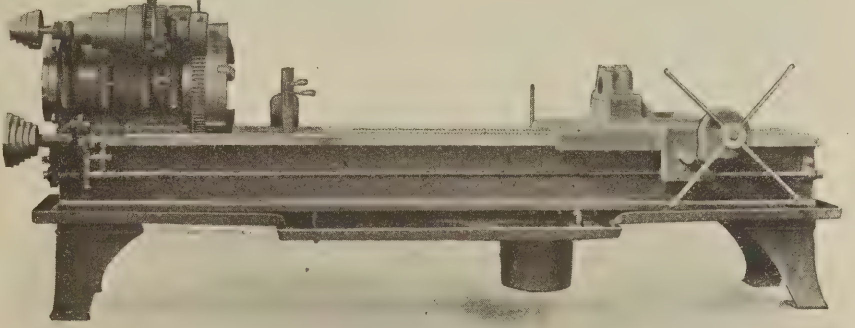

Fig. 1. Springfield Axle Boring Lathe.

A long carriage, which supports the drill and boring tool, slides on large V-s and is gibbed its full length to the outside of the bed. Two racks are provided, one on each side of the top of the bed, into which the pinions mesh, so that the feed is more steady than it would be if but a single rack and pinion, on one side of the bed, were used. The carriage may be rapidly moved into any position by the pilot wheel and the power feed is engaged with a powerful friction. With a five-step cone on the driving shaft, which makes 3¾ revolutions to one of the spindle, motion is transmitted to a feed cone geared to the feed rod in such manner that two speeds may be obtained from each cone step, thus giving ten rates of feed, ranging from .0005 to .01 inch per revolution of the spindle.

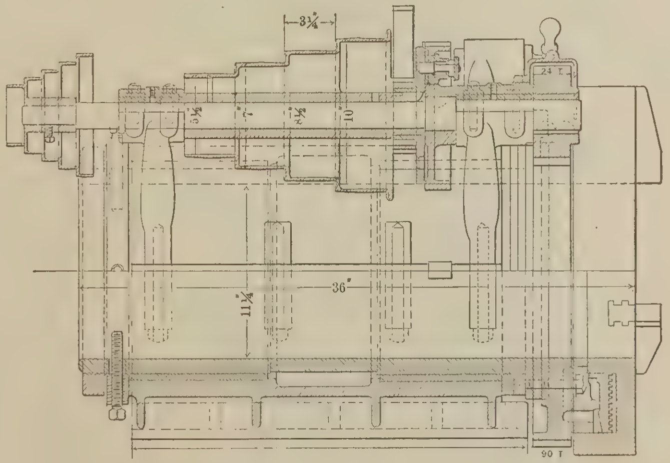

Fig. 2. Section through Head of Axle Boring Lathe.

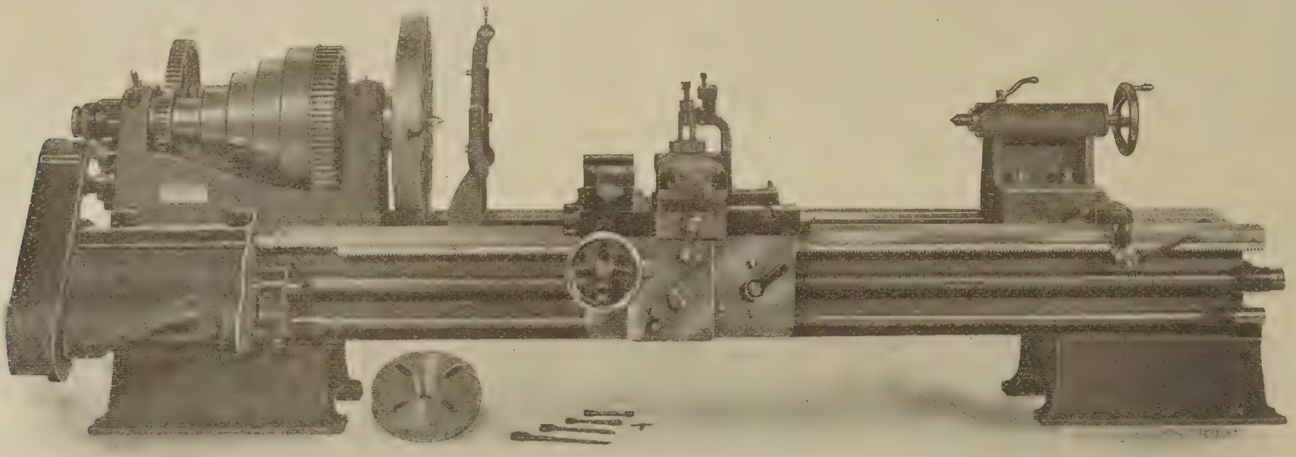
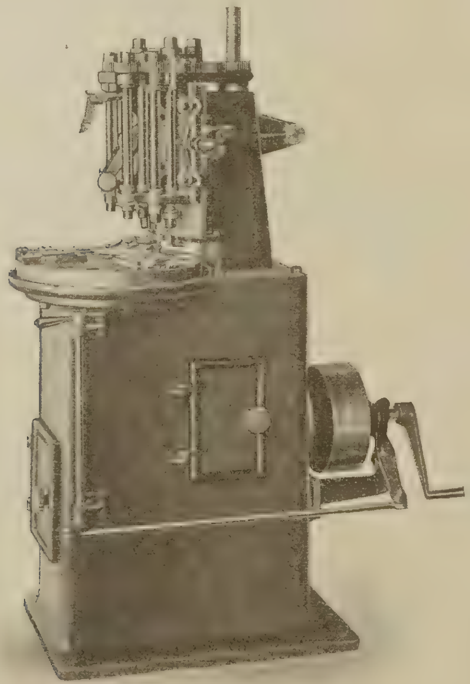
A force pump is supplied for lubricating the cutting edges of the drill and the machine is surrounded with a pan having an oil reservoir of ample capacity so that the lubricant has sufficient time to cool before it is used again. A guide is furnished for centering the tools at the beginning of the hole, but as soon as the hole is started this is swung out of the way.

NEW 32-INCH BANK-GEAR ENGINE LATHE.

The half-tone presented herewith illustrates a new 32-inch lathe just brought out by the Prentice Bros. Co., Worcester, Mass., which embodies several new and improved features of construction as relates to the apron, bank of feed gears and the method of putting on the feed rod and lead screw. As will be seen in the cut, the feed rod and lead screw stop at the end of the gear box. A bank of gears is mounted on a shaft, independent of either the feed rod or the lead screw but so arranged that it may be connected with either by means of a sliding gear, thus making it possible to cut 48 pitches, from ½ to 24, or to give 48 feeds. A tumbler gear connects the shaft, which takes the power from the head end of the lathe to any one of the gears in the cone. The different pitches are obtained by sliding the tumbler along, as indicated on an index plate, giving 12 changes thereby. There are, on the head end of the lathe, four other gears which can be changed and these in combination with the cone, make 48 pitches, there being 38 changes without any repetition. This lathe has a double apron and bevel gear drive and there is a device which obviates any chance whatever for both the feed and screw gearing to become meshed at one time.



Thirty-two inch Prentice Bank-gear Engine Lathe.

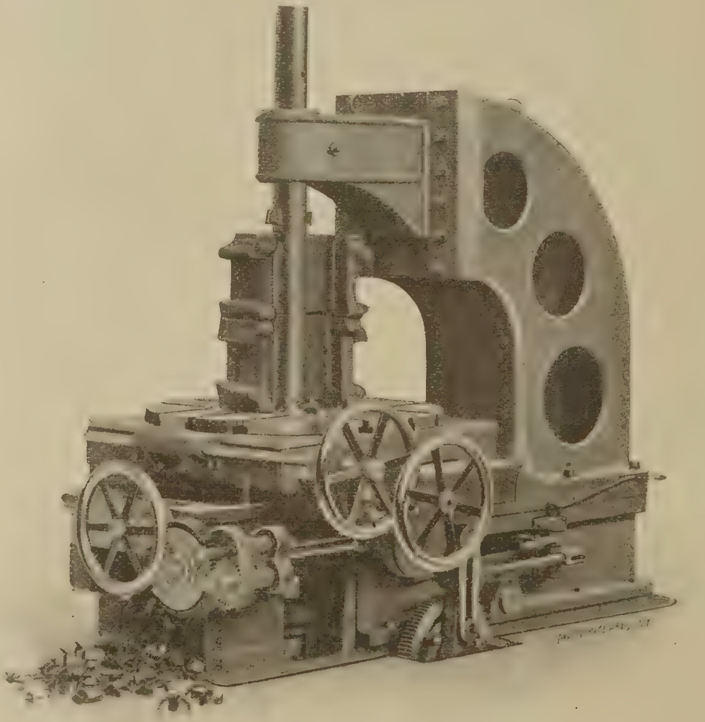


Rotary Platen Multiple Drill.

ROTARY PLATEN AUTOMATIC MULTIPLE DRILL.

The National Automatic Tool Company, Dayton, O., have just placed on the market a new machine for multiple drilling which is designed to meet the demand for a drill press of smaller capacity than their automatic turret drill which has previously been described in these columns. This drill performs practically the same class of work as the turret drill, but has only two clusters of drills instead of six. From four to ten spindles may be used in each cluster, and each spindle is adjustable in any direction. The idea of the double cluster is that one set of drills will drill and the other set may be used to ream or counterbore the same holes, or where two holes are drilled in close proximity, one hole is drilled with the first cluster and the next one with the second cluster.

The feed table, or platen, revolves automatically and may be indexed from two to six times. From three to six jigs may be mounted on the platen, and the operator, standing in front of the machine, simply loads and unloads the jigs as the platen revolves. The operation is thus continuous, two jigs being worked while the others are being loaded. The drills are automatically depressed to meet the work and the machine may be stopped instantly at the will of the operator. The spindles are gear driven, and each drill runs at its own proper cutting speed. The machine is adapted for drilling in steel, cast iron, brass or wood, three changes of feeding speed being provided. It is built in two sizes, the smaller having a capacity for drills from No. 60 wire gage up to ⅜ inch, and the larger taking drills from No. 60 wire gage up to ¾ inch.



Thirty-inch Draw-stroke Slotter.

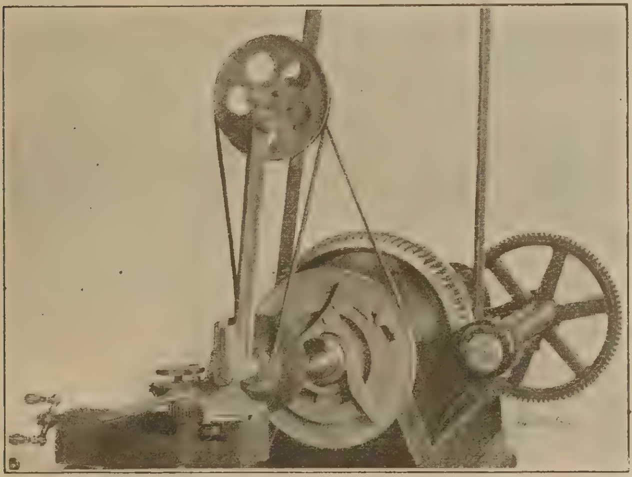
THIRTY-INCH DRAW-STROKE SLOTTER.

The accompanying half-tone illustrates a heavy slotter, acting on the draw-stroke principle, which, although originally designed for machining steel locomotive driving boxes, is equally adapted to a great variety of other slotting of castings and forgings, especially in long, deep holes, which cannot be reached by the ordinary type of slotter. It is also adapted to shaper work on the ends of long pieces of such irregular shape that it is impossible to chuck them in a planer, and in addition to these uses, it makes a very handy keyseater. The working table, which is 38½ inches in diameter, is placed low so as to be convenient to the operator. Full automatic feeds in all directions are provided, all of which are readily engaged from the front of the machine, all hand feeds being operated from the same position. The length of feed is adjusted from the right hand side of the machine.

The ram is rack and pinion driven through a heavy train of gearing and is counterbalanced. The reverse is accomplished by shifting belts, which are very wide and shift freely. The bar carrying the cutting tool can be of any shape or size up to 4½ inches in diameter, and one bar may be readily replaced by another by the substitution of suitable bushings. The support of the bar is very rigid, as it is fixed at one end by clamping in a long bearing in the driving ram, is supported by a bushing in the lower table directly below the work, and in a bushing in the upper arm directly above the work. The tool relief on the return stroke is secured by means of a clapper box in the cutter bar. This slotter is the product of Baker Brothers, Toledo, Ohio.

A NEW LATHE CENTER GRINDER.

One of the constant trials of the machinist is the necessity of keeping the lathe centers in good condition, and many styles of grinding attachments have been devised for accomplishing this end. The requirements of any such a device are, that it shall be simple in construction and easily placed in position and that it shall be of suitable mechanical construction to insure smooth grinding at an accurate angle. These conditions seem to have been met in the new center grinder illustrated herewith, which is the product of the Mueller Machine Tool Company, Cincinnati, O.

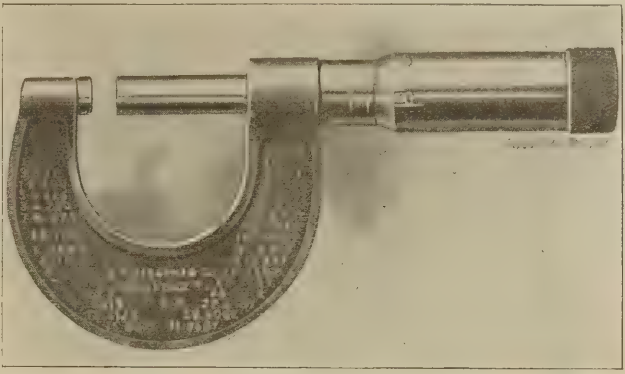


Mueller Lathe Center Grinder.

The pulley by which this attachment is driven is clamped to the nose of the spindle by a universal friction clamp so that marring or scoring of the spindle is entirely avoided. The base of the grinder is bolted to the tool block, its spindle being set parallel with the axis of the lathe by placing it between the lathe centers while setting it in the tool block. The upper part of the attachment slides on the base at an angle of 30 degrees with the axis of the lathe, and this upper part, carrying the wheel, is moved back and forth by a hand lever through the medium of a pinion and rack. The spindle is tapered for adjustment and is driven at about 1,600 revolutions when the lathe spindle is running 250 revolutions per minute. The driving is accomplished by two round belts, provision being made in the intermediate wheel stand for adjusting them to the proper tension. This attachment is also useful for light circular grinding, when it is then operated from an overhead drum. A rest attachment renders it available for sharpening saws, cutters, small drills, etc.

A NEW STYLE OF MICROMETER CALIPER.

The J. T. Slocomb Company, Providence, R. I., have just added to their line of micrometers and shop tools the one-inch micrometer shown in the photograph herewith. This instrument has a polished frame of I-section, and the space within the ribs is utilized for a full table of decimal equivalents—eighths, sixteenths and thirty-seconds appearing upon one side and sixty-fourths upon the other. These figures are raised from the surface by a new process, in a hydraulic press, a pressure of about three hundred tons being required. They therefore stand out very clearly, and together with the ribs form a very convenient finger hold as well as bearing the reference table of equivalents where it can be most easily referred to. It has also been noted that the compression of the steel makes the frames very materially stiffer. The other features of the instrument are practically the same as are embodied in the regular line of micrometers manufactured by this company.



New Style of Slocomb Micrometer.

A NEW BALL AND SOCKET HANGER.

A shafting hanger of new and novel design has been brought out by the Bantam Mfg. Co., makers of roller and ball bearings, Bantam, Conn. The hangers are planned to accommodate conditions met with in nearly all cases where shafting is employed—namely, shafting out of line, either through the settling of the building or through unequal belt pull tending to deflect the shafting between the hangers.

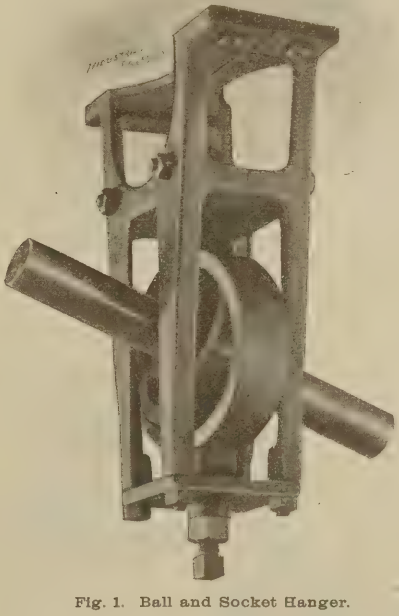


Fig. 1. Ball and Socket Hanger.

In Fig. 1 is a view of a hanger as it appears when suspended from the ceiling and the inclination of the short shaft which projects through the bearing shows to how great an extent this bearing can accommodate itself to the angularity of the shafting. The design of both the hanger and the bearing is along original lines. The frame consists of two main castings bolted together, and there are an upper and lower horizontal plate for the support of the bearing. A ball bearing is used and the parts of the bearing are contained within a ball-and-socket joint which allows the inclination of the shaft shown in Fig. 1. The ball-and-socket joint is formed by means of two rings, one of which is spherical outside and the other spherical inside. The outer ring is split in a vertical plane so that it can be fitted over the inside ring, and it has two trunnions by which the ring is pivoted to the upper and lower plates mentioned above. The joint in this ring passes through the trunnions, and the two halves of the ring are held together by two caps, one of which fits over each trunnion. These caps are held in place by setscrews. One of the setscrews is seen projecting below the hanger in Fig. 1, while the upper one passes through the upper horizontal plate. The runways for the balls are hardened and ground. The ring forming the internal runway of the ball bearing is bored large enough to accommodate a taper bushing which fits over the shaft, and by changing these bushings, which can be done very easily, each countershaft is adapted to several diameters of shafts without making any further change, and thus it is not necessary to have many sizes of hangers to accommodate all sizes of shafts. The manufacturers now make three sizes of hangers, which are sufficient for any ordinary plant.

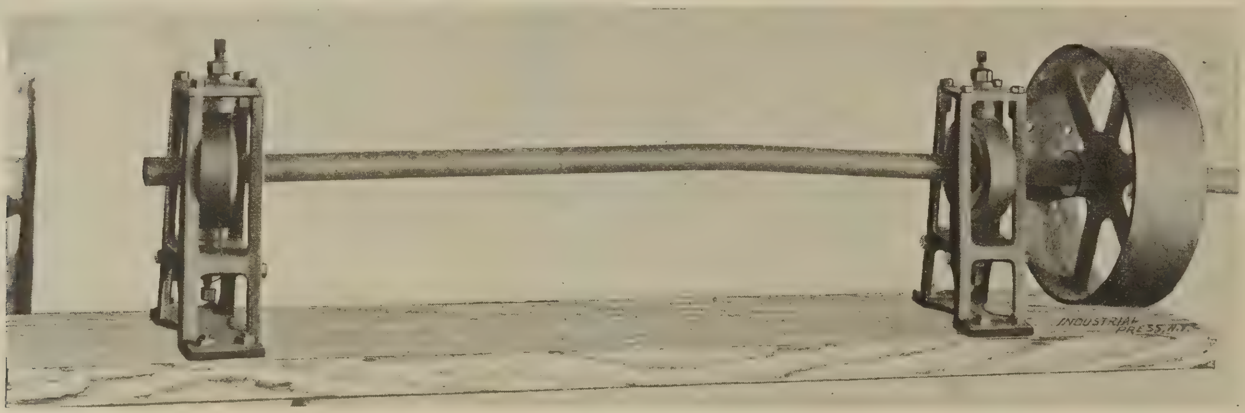

Fig. 2. A Pair of Ball and Socket Hangers being Tested with a Crooked Shaft.

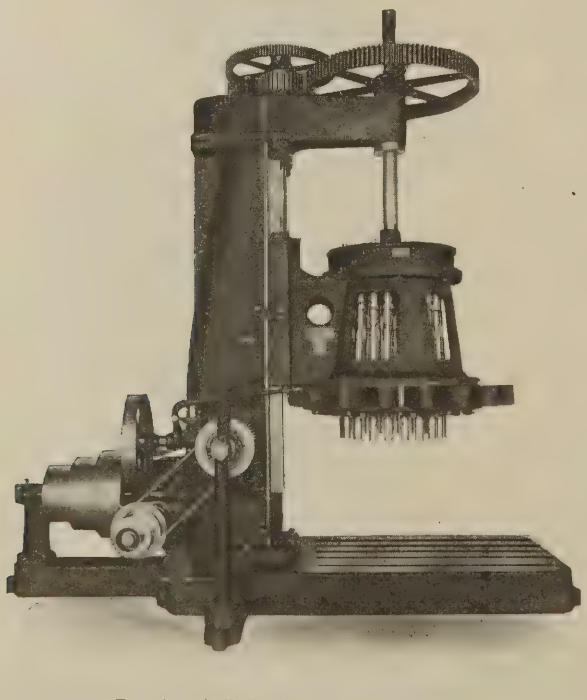
Fig. 2 shows two of the hangers mounted on a plank to test their ability to operate smoothly when supporting a very crooked shaft. A 1 7-16-inch shaft was bent as shown and was operated at 180 revolutions per minute with ease by means of a twine serving as a belt to drive the pulley. The conditions of alignment of the shaft were so bad that a belt would not stay on the pulley. We have received a photograph taken while this shaft was running, which, however, is not reproduced.

HIGH SPEED ADJUSTABLE MULTIPLE DRILL.

The accompanying half-tone illustrates a new twenty-spindle multiple drill that has recently been designed and built by the Baush Machine Tool Co., Springfield, Mass., for drilling valves at a high rate of speed. The machine is driven by a 7-inch belt and is provided with roller and ball bearings. The head is moved up and down on the post by a screw operated by an automatic feed and stop device, which makes it very easy to handle and rapid to operate, besides relieving the workman of much unnecessary handling. A quick return is also provided.

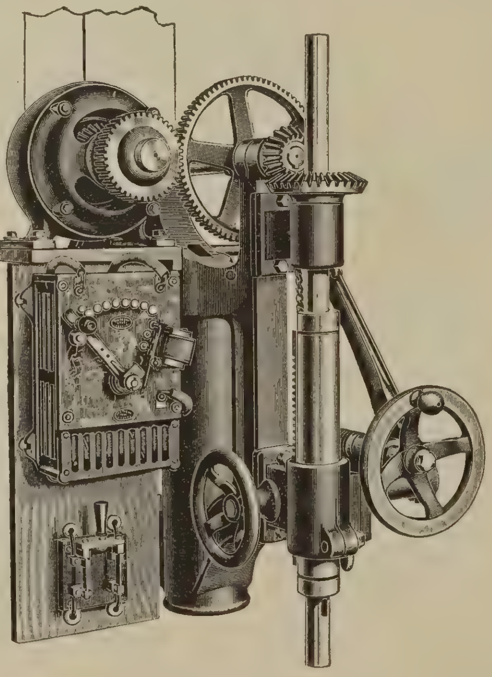


Twenty-spindle High-speed Multiple Drill.

High-speed tool steel drills are used in these machines with speeds ranging from 500 revolutions per minute for ½ inch drills to 175 revolutions for 1¾ inch drills, and with corresponding feeds of 3¼ and 1¾ inches per minute respectively. These speeds are based on a peripheral speed of 65 feet per minute. The feeds increase from 1 inch of feed per 150 revolutions to 1 inch of feed per 100 revolutions. The Bocorselski joint is used throughout for transmitting motion from the central spindle to the different drills. The total weight of this drill is about 23,000 pounds.

ELECTRICALLY-DRIVEN OVERHEAD DRILL.

A new electrically-operated, overhead drill has just been brought out by Boynton & Plummer, Worcester, Mass., which is designed to be placed on a beam or post so that work of any diameter may be brought under it. The spindle of this drill is counterbalanced by means of a weight in the frame, and has a vertical motion of 11½ inches. Both lever and worm feeds are provided, the worm feed being instantly engaged or disengaged by a small lever which raises the worm or lowers it into mesh.

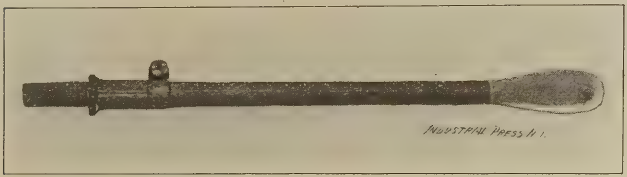


Overhead or Post Drill.

A shelf is attached to the side of the frame and on this is mounted a 220-volt, ½-horse power motor built by the Northern Electrical Mfg. Co., Madison, Wis. This runs at a speed of 900 revolutions per minute and carries on its shaft a rawhide pinion which meshes with the driving gear on the drill. Bevel gear connections, between the driving gear shaft and the splined spindle, give a maximum speed to the drill of 270 revolutions per minute. The illustration shows the arrangement of rheostat and switch which are so placed as to be convenient to the operator. The same drill may, if desired, be furnished with belt-driving pulley and the motor omitted.

THE DIAMO-CARBO EMERY WHEEL DRESSER.

One of the most expensive requisites of the tool room is the black diamond which is required for truing and shaping emery and other grinding wheels. In order to afford a means for doing this with a less expensive tool the Desmond-Stephan Manufacturing Co., Urbana, Ohio, have placed upon the market the emery wheel dresser which is illustrated below. This consists of a brass or copper tube which is filled, by a vitrifying process, with an abrasive of sufficient hardness to cut emery or carborundum wheels. On the outside of this tube is an adjustable collar, which is moved so as to form a back stop over the emery wheel rest. The dresser is then passed lightly over the surface of the wheel, which it trues or shapes to any desired form.



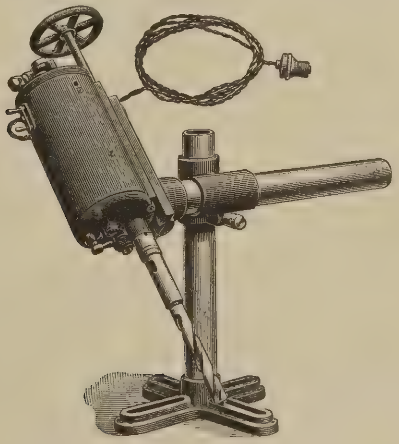
INDUSTRIAL PRESS N.Y.

Diamo-Carbo Emery Wheel Dresser.

PORTABLE ELECTRIC "SCOTCH" DRILL.

The accompanying engraving of a portable electrically-driven Scotch drill appeared in this department in the November number and is reproduced herewith, because the engraving was inadvertently placed with the description of another tool, without suitable title, so that it was not clear who manufactured the drill. This drill is made by the Hisey-Wolf Machine Co., Cincinnati, O. It has a capacity for holes up to ⅞-inch diameter, and a feed of 7 inches by the hand wheel.

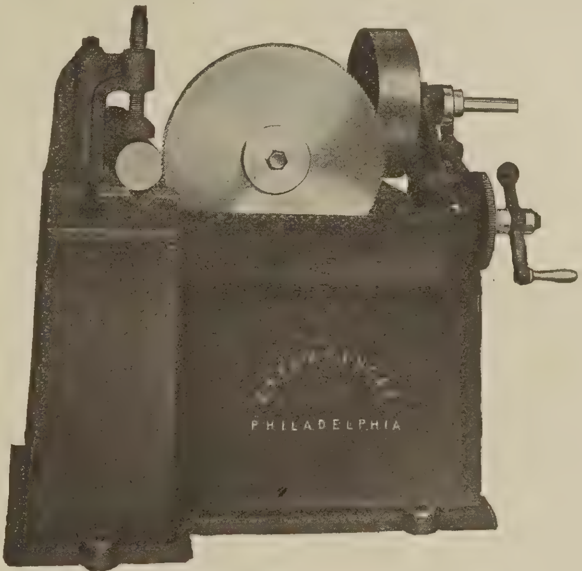
The adjustable bracket upon which the drill is mounted has a movement of 20 inches in any direction, making the machine universal. The drill has two speeds, the power being obtained from any incandescent lamp circuit where direct current is employed, the motor being wound for 110 and 220 volts. The motor is inclosed and dust proof and is suitably geared to develop the necessary power up to the capacity of the drill. The machine may be carried from point to point around the shop, its sphere of action being limited only by the length of the flexible wire connection. Its weight is 95 pounds and extreme height 30 inches over all.



Electrically-driven "Scotch" Drill.

COLD SAW CUTTING-OFF MACHINE.

A new cold saw cutting-off machine that has just been designed and built by the Espen-Lucas Machine Works, Philadelphia, Pa., is illustrated in the half-tone herewith. It has a capacity for cutting 4-inch round stock, and structural shapes up to 6-inch I-beams, at one cut. The saw has variable automatic feed, automatic safety stop, and swivel clamp on the platen for holding different shapes and sizes of material to be cut straight or at an angle. This clamp may, if desired, be entirely removed, allowing jig work to be placed on the table. The machine is driven by steel worm and phosphor bronze worm wheel running in an oil bath. The design of the machine is such as to occupy very little floor room but at the same time the materials of construction are so disposed as to give the unusual stiffness necessary for cutting the large sizes of stock for which the machine is built. Arrangement is made for carrying saw blades up to 14 inches in diameter.



Cold Saw Cutting-off Machine.

OBITUARY.

James N. Skinner, late superintendent of the Skinner Chuck Co., New Britain, Conn., died at his home in that city November 8. Early in his career Mr. Skinner served in the regiment of the Connecticut Volunteers during the Civil War, and later entered the service of the Government at the Springfield Armory. After this he was employed by the Howe Sewing Machine Co., of Bridgeport, and from there went to the works of the E. Horton & Son Co., at Windsor Locks, where he remained for fourteen years. It was while with this concern that he took out several patents on chucks, and in 1887, when the Skinner Chuck Co. was organized, he was elected superintendent and director of that company, a position which he held until his death. Mr. Skinner was well known as the originator of several inventions and of many improvements in the line of manufacture to which he devoted his life.

DECEMBER MEETING OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

The forty-eighth meeting of the American Society of Mechanical Engineers will take place December 1 to 4. At the opening session, December 1st, Mr. James M. Dodge, president of the society, will deliver the annual address, "The Money Value of Technical Training." The papers for the following sessions are as follows:

Wednesday morning, December 2, at 113 West 40th St.—"Is Anything the Matter with Piece Work?" by Frank Richards; "Modifying Systems of Management," H. L. Gantt; "Slide Rules for the Machine Shop as a Part of the Taylor System of Management," by C. G. Barth; "What are the New Machine Tools to be?" by John E. Sweet; "Suggestions for Shop Construction," by F. A. Scheffler.

Thursday morning, December 3, at Stevens Institute of Technology.—"The Pitot Tube," W. B. Gregory; "Method of Determining Rates and Prices for Electric Power," F. B. Perry; "Three and Four Wire Multiple Voltage Systems," Louis A. Gillet; "Test of a Compound Engine Using Superheated Steam," D. S. Jacobus; "The Pressure Temperature Curve of Sulphurous Anhydride (SO)," E. F. Miller; "Construction and Efficiency of a Fleming Four-valve Engine," Benj. T. Allen.

Friday morning, December 4, at the Society House, 12 West 31st St., New York.—"A Compact Gas Engine, Beam Type," C. H. Morgan; "Standard Unit of Refrigeration," J. C. Bertsch; "Series Distilling Apparatus of High Efficiency," W. F. M. Goss; "Air Motors and Air Hammers, Apparatus and Methods for Testing," Max H. Wickhorst; "Valve Motion of Duplex Air Compressor," S. H. Bunnell.

It has been decided to hold the spring meeting, 1904, at Chicago. This will enable members who intend to visit the Louisiana Purchase Exposition to make an easy journey to St. Louis, and will obviate the discomfort incident to a convention in a crowded exposition city.

TECHNICAL EDUCATION.

Louis Duncan in Engineering Magazine, November, p. 161.

The fault of our technical education in America is that it is too technical and that there is too much instruction. It seems to be the idea that the longer contact the student has with his lecturers or with his text books the more information he will obtain. It does not seem to be considered that information, as such, is not of great importance. It can be obtained easily and cheaply when occasion arises; and the end and aim of a technical education should be not to obtain information, but to apply it. We should not attempt to make mental storehouses of men, but mental factories.

Another thing is this: that to a large extent, the ability of a man to work out any specific problem depends on his being able to make a mental plot of the problem, and to keep it constantly before him. For instance, a railroad proposition for a city, presented to an engineer, involves an infinity of different considerations—the population of the different districts of the city, the character of the population, the growth, the franchises under which the road is to be built, the political complexion of the city government, the question as to whether the capitalists who are building the road intend to operate it or to sell it—these and a hundred other considerations must form part of the plan adopted. To take all these into account, to keep them constantly before one until the scheme works itself out, requires an imagination that has been developed and not suppressed. A large part of the work is done outside of any office—in street cars, at dinner—unconsciously to a certain extent.

I wish specially to emphasize this point. The amount of work done at desk or before a drawing-board is a very small proportion of the total work needed for a large engineering proposition. The successful engineers are those who can see the problem as plainly while they are walking on the street as they can see it on a blue-print.

I saw some time ago in one of the daily papers a discussion of the requisites for success in life, and some one, I think it was Mr. Cleveland, summed things up by giving as the three requisites—character, persistence, and intellect. The fact that intellect was placed third on the list surprised many people, but this is true. Suppose a brilliant man does a certain piece of work in a certain time; another man does the same work in twice the time; the first is usually considered has having about twice the intellect of the second, and by the ordinary definition of intellect, which emphasizes the time element, this is true. But any one with average brains can work out any reasonable proposition, provided he works at it long enough, and his ability, of which I have spoken—the ability to keep a proposition constantly in front of one, the quality of imagination—constitutes the difference between the finally effective man and the so-called brilliant thinker. Brilliancy is merely the time-factor of application. Newton said that his success was not due to the fact that he was smarter than other people, but to the fact that he thought more than other people.

In looking over the list of successful engineers (I am speaking now of electrical engineers, because I know very little of any other branch), we do not find that we can point to any one institution as having produced more successful engineers than any other in such a way as to make the difference marked. In fact, I am afraid that our largest and best equipped institutions do not show as fair a percentage of leading engineers as some of the smaller, poorly equipped colleges. I think this is due to two things; the first is that the larger institutions have presented courses including more instruction than can be given in smaller institutions, and I believe that at least half of this has done harm rather than good. The other cause is obvious, i. e., that in the smaller institutions the students are more directly in contact with the instructors, and that they do not have the facilities for work that the more ambitious colleges have; that is, when an experiment is to be tried, the ingenuity of the student, and not his patience, is exercised.

The power mechanism for the vertical traverse of cross-rails on planers and boring mills has generally been made to give the same speed whether going up or down. It is obvious that the power required when moving upward is much greater than when going down, but with the mechanism using the ordinary tumbler gears for reversing the direction of travel, it has not been easy to vary the ratio, consequently it has usually been made in a 1 to 1 ratio. If, however, a friction clutch is used for reversing the direction of vertical traverse, the ratio is easily made whatever good design would suggest. We believe the Cincinnati Planer Company was the first to do this regularly, their planers all being made with the ratio of upward to downward travel as 1 to 2. The King Machine Tool Company have applied the same idea on the new line of boring mills which they are bringing out. The plan of using friction clutches instead of tumbler gears has another advantage, and that is there is less racket, especially when spiral gears are used in the combination.

Commissioner Lindenthal of the New York Bridge Department announces that the new Williamsburg bridge (New York to Brooklyn) will be opened to pedestrians and teams about December 19. The approaches are rapidly nearing completion, and the bridge itself is finished save for minor details which will be ready by the time the approaches are done. It is not expected that street cars will run over it for some time as it has not yet been decided what company will be granted the privilege. The Brooklyn Rapid Transit and the Interborough companies are competing for it.

The great advance in the art of forming difficult metal shapes by heavy pressure is indicated by the organization of a company in Milwaukee, Wis. (the American Standard Steel Fitting Company), to make pressed steel pipe fittings from ordinary boiler-plate steel. These fittings will, it is said, be somewhat more expensive than cast iron, and about the same price as steel castings. Being seamless and non-porous such fittings should be superior to all castings, and, therefore, particularly acceptable in refrigerating plants because of the well-known difficulties of handling ammonia in extensive pipe systems without serious loss, due to defective fittings, etc.

* * *

FRESH FROM THE PRESS.

The Mechanical Engineers' Pocketbook, by D. K. Clark. Published in America by the D. Van Nostrand Company, New York. 690 pages. Illustrated. Price, $3.00.

This is a new edition of Clark's well-known English handbook. Mr. Clark died previous to its complete revision and Mr. H. H. P. Powles, an English engineer, is responsible for the corrections, revision and additions made necessary in bringing out this edition. The book is handsomely bound in leather, with round corners, and is very convenient for use.

Engineering Preliminaries for an Interurban Electric Railway, by Ernest Gonzenbach. Published by the McGraw Publishing Company, New York. Illustrated. Price, $1.00.

As the title indicates, this book of 71 pages is a review of the engineering preliminaries that should be considered in the projection of an interurban electric railway, which are taken up under the captions: Estimated Income, General Requirements, Third Rail vs. Trolley, Location, Roadbed and Track, Rolling Stock, Electrical Car Equipment, Car Shops, Power Stations, Transmission Line, Distributing System, Third Rail, Accessories, Estimate, Operation, etc.

Fowler's Mechanical Engineers' Pocketbook for 1904, edited by William H. Fowler, published by the Scientific Publishing Company, Manchester, Eng., and for sale in this country by the Derry-Collard Company, New York. Price, 60 cents.

This book has been added to from year to year until now it contains 450 pages of closely printed matter and has a great deal of valuable information upon all branches of mechanical engineering.

The policy of revising this book each year, and adding to it, has made it possible to keep it in touch with recent practice, and much information is gathered within its pages that is not available in any other one place. The index is unusually complete.

Compressed Air, by William Charles Popplewell. Published by the Scientific Publishing Company, Manchester, Eng., and for sale in this country by the Derry-Collard Company, New York. 285 8vo pages. Illustrated. Price, $3.00.

This is a new book treating of the theory and practice of pneumatic power transmission. There are descriptions of several types of air compressors or motors, and of the numerous compressed air tools that have been placed on the market during the past few years. There is also a brief treatment of air transmission and the efficiency tests of compressors and transmission system. The book is almost entirely descriptive, but one chapter being devoted to compressed air calculations.

Airbrake Catechism, by Robert Blackall, Airbrake Instructor and Inspector with Westinghouse Airbrake Company. 304 12mo pages and 98 illustrations. Published by Norman W. Henley & Son, 132 Nassau Street, New York. Price, $2.00.

An extended review of this book, which may be said to be the standard catechism of the airbrake, is not necessary; it is too well known to require it, having passed through seventeen editions. The present edition, the eighteenth, has been revised and brought thoroughly up-to-date. It is a complete study of the airbrake and signal equipment, and we are told that it has been endorsed and is used by nearly every instructor and examiner on the railways of the United States. Two large Westinghouse airbrake educational charts, each 14 x 50 inches, printed in colors, accompany each book.

Electric Railway Economics, by W. C. Gotschall. 252 pages. Illustrated. Published by the McGraw Publishing Company, New York. Price, $2.00.

This book is based on a series of lectures delivered by the author at Lehigh University upon the economics and preliminary engineering of high-speed and heavy traction interurban electric railways. The great interest that has been aroused in high-speed electric railways by the recent tests abroad and the strong probabilities of very extensive work in this line in the near future here, make any authoritative literature on the subject of timely interest and most acceptable to engineers and others. The work not only takes up the engineering features of survey and construction, but also treats of the organization of the operating department and the economic considerations determining the magnitude and details of the proposed road. Several folded diagrams and cuts are presented. The appendices give the specifications for a moderate-sized interurban road and a bibliography referring to important articles on high-speed and heavy traction that have appeared in some of the various technical journals.

Home Mechanics for Amateurs, by the late George M. Hopkins, of the editorial staff of the Scientific American. Published by Munn & Co., New York. 370 pages. Illustrated. Price, $1.50.

This is a companion book to the "Experimental Science" by the same author, which has had a very large sale. As the title of the book indicates, it is for the amateur, not for the workman who understands practical methods or who has practical work to do. In this country the amateur is mainly the American boy. Amateur work in wood and metal is not so popular here as in England, but nevertheless this book, which seems to be practical, will probably appeal to many, both old and young, who like to make knicknacks and all sorts of devices for use about the house, but who have not the practical knowledge necessary to either invent them or to make them without instructions from outside. The chapters are seven in number, taking up woodwork, household ornaments, metal work, model engines and boilers, meteorological instruments, telescopes and microscopes and electricity. Mr. Hopkins, the author, died just previous to the completion of the work, but he had given the proofs their final revision, so that the book is completely the work of its author.

Engine Tests and Boiler Efficiencies, by J. Buchetti. Translated by Alexander Russell, an English authority, and published in this country, by Norman W. Henley & Son, 132 Nassau Street, New York. 256 8vo pages. Illustrated. Price, $3.00.

The first hundred pages of this book are devoted to an explanation of the indicator and indicator diagram, with descriptions of several kinds of instruments, some of which are not entirely familiar to American readers. After this follow chapters on testing gas and oil engines; the measurement of brake horse power; the use of a dynamo as a brake, and a very brief chapter on testing steam turbines. The book concludes with chapters on the properties of steam, evaporation, combustion, and an appendix containing notes, tables, etc. All the tables and calculations which in the original appeared in the metric or French units have been converted into English units, so that the book can easily be used by readers in this country. The subject is clearly treated and as it undoubtedly fairly represents continental practice, the volume should prove of considerable interest to consulting engineers who are engaged in testing according to methods which have become standard in the United States. From the fact, however, that continental practice differs somewhat from our own, the book would not be as well adapted to a student as one which followed the standard methods of this country.

Locomotive Breakdowns, Emergencies and Their Remedies, by George L. Fowler, M.E., 250 12mo pages and 96 illustrations. Published by Norman W. Henley & Son, 132 Nassau Street, New York. Price, $1.50.

This book treats, in catechism form, of the various accidents and breakdowns to which the steam locomotive is liable, and gives in each case a practical and simple method of handling same, so that a locomotive may proceed under its own steam or be safely towed in. It is a book containing many practical suggestions that should be of value to almost every locomotive engineer,, wrecking boss, roundhouse foreman, shop foreman and others desiring to make themselves proficient in the handling of locomotive repairs and emergencies. For instance the first chapter, treating of valve defects, tells how to locate and distinguish valve and piston steam leaks or "blows," as they are commonly known in railway parlance, and it alone should be worth the price of the book to those having to do with these sometimes obscure and puzzling defects. Besides the chapters treating of road repairs to valves, steam chests, cylinders, pistons, guides, crossheads, running gear, springs, frames, throttles, trucks, airpumps, injectors, lubricators, etc., a chapter is devoted to certain methods of shop repairs that are good; also one on aid to the injured. When it is considered that often a man's life is sacrificed simply because of the ignorance of his companions as to the proper treatment of a ruptured artery, it certainly seems worth while to instill some elementary surgical knowledge into the training of railway men.

Machine Design. Part I. Fastenings. By William Ledyard Cathcart, adjunct professor of mechanical engineering, Columbia University. 290 8vo pages. Illustrated. Published by D. Van Nostrand Company, 23 Murray Street, New York. Price, $3.00.

Several years ago we gave favorable notice of the work on machine design by Prof. Forrest R. Jones which was issued at that time, and said that it was of peculiar interest as being the first comprehensive treatise on the subject which covered machine design very thoroughly, being comparable in this respect to the English work by Unwin. This new book by Prof. Cathcart should also receive favorable notice and, although not a pioneer in its field, like the other treatise, is none the less interesting, since it apparently is the beginning of what will eventually be a more extended and perhaps complete, though we judge hardly a more workable, presentation than the volumes by Prof. Jones. The thoroughness with which Prof. Cathcart has gone into the matter is evident from the fact that this whole volume is devoted to this one subject of fastenings. The first chapter gives the most complete and satisfactory treatment with which we are acquainted, of shrinkage and pressure joints. The treatment is theoretical, supplemented by tables, several of which have been made up from similar tables appearing in Machinery. The chapter concludes with a treatment of shrinkage in gun construction. Following this come screw fastenings, riveted joints, keyed and pin joints. Throughout the work there are theoretical mathematical discussions and tabulated sizes, for convenient reference. The book abounds in tables, not only of dimensions, but of strength of materials, the properties of matter, etc. Considerable attention is given to U. S. Government specifications for screws, riveted joints, etc. To illustrate what is done in the way of theory may be mentioned the stresses in screws, torsion due to thread friction, stresses in nuts, efficiency of the screw. Altogether the volume is to be recommended as an advanced and practical reference work on such parts of machine design as its pages treat.

The Gas Engine, by F. R. Hutton, professor of mechanical engineering, Columbia University. 483 8vo pages. Illustrated. Published by John Wiley & Sons, New York. Price, $5.00.

The most widely-known books on the gas engine at the present time are the three English works by Donkin, Robinson, and Clerk. These consider the British types of gas engines, and while they go into the subject exhaustively, they are not of such character as to place the reader in touch with the wonderful gas engine development in this country in the past few years. Up to the time of the appearance of Prof. Hutton's volume there has been no comprehensive American treatise on the gas engine, such as have appeared being either of a popular nature or else dealing specifically with gas engine design. The present volume is intended to be a comprehensive American treatment, unsparing in its theoretical deductions, with due consideration of the application of theory to practice. The most exhaustive chapter, and one which will be appreciated by the investigator, although deeper than the average student would be anxious to go into—unless he were an accomplished mathematician—is one on the theoretical analysis of the gas engine. This chapter takes up the different gas engine cycles more completely than any previous work. The volume presents what is latest in connection with the blast furnace and producer gas apparatus. The first three chapters are introductory, reviewing the physical properties of hydrocarbon for power purposes, touching upon the various gases available, for use in an internal combustion engine. Following this is a discussion of a heat engine cycle; chapters on gas, gasoline, kerosene, and alcohol engines; carbureters; methods of ignition; governing, etc. There is a chapter on experiments with explosive mixtures, one on the performance of gas engines by tests, and one on the manipulation of gas engines which considers the ills that such machines are heir to. While many of the chapters are easily read and free from mathematics, the work on the whole is an advanced treatise and one to interest the mechanical engineer or designer.

The following books have been received:

A Textbook of Electrical Machinery, Vol. I. Electric Magnetism and Electrostatic Circuits, by Profs. Ryan and Norris, of Cornell University, and Mr. George L. Hoxie. Published by John Wiley & Sons, New York. Price, $2.50.

This is a theoretical textbook for students' use.

The Arithmetic of Electricity, by T. O'Connor Sloane. Published by Norman W. Henley & Son, 132 Nassau Street, New York. 160 12mo pages. Illustrated. Price, $1.00.

This is the sixteenth edition, revised and enlarged, of this popular work on electricity.

Electric Toy-making for Amateurs, by T. O'Connor Sloane. 185 12mo pages. Illustrated. Price $1.00.

This is the fifteenth edition, revised, to which several chapters have been added containing descriptions of a number of new and interesting devices.

Manual of Screw Cutting, by William Simpson, Lock Box 8, Wollaston, Mass.

This little handbook deals with screw cutting and change gears, has several useful tables, and gives directions for making a number of calculations, such as sizes of pulleys, etc. It contains 73 pages. This is the sixth edition.

Roof Framing Made Easy, by Owen B. McGinnis. Published by the Industrial Publication Company, New York. Second edition. Price, $1.00.

St. Nicholas, for December, is a real Christmas-stocking number, brim full of holiday stories and pictures, verse and fun. "An Interrupted Auction," by Carolyn Wells; "The Road to Fairyland," by Ernest Thompson Seton; "St. Saturday," by Henry Johnstone, with a page picture of the old Saint; "Happy Days," by Sarah S. Stilwell, and there are other shorter jingles pleasant to read between the stories.

Temple Bailey's "The Bachelor's Doll," is a delightful tale. In "The Three Caskets" George M. R. Twose retells for young readers the story of Portia and her three caskets. Ralph D. Paine gives an account of "A Chinese Army That Cheered for Yale"; Anna Porter Rex tells of "President Washington's Turkey Dinner"; Cyrus Townsend Brady, a humorous account of "The Baby's Adventurous Day—and Mine"; the "Adventures of a Tin Soldier" are recounted by Charles Raymond Macauley; Julian King Colford writes interestingly of "The Signs of Old London." New chapters of B. L. Farjeon's "A Comedy in Wax" carry the characters through many exciting adventures, etc.

The *Century* for December is particularly attractive and entertaining. There is an artistic cover and quite a number of pictures in color throughout the magazine. Of course a number of articles have the Christmas flavor, such, for instance, as "A Christmas Rescue," by Alfred Bigelow Paine, illustrated with pictures by Miss Cory; "How Santy Claws Treated Pop Baker," by the late Elizabeth Cherry Waltz; "Christmas Mangers," by Emma E. Porter, and "A Christmas Dilemma." Alice Katherine Fallows in "Temptations to be Good" sets forth certain good influences on the New York East Side boy, while Lucy Derby Fuller contributes a reminiscent paper on "Phillips Brooks and the Girls' Club." Another instalment of the new Thackeray find, consisting of his letters to the Baxter family of New York and some of his drawings, show him in intimate and lovable moods. There is a group of negro songs by Joel Chandler Harris, Paul Laurence Dunbar and others, with pictures by A. B. Frost. The range of fiction is further enlarged by a story by Roy Rolfe Gilson, "The Poet of a Day," illustrated; a humorous story by Maurice Francis Egan; a character sketch by J. J. Bell, a story of peasant life entitled "The Promise," by Maarten Maartens, the Dutch novelist, etc. Ernest Thompson Seton has another group of sketches of nature, entitled "Fable and Woodmyth." There is a curious paper by André Saglio on "The Bigoudines" of Brittany, with illustrations; a sketch entitled "Chrysanthemums," by Maurice Maeterlinck. Dr. James M. Buckley writes of "Fanaticism in the United States," in which there is additional reference to "Elijah the Restorer." Franklin Clarkin describes "The Daily Walk of the Walking Delegate."

NEW TRADE LITERATURE.

The Buffalo Steam Pump Company, Buffalo, N. Y. Leaflet describing the Buffalo Underwriter fire pump.

E. G. Smith, Columbia, Pa. Circular, just published, of the calipers and levels manufactured, will be sent to any one interested.

The American Diesel Engine Company, 11 Broadway, New York. Pamphlet describing and illustrating the Diesel engine, American type. This engine is here treated very fully and illustrations show its pump, motor, admission valve, etc.

The Cincinnati Punch & Shear Company, Cincinnati, O. Catalogue No. 9, illustrating and describing the full line of power punching and shearing machinery, rolls, etc., designed and built by this company.

The Detroit Pump Company, Detroit, Mich. Catalogue of the Blackmer rotary pump. Illustrations show its interior construction, also the No. 4 and No. 6 belt pump, a No. 4 special and a No. 4 hand pump.

Warren Webster & Co., Camden, N. J. Part 5 of general catalogue, which describes and illustrates the Webster motor valve for use in connection with the Webster system of low-pressure steam circulation for heating.

H. B. Underwood & Co., Philadelphia, Pa. Illustrated catalogue, 1903, of portable tools for railway repair shops. Boring bars, for various purposes, crank-pin turning machines, portable milling machine, portable rotary planing machine, valve seat rotary planing machine, etc., are here described.

The Divine Brothers Company, Utica, N. Y. Circular descriptive of polishing wheels, samples of which are shown. These include sheep skin wheels, bull neck solid-leather wheels, wool felt, canvas, sheepskin, compress felt and cloth wheels. The circular describes each style.

The E. F. Reece Company, Greenfield, Mass. Catalogue No. 5 of screw plates, taps, dies, etc. The different sizes and varieties of these tools are given, together with price; and the manufacturers state that for taps and dies of special form, size or pitch not listed in this catalogue prices will be quoted on application.

The American Tool Works Company, Cincinnati, O. Illustrated booklet describing several types of improved metal-working machinery designed and built by this company. These include engine lathes, a high-speed lathe, crank shapers, standard metal planers, drill presses, radial drills and a 37-inch boring and turning mill.

The Crocker-Wheeler Company, Ampere, N. J. Bulletin No. 39 describing the equipment of the Orange, N. J., Brewery with the Crocker-Wheeler system of electric motor drive. Different views show: The electric generating units, the power plant where the refrigerating machines and electric generators are installed; the cooker, driven by motor, and a pump and a keg-washing machine, both motor driven.

The Peerless Rubber Company, 16 Warren Street, New York. Illustrated catalogue No. 60, October, 1903, of rubber goods for mechanical purposes. This book contains 150 pages and lists packings of all kinds for various purposes, gaskets, a large line of rubber belting, rubber hose, rubber tubing, rubber valves—in fact everything in this line—in a very complete manner. All the varieties of goods are illustrated and briefly described.

The Prentice Bros. Company, Worcester, Mass. Booklet entitled "Radial Efficiency," which describes the radial drilling machines of the company's make. They state incidentally that they have built, up to July 1, 1903, 2,064 radial drills, and this booklet calls attention to the novel and important features of their new line of radials, which are described quite fully and whose parts are illustrated by half-tone cuts.

The Woolley Foundry & Machine Works, Anderson, Ind. Illustrated catalogue, standard size, of the "Burger" gas engines. The company claim for these engines simplicity of design and construction and small number of working parts; durability and freedom from repairs; ease in starting and operating, and economy in consumption of fuel. The Burger type of engine and its various parts are here shown.

The National Automatic Tool Company, Dayton, O. Illustrated catalogue of automatic drilling and reaming machinery. This contains handsome illustrations of "Nutting's" automatic universal multiple spindle drill press, described some time back in the columns of our paper; of the Nutting automatic multiple drilling machine for sewing machine arms, and of the Nutting rotary platen automatic multiple drill which is described elsewhere in this issue.

The B. F. Barnes Company, Rockford, Ill. Illustrated catalogue of drills, lathes and a water tool grinder. The drills range from the 12-inch to the 31-inch size, and are built with from two to six spindles, in many varieties. One illustration shows a battery of six 20-inch drills, with round base and power feed, which is furnished with various combinations of feed required and arranged for all sizes of drills. The lathes include 9 and 11-inch screw cutting lathes.

The Abendroth & Root Manufacturing Co., Newburg and New York. Advertising literature of the products of this company. A catalogue of 64 pages illustrates and describes their "Root" water-tube boilers, and half-tone views show the method of replacing a tube in these boilers, the operation of removing and replacing requiring but 48 minutes. A large number of cuts show prominent plants and public buildings equipped with "Root" boilers. A price list, June, 1903, of the "Root" spiral riveted pipe and a number of other pamphlets dealing with the "Root" boilers and pipe, have also been received.

The Buffalo Forge Company, Buffalo, N. Y. Sectional catalogues of Buffalo mechanical forced draft and of steel pressure blowers, just issued. These are attractive pamphlets, the first describing the works of the company and the fan for forced draft which they manufacture. A number of interesting views illustrate the many varieties of fans, some being shown applied to boilers, engines, pumps, etc. The booklet on blowers illustrates the various types, and tables of their dimensions and the prices are given. The Buffalo automatic cut-off engine, of their manufacture, is also illustrated.

The Joseph Dixon Crucible Company, Jersey City, N. J. "Graphite Suggestions," an attractive booklet treating, as the title indicates, of the company's product—graphite. This is made for a great variety of purposes, as follows: For the extensive line of pencils, about one thousand different kinds, which the company make; for use in the foundry; for lubricating purposes; for belt dressing; as a pipe joint compound; for stove polish, etc. The Dixon Company here state that they issue special circulars or pamphlets of their many and various productions, in which each is treated individually and fully.

The McCullough-Dalzell Crucible Company, Pittsburg, Pa. Folder calling attention to the crucibles and plumbago products of this company. This concern have been making crucibles exclusively for thirty years and have a very extended trade among the steel industries. They state that their crucibles run uniform, that their life under like conditions will last through the greatest number of heats, etc., and that the material used in their manufacture is the best procurable. They also inform us that they are one of the four largest importers of plumbago in this country and being able to pick out their stock always procure the best material available.

The American Blower Company, Detroit, Mich. Three illustrated catalogues of the company's products, as follows: Illustrated sectional catalogue, No. 118, second edition, treating of the "A B C" system of mechanical draft, forced and induced by the use of blowers and fans, and several applications of these fans and blowers to boilers in various plants are shown; catalogue No. 145 (second edition) dealing with the fan system of heating and ventilation as applied to manufacturing establishments; catalogue No. 155 illustrating and describing the "A B C" steel plate fans. All three catalogues are handsomely gotten up.

The Hess Machine Company, 1002 Pennsylvania Building, Philadelphia, Pa. Illustrated catalogue, standard size, of milling machines and milling cutters. The company's 30, 36 and 42-inch machines for heavy work are listed here and they state they are prepared to widen out these machines to take in wider work, and they will build to order larger machines of proportionately greater power. Their specialty is heavy milling, fast milling and combined heavy and fast milling. The machines are furnished with electric drive when desired. This type of milling machine was described in Machinery in the September, 1903, issue.

The Ingersoll-Sergeant Drill Company, 26 Cortlandt Street, New York. Form No. 4—an advance copy of the new pamphlet which is being prepared for publication by the company, treating of the air hammers, drills, couplings, etc., manufactured. The Haeseler hammers, which were illustrated in Machinery, July, 1903, issue, are here described and illustrated in detail. The chipping hammers are made in five standard sizes; the riveting hammers in three sizes. The duplex pneumatic "holder-on," for use when hand-riveting, a portable oil rivet forge, the Haeseler No. 3 piston drill, a radial drilling frame for use with No. 3 drill, a rotary breast drill, etc., are also shown.

MANUFACTURERS' NOTES.

The Walworth Manufacturing Company are building a new brass foundry adjoining their works in South Boston, Mass., which will be 54 x 260 feet, six stories high.

The National Steel Foundry Company, New Haven, Conn., announce the establishment of an acid open-hearth steel casting plant, the first pouring to occur about December 1, 1903.

The Steel Set Diamond Company, New York City, manufacturers of emery wheel dressers, wire dies, etc., have removed from 275 Water Street to 36 Gold Street, New York.

The Lunkenheimer Company, Cincinnati, O., advise us that they have opened a branch office in Paris, France, at 24 Boulevard Voltaire, where they will carry a complete stock of their goods.

Frank Mossberg Company, Attleboro, Mass., manufacturers of metal stampings and metal machinery, have sent us a sample of their work in the shape of a handsome nickeled paper knife for opening letters, etc.

The Crocker-Wheeler Company, Ampere, N. J., inform us that they have established headquarters for the Southern representative of their Washington office, Mr. S. M. Conant, at 425 Empire Building, Atlanta, Ga.

The Pedrick & Ayer Company, Plainfield, N. J., announce that Robert O. Cumback, for several years with the C. R. R. of N. J., and later at the Elizabethport shops on special work, has accepted the position of superintendent of their new plant at Plainfield.

The L. S. Starrett Company, Athol, Mass., manufacturers of fine mechanical tools, have purchased the fine tool business of the J. Stevens Arms & Tool Company, of Chicopee Falls, Mass., including the entire stock of tools made up and in process, special tools and fixtures for manufacturing, patents and good will.

The American Tap & Die Company held a meeting of the directors October 21, at which Mr. Edward Wilbur tendered his resignation and J. Henry Nichols was elected president. It is the intention of the company to place its line of dies on the market January 1, 1904. At present they are making a full line of taps.

The Moore Drop Forging Company, Springfield, Mass., have recently increased their capital stock from $30,000 to $40,000. Mr. A. L. Moore was elected president and manager and Mr. A. H. Chapin, treasurer. The company's new plant is at Brightwood, Mass. It consists of three buildings: A drop shop, 50 x 74 feet; a press room 20 x 40 feet; and a machine shop, 45 x 64 feet.

The Savage & Love Company, 710 South Main Street, Rockford, Ill., manufacturers of engines, boilers, shafting, hangers and pulleys, are getting out a new catalogue which they state will soon be issued and which is to be very comprehensive. They also announce that they have taken over the selling end of the business of the National Engine Company. The Savage & Love Company also build woodworking machinery.

The Ingersoll-Sergeant Drill Co., Cortlandt Street, New York, manufacturers of air and gas compressors, rock drills, etc., announce that while awaiting the completion of their new compressor catalogue, they have issued a temporary reprint, No. 33B, designed to supply their needs until the new one is ready. Besides the matter contained in their former catalogues, it presents some new illustrations, and the tables have been revised and brought up to date.

The Standard Roller Bearing Company, Philadelphia, Pa., who recently purchased the ball business of the Grant Tool Company, inform us they have secured as sales manager of the ball business of their company Mr. T. J. Heller, formerly New York agent for the steel ball department of the Federal Manufacturing Company. Mr. Heller will make his headquarters care of the Standard Roller Bearing Company, 48th and Girard Avenue, Philadelphia, Pa.

The Carborundum Company, Niagara Falls, N. Y., are again enlarging their plant, having made a contract for 2,000 additional electrical horse power, which will be turned into the works this month, giving the plant a capacity of 10,000,000 pounds of carborundum a year. A new factory site has been secured on which is being erected a new mixing and furnace building, 146 x 134 feet, capable of being extended in two directions.

The American School of Correspondence, Armour Institute, Chicago, Ill., announce that Dr. Wm. A. Colledge, F.R.G.S., well-known as lecturer in English at the University of Chicago, has been appointed Dean of the American School of Correspondence at Armour Institute. Dr. Colledge is ably fitted for this position. He was educated at Glasgow and London and has spent many years in travel. By reason of his large acquaintance with unfrequented parts of the earth he was made a Fellow of the Royal Geographical Society. The office of Dean is a new departure for correspondence schools and marks the approach of these schools to the dignity of resident educational institutions.

The Standard Roller Bearing Co., Philadelphia, Pa., have purchased the entire ball business of the Grant Tool Co., Franklin, Pa. (formerly of Cleveland, Ohio), and are prepared to fill all orders for the celebrated Grant ball, formerly made by the Grant Ball Co., of Cleveland, Ohio. To supply the demand at once for balls, the business will be run for a short time in Franklin, so that orders can be filled without delay, but it will eventually be moved to Philadelphia and consolidated with the Standard Roller Bearing Company's plant in that city. All orders should be sent to the Standard Roller Bearing Co., Philadelphia, Pa. R. H. Grant, formerly manager of the Grant Ball Co., will have charge of the ball making plant in Philadelphia, and a number of the former employees of the Grant Company will remove from Franklin to Philadelphia, and enter the employ of the Standard Roller Bearing Co.

MACHINERY.

January, 1904.

THE NEW HAMILTON-CORLISS ENGINE WORKS.

THE shops of the Hooven, Owens & Rentschler Co., Hamilton, O., builders of the Hamilton-Corliss engines, have been rebuilt and greatly enlarged the past two years, and the new machine equipment is now practically completed. The scheme of arrangement of buildings, power plant, tracks, machines, etc., is that of Colonel J. C. Hooven, president of the company, and the details were worked out by the architect, Mr. George Barkman, of Hamilton. The buildings are most substantially constructed of steel frames with brick walls. The roofs are high and the lighting exceptionally good. The machine-tool equipment is in many instances of a special character, and is designed for handling both horizontal and vertical Corliss engines up to the heaviest units, say 5,000 or 6,000 horse power. The large tools are independently driven by electric motors, and electrical distribution of power is used throughout. In fact the plant is up-to-date, and is perhaps one of the best equipped plants in this country for building heavy Corliss steam engines.

The layout of the plant is seen in the plan, Figs. 5 and 6. The machine, erecting and blacksmith shops lie on the south side of Heaton street, and the foundry, pattern shop, pattern storage and power plant are on the north side. A large tunnel beneath the street connects the machine shop and power plant. In this tunnel the electric cables, steam pipes, water pipes and other connections are laid. The motive power in the power house consists of a 500 kilowatt Hamilton-Corliss cross-compound condensing engine, exhausting into a Baragwanath barometric condenser, and direct-connected to a "Wood system" generator built at Fort Wayne, Ind. For lighting a 150-kilowatt generator, belted to an 18 x 36-inch engine, is provided. For view of engine room see Fig. 18. The engine house is a handsome two-story building of pressed brick, and may be seen at the right in Fig. 19.

The tracks of the Panhandle Route (P. C. C. & St. L. branch of the Pennsylvania Railroad) are immediately adjacent to the shop buildings on the east, and the Cincinnati, Hamilton & Dayton Railroad runs along the west boundary. A switch from the latter curves through the side of the erecting shop, passes through the machine shop and back of the blacksmith shop, where it intersects that from the Panhandle Route. An industrial railway connects the machine shop with the foundry, foundry yard, etc., but transportation within the shops is mainly effected by the electric traveling cranes, with which the plant is exceptionally well equipped, there being eight in machine shop and erecting shops alone. The foundry has two, each of thirty tons capacity, besides which there is one of thirty tons capacity in the flask yard. For handling heavy patterns in the pattern shop a small traveling crane is provided there.

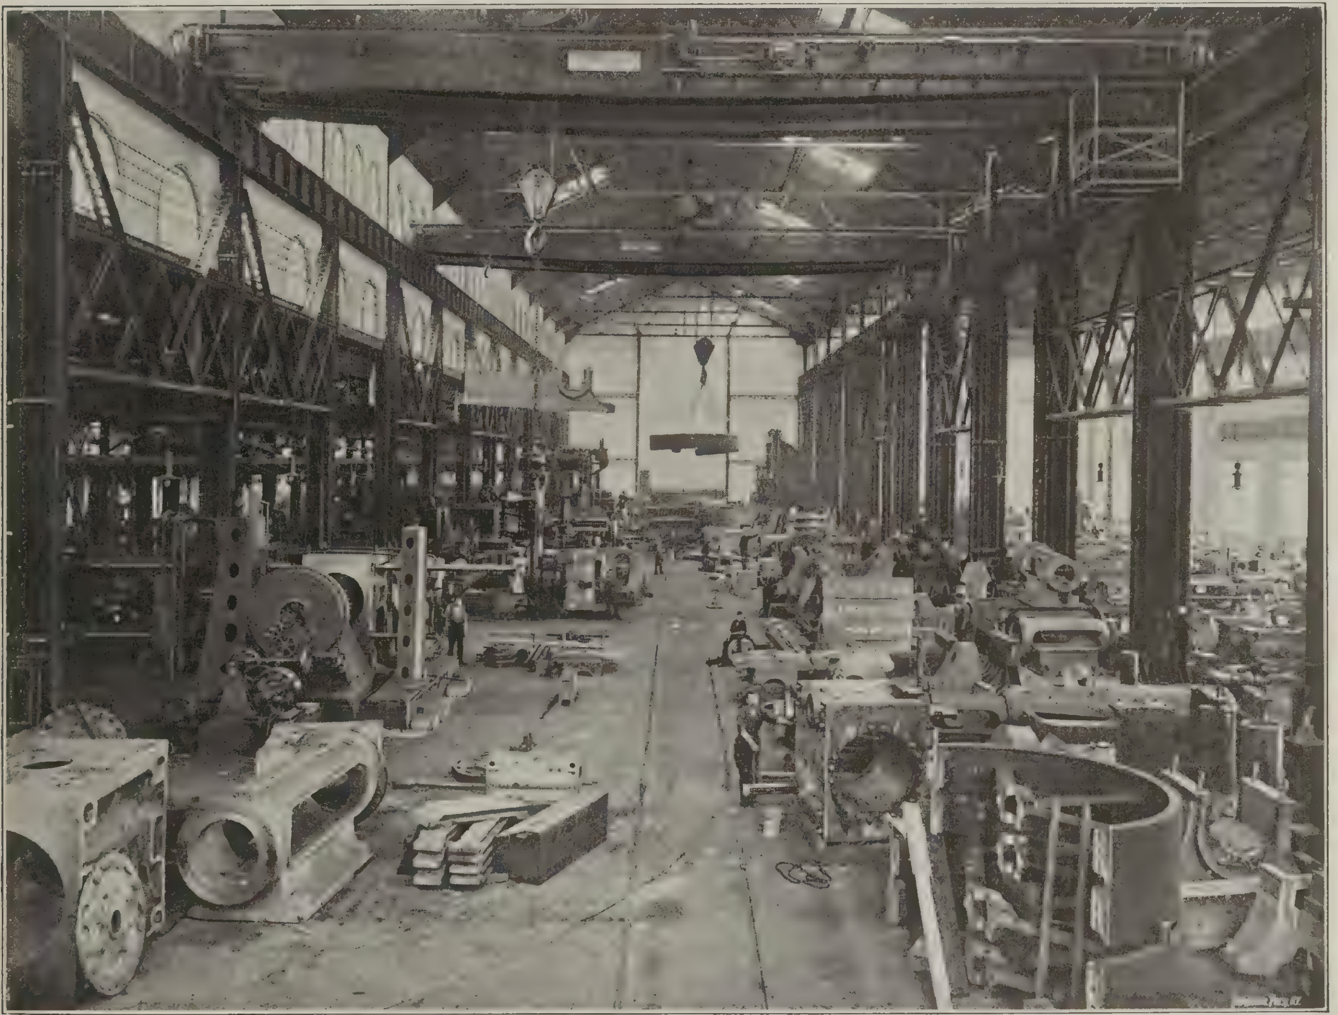

Fig. 1. Heavy Machinery Bay of new Hooven, Owens & Rentschler Engine Works, looking South, served by two Four-motor Fifty-ton Cranes of 73 feet 6 inches Span. Length of Bay, 370 feet.

The length of the foundry is 406 feet, and the width of the main part, in even figures, is 74 feet. A lean-to is built on the west side, as is the usual practice, for the cupolas and core ovens. The lean-to is continued, however, from the cupola room to the end of the structure, a distance of about 233 feet.

The width of the foundry with the lean-to is 113 feet. The foundry floors are composed of clay and molding sand, except in the charging and cupola rooms, where the floor is made of one-inch steel plates laid upon steel I-beams. The roof over the cupolas is fireproof, being built of steel rafters with porous book tile between and covered with sea-green slate laid in a bed of hot asphalt. This roof is especially recommended for cupola rooms, not only because of its fireproof qualities, but because the fumes and gases do not deteriorate it. Three cupolas of 67, 81 and 90 inches diameter, give ample melting capacity for the largest castings. Three wheel casting pits are provided in the north end of the molding floor. The wall of each pit is a cast-iron ring about 5 feet high, 3 inches thick and 23 feet internal diameter. As already stated, the foundry has two electric traveling cranes of thirty tons capacity each. The span is 69 feet 9 inches. A cross section of the foundry and lean-to appears in Fig. 9. The crane in the foundry yard for handling flasks is a lattice girder crane of thirty tons capacity, and is of the same length of span as those in the foundry. A view of this crane and the flask yard appears in Fig. 26, and view of the foundry lean-to, looking towards the machine shop, in Fig. 20.

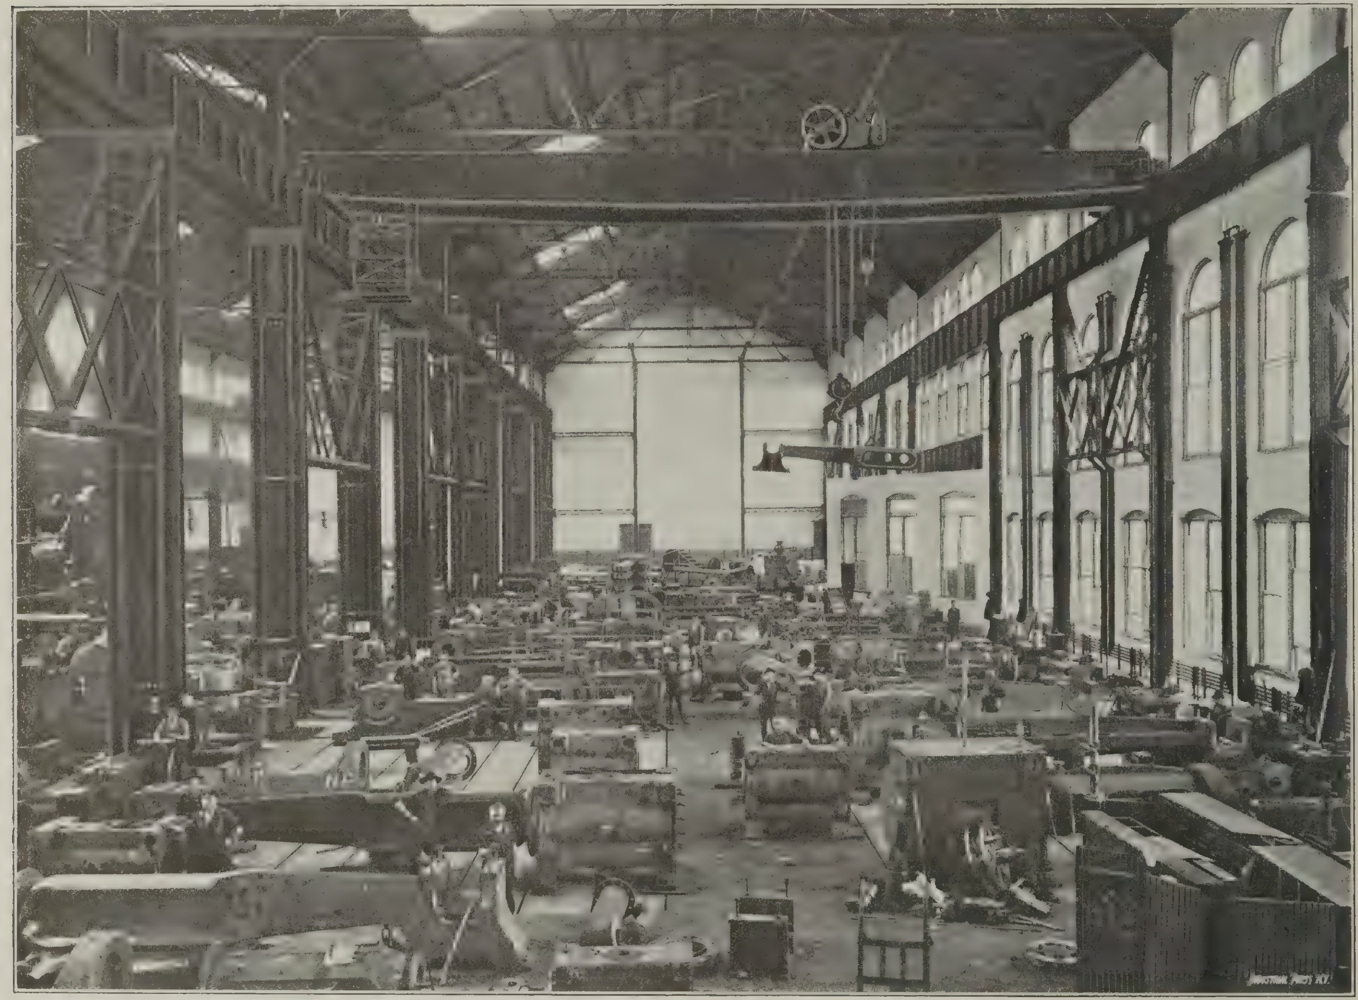

Fig. 2. Erecting Bay, 320 feet long. Has two Iron-concrete Erecting Floors, each 27 feet wide and 102 feet long; one Four-motor Thirty-ton Traveling Crane. Entrance for Railroad Switch shown by "jog" in Wall.

The machine shop extends along Heaton street 316 feet. The rebuilt part of the machine shop was part of the old foundry. This portion runs parallel with Heaton street and consists of two bays, each provided with traveling cranes. Views of these bays are shown in Figs. 4 and 24. The main erecting and machinery bays, four in number, 370 feet long and 230 feet wide, are at right angles to the street, as may be seen from an inspection of the plan, Fig. 6. A cross section of these bays is shown in Fig. 8, and half-tone views in Figs. 1, 2, 3, 21 and 22. The rectangular space included in the angle made by the east bay (running north and south) and the south bay (running east and west) is used as a fitting department for such engine parts as cam hooks, dash-pots, governors, etc. Beyond this department, toward the blacksmith shop is an old five-story building used for light machinery and storage. The screw machine department is on the ground floor, and the appreciation of the Jones & Lamson machines is shown by the fact that seven machines are in use, three of which are 2 x 36 inches capacity.

The most impressive parts of the plant are the high sections indicated in the cross section, Fig. 8, and of which half-tone views appear in Figs. 1, 2 and 3. The steel columns supporting the roof, are very heavy and are spaced 29 feet apart. All the weight of the roof throughout the plant, including the shafting, is supported by the columns, the brickwork acting only as a filling between the outside columns. The height of the roof trusses from the floor is 57 feet, and the tops of the crane runways are 45 feet above the floor. All the foundations are made of concrete, as actual tests had satisfied the company that concrete formed a more stable foundation than stone; besides its use hastened the work and cheapened the cost. The foundations of the floors are also of concrete, 8 inches thick. Upon this 4 x 6-feet cedar sleepers are laid, 2 feet apart center to center. The sleepers are coated on all sides with hot asphalt, and the space between them is filled up to the level of the top with fine concrete. Upon the sleepers the flooring is laid, which consists of 3-inch plank covered with a finished floor of 1¼-inch tongued and grooved edge-grained yellow pine. The sleepers are somewhat wider at the bottom than at the top, so they cannot lift, being dove-tailed, as it were, into the concrete.

The erecting floor space is 102 feet long and in two parallel sections each 27 feet wide. These are built of concrete, in which are embedded cast-iron rails each made with longitudinal T-slots. These rails are 6 inches deep and are made in 6-foot lengths, each of which is held down with six bolts. A bed of concrete 12 inches deep was rammed up to within one inch of the bottoms of the cast-iron rails, which were leveled and held in place by temporary supports. Liquid cement was then floated over the concrete up to the under side

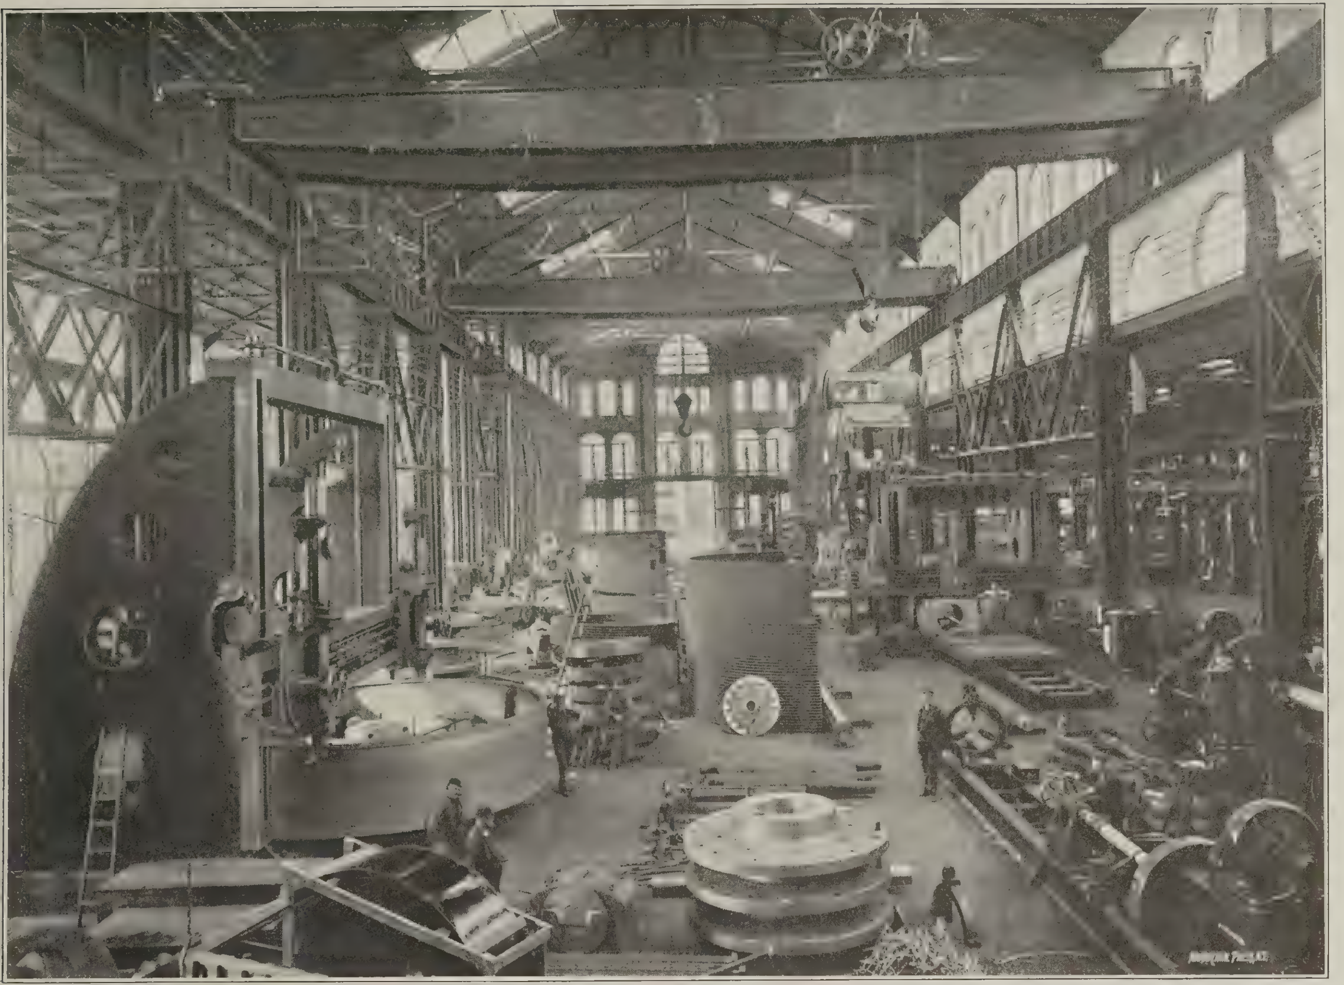

Fig. 3. Heavy Machinery Bay, looking North.

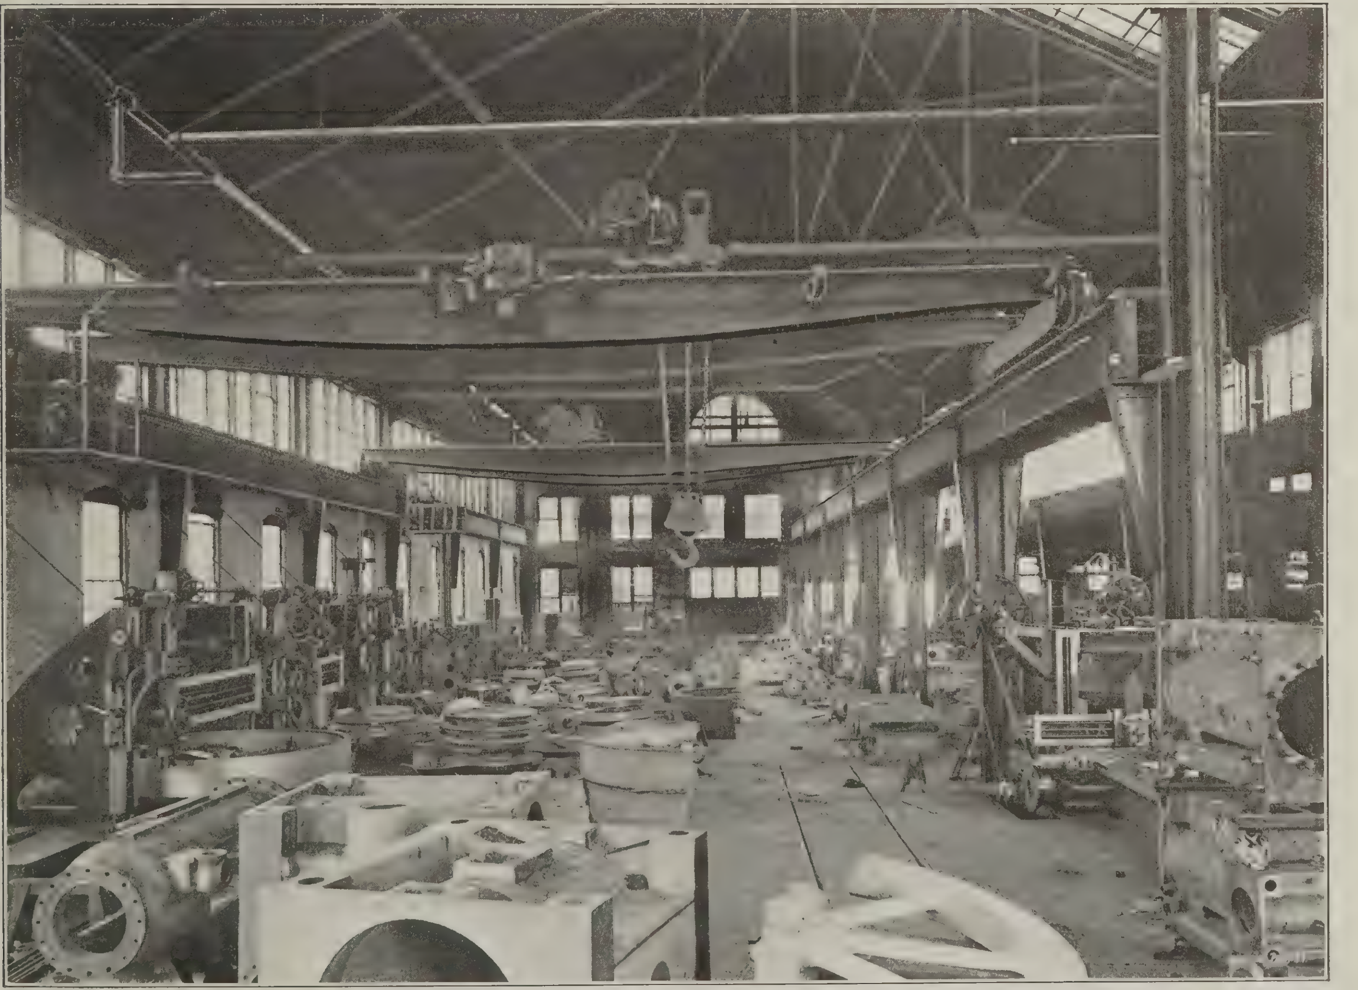

Fig. 4. Machinery Bay parallel to and next to Heaton Street, served by two Twenty-ton Traveling Cranes of 47 feet Span.

of the rails, thus giving them a perfectly even bearing under all parts of their bases, which are about 12 inches wide. The spaces between the rail were then filled in with rammed concrete up to within one inch of the top, and the intervening space was floated level full with liquid cement. The rails are laid about 3 feet apart center to center, and the T--slots may be plainly distinguished in the view of the erecting floor, Fig. 2.

The traveling crane over the erecting floor is of 30 tons capacity. It has four motors, the main hoist being driven by a motor of 30 horse power. The power of the other motors and of those of the two 50-ton cranes in the next bay may be read from the cut, Fig. 6. Save tools of a portable nature, there will be only one machine tool in the erecting section or bay. This is a 40 x 12-foot pit lathe, located at the south end. This machine had not yet been erected at the time the photograph was taken. It is a home-made tool and is now in process of construction. At the opposite end of the erecting floor is the office, which is four stories high and has a cellar. The stairways leading to the second and third floors are indicated in Fig. 8, and are on the shop side of the partition wall.

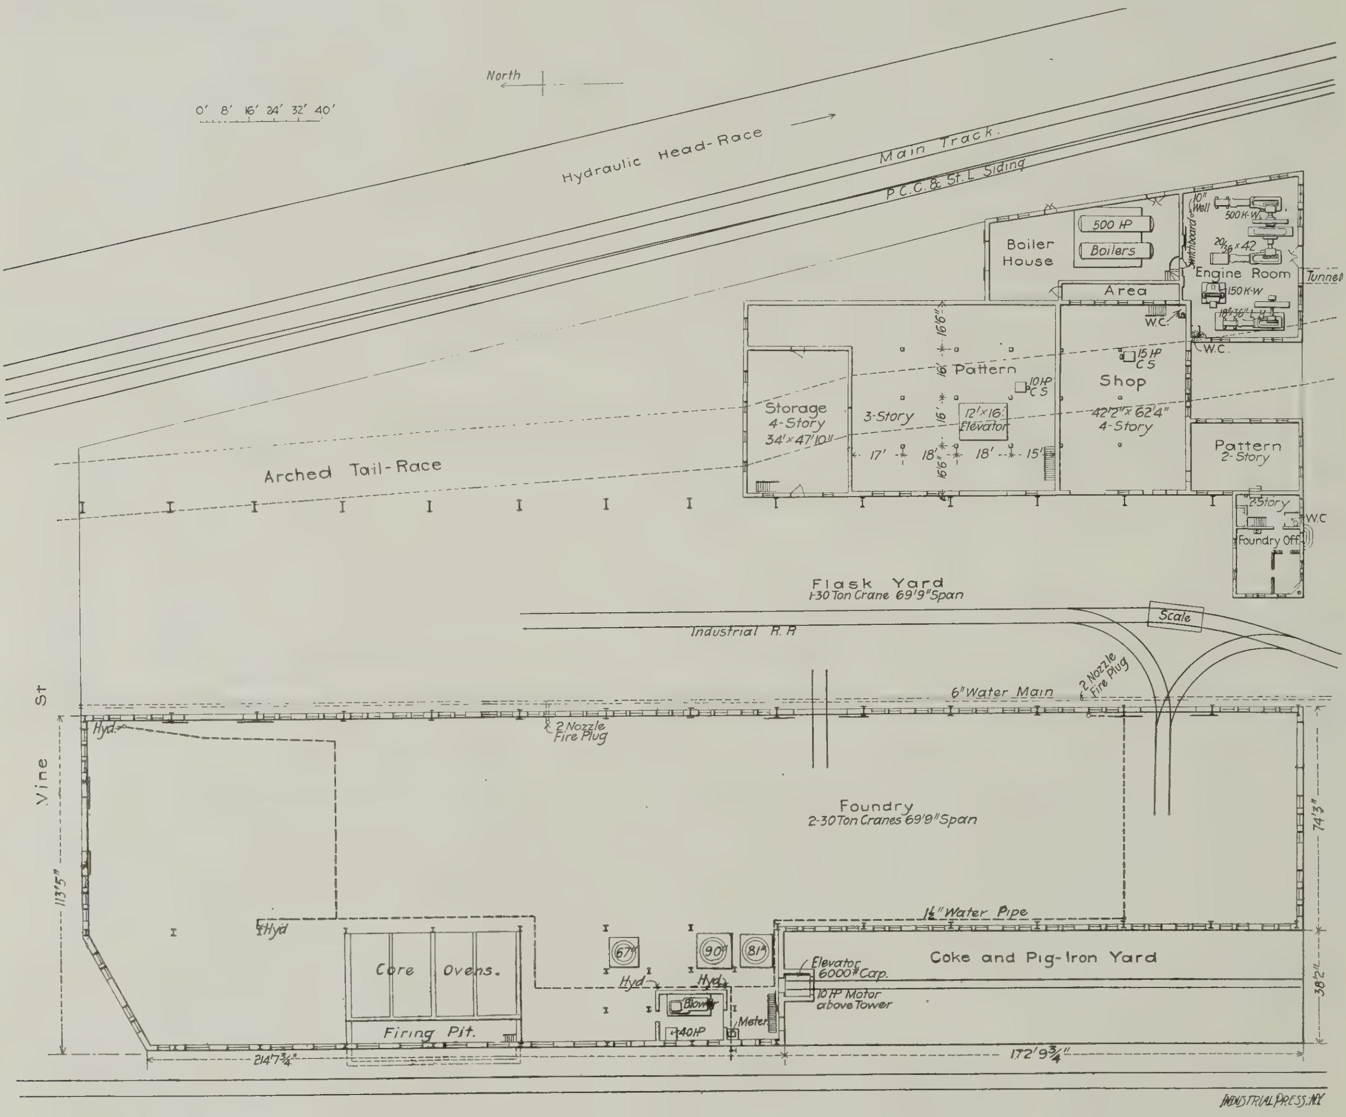

Fig. 5. Plan of Hooven, Owens & Rentschler Works, showing Foundry, Pattern Shop, Power Plant, etc. (See next page.)

The heaviest machine tools are in the next bay, which is served by the two 50-ton cranes. The heavy planer shown individually in Fig. 13 was built by the Niles Tool Works, as were most of the other heavy machines. It is a 12 x 12 x 30-foot machine, with four heads, and is driven by a 40-horsepower constant speed motor. Fig. 14 shows a view of a heavy 20-foot boring and turning mill from the rear. This machine has an auxiliary post or housing, carrying the tools for turning the rims of fly-wheels. It is driven by a 20-horsepower variable-speed motor, and has a 7½ constant-speed motor for rail elevation. The cylinder borer appearing in Fig. 15 handles Corliss cylinders up to 72 inches diameter, and bores the ports simultaneously with the machining of the main bore. The main bar is driven through worm gearing by a 12-horsepower variable-speed motor. The two port boring bars are independently driven by a 7½-horsepower variable-speed motor. Another interesting heavy tool is the bed-facing machine seen in Fig. 16. This machine has two boring bars mounted at right angles. One bar bores the main shaft bearing, while the other bores the guides and faces the end of the frame for the cylinder fit. Large and small bars with bushings fitting the machine so that they may be readily interchanged are provided, so that large and small frames may be handled on the same machine. The shaft bearing boring bar is driven by a 7½-horsepower variable speed motor, and the guide boring and facing bar is driven by a 12-horsepower variable-speed motor.

The Bullock four-wire multiple voltage system is used for the variable-speed motors. A balancing set consisting of three machines of 17½ kilowatts each, mounted on one base, is located centrally in the shop near the tool room. The power wires are all carried beneath the floor, and connection boxes are placed at frequent intervals. The only overhead wiring is that necessary for the electric lights. Near the balancing set is a 45-horsepower constant-speed motor, belted to the line shaft in that bay. In this section all the tools are belt-driven from the line shaft. A view of it is shown in Fig. 21.

This bay, of course, is not served by traveling cranes, because of the presence of the lineshaft, but primarily because of the low roof, this section being a lean-to, although the next bay is covered with an ordinary ridge roof. In the next bay there are two 20-ton traveling cranes of 34 feet 3½ inches span, and the tools are independently motor-driven. The power of the individual motors is, in most cases, given on

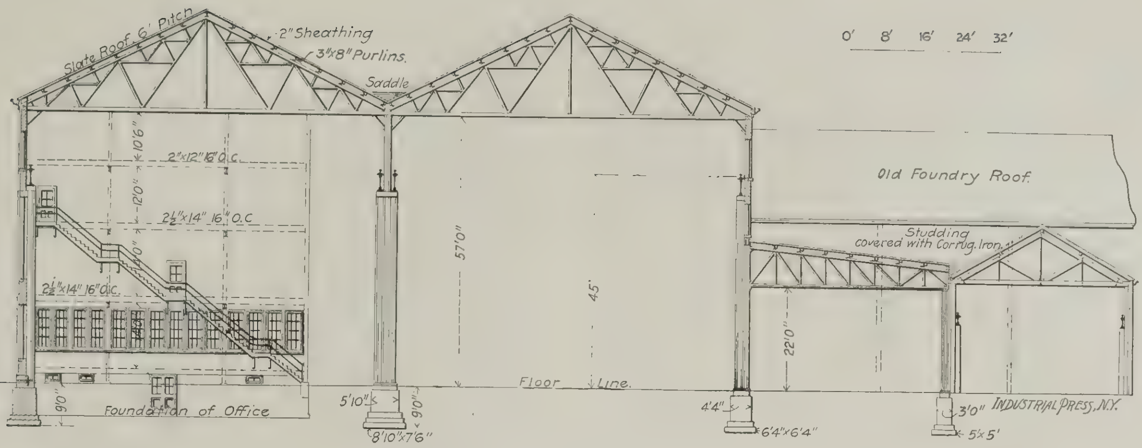

Fig. 8. Cross-section of Erecting and Heavy Machinery Bays; also of Lean-to and Ridge-roof Section.

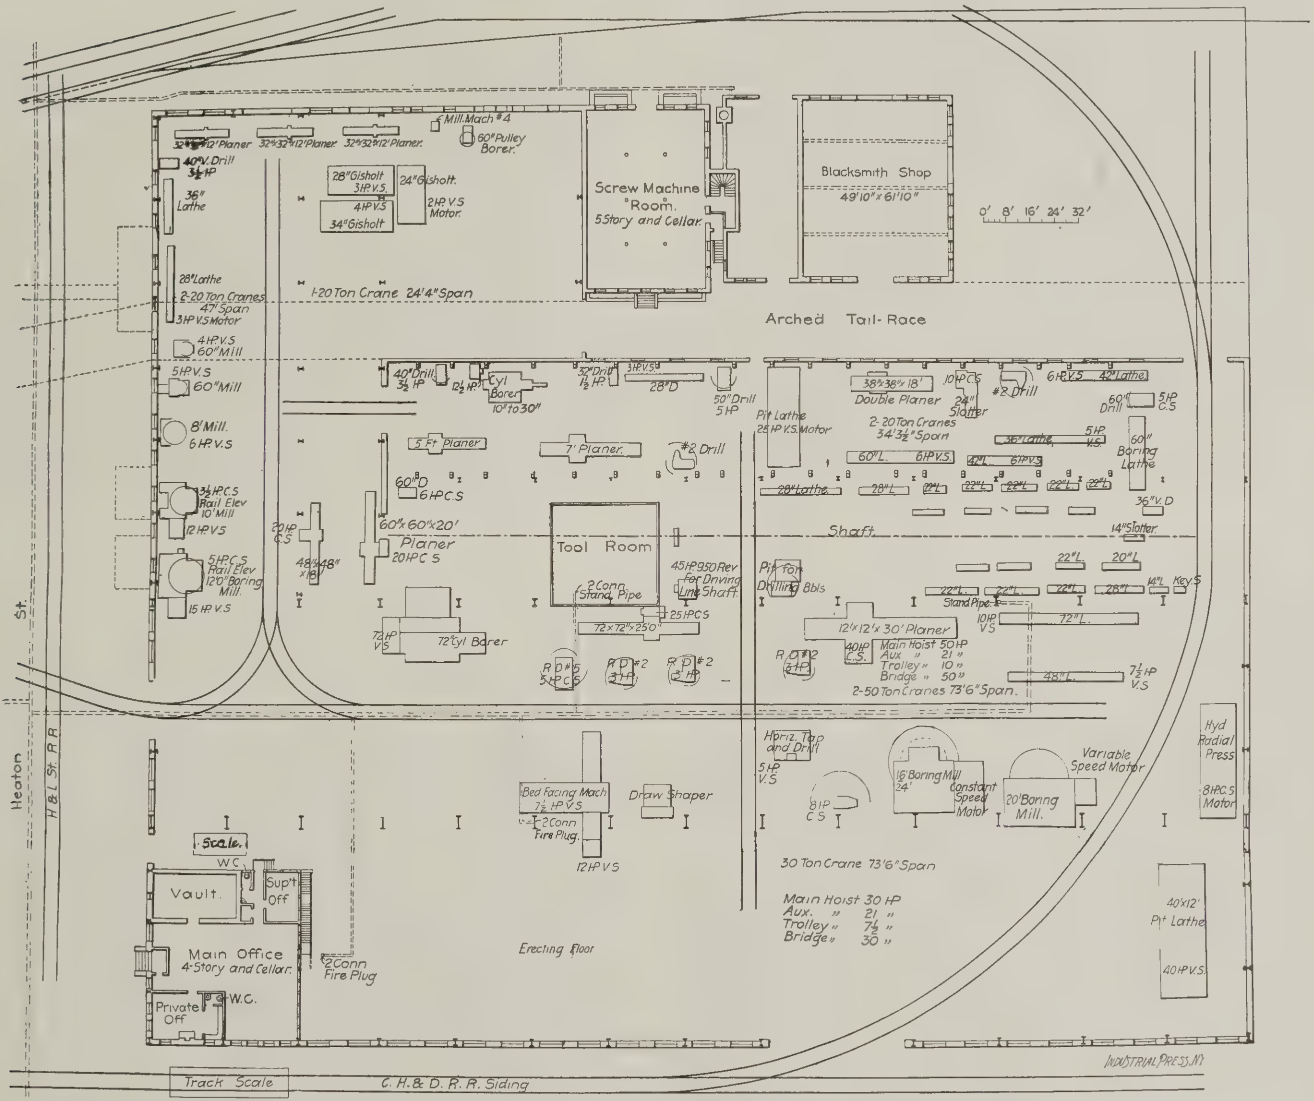

Fig. 6. Plan of Works showing Machine and Erecting Shops and Blacksmith Shop.

the drawing, Fig. 6. One of the interesting tools in this section is the Niles double connecting-rod planer, with which both ends of connecting-rods may be planed simultaneously; it is shown in Fig. 17.

The boring mill seen in Fig. 11 is one of a row of mills located along the Heaton street wall, shown in the general

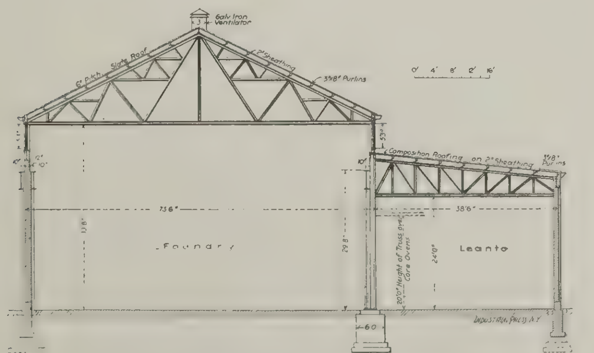

Fig. 9. Cross-section of Foundry.

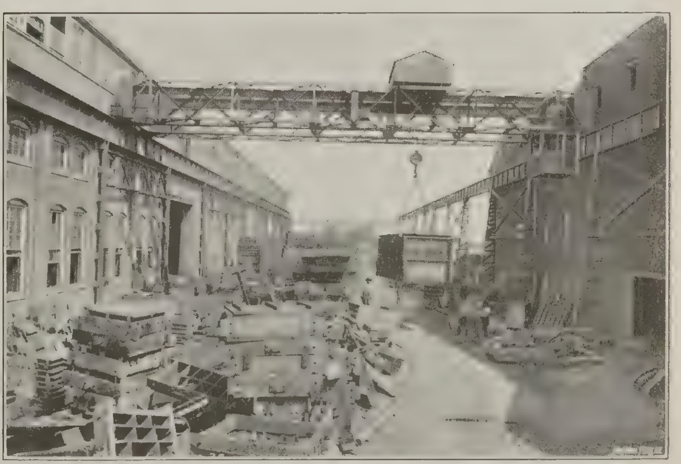

Fig. 26. Flask Yard and Traveling Crane.

view, Fig. 4. This mill swings 10 feet and has a boring bar which is used for boring crank-pins holes in crank disks, the table and disk, of course, standing still during such operations. With this machine the crank-pin and shaft holes can be bored and the disk turned and faced at one setting. This tool, it may be safely said, is about the best example of a combination machine. Ordinarily a combination tool is not much of a success, that is, those in which radically different operations like slotting and boring are conducted on the same machine.

Attention is called to the large hydraulic press seen in Fig. 12, which is used for pressing shafts into crank disks, etc., to observe the convenient manner in which electric controller and valve connections are located, all being brought to one spot, where the operator can watch the pressure gage. The press is belt-driven by a 8-horsepower constant-speed motor.

The cubic space of the various sections of the machine shop just described, which are practically all in one room, measures about 5,000,000 cubic feet, and the area of exposure is proportionally enormous. The original plans of heating proposed by Mr. Thomas G. Smith, of Cincinnati, the consulting engineer, contemplated the use of the hot air plenum system as being best suited to the needs of large open buildings such as these, but this system was finally abandoned for direct radiation from low-pressure steam coils. This action was taken partly because of the difference in cost, but largely because the company did not want the large underground ducts which would have been necessary with the hot-air fan system. Because of the great cubic space and large exposures it was quite a problem to secure the space for the pipe coils giving the necessary amount of radiating surface, and for this reason the installation is somewhat unusual, inasmuch as the most of the coils are placed vertically between the windows. This may be seen in the view, Fig. 2, where it will be observed that the proportion of horizontal piping beneath the windows is small as compared with the vertical pipes between them. Ceiling coils are also placed so as to aid the circulation and contribute to heating the large body of air in the center of the shop.

The Webster system of steam distribution is used. The steam supply from the power plant is carried across the street in the tunnel into the machine shop where the main rises to the level of the roof trusses and extends throughout the bays to supply the coils. The returns are conducted back to the tunnel in trenches near the walls of the building, and through the tunnel to the vacuum pump located in the basement of the main engine room. Branch mains, of course, are run to the pattern shop, pattern storage warehouse, and screw machine department. The exhaust of the main engine, supplemented with live steam through a pressure-reducing valve, is used for heating, so that the engine is practically run non-condensing in winter so far as any contribution from atmospheric pressure is concerned. It is only in summer when this economy can be realized.

The offices are in the northwest corner of the erecting shop, the required space being taken from the north end of the erecting bay. On the first floor are the main and private offices and the superintendent's office. The latter is so located that the interior of the shop may be seen through windows cut through the partition wall for this purpose. These rooms are handsomely finished in mahogany and present a fine appearance. The second floor is used for drawing room, and the third floor is reserved for the same purpose when a large force is being employed. A three-story fireproof vault affords safe storage for valuable papers for each floor.

* * *

A distinctive feature of electric welding is that the interior is raised to the welding temperature before the surface reaches that heat; heating in the forge is the converse of this condition. With electric welding if the exterior surfaces weld the operator is sure that the interior is also welded since it must be at a somewhat higher heat. With forge welding the surfaces may be welded perfectly and cover an imperfect job within. Unfortunately electric welding seems practicable only for comparatively small pieces on account of the enormous amperage required for large sections.

REFINEMENT OF TAPER ATTACHMENT GRADUATION.

One of the useful American improvements of the engine lathe is the Slate taper attachment by which tapered work can be turned with the centers in line, coincident with the longitudinal axis of the lathe. The general construction of the taper attachment is too well known to require any description here beyond such general outline as will serve to make the following references clear:

Instead of setting the tailstock over, thus throwing the axis of the work out of parallel with the longitudinal travel of the carriage, a guide-bar, supported by suitable brackets on the back of the lathe bed, is used to produce the desired taper. The guide-bar is pivoted so that it may be swung through an arc of limited length, either side of the line parallel with the lathe axis, and provision is made for clamping it at any required setting. The guide-bar is made with parallel sides on which is fitted a slide connected with the auxiliary cross-slide on the carriage. In later constructions the attachment is made to the cross-slide nut, thus doing away with one slide and simplifying the construction. The guide bar being set out of parallel with the longitudinal carriage travel and remaining stationary, it causes the cross-slide and tool to travel toward or away from the center of the work as the tool traverses it, thus causing the tool to turn a taper, the degree of which will depend upon the setting of the guide-bar.

TABLE I.

5	10	6¼	.630	1.80	1.475
6	12	8½	.626	2.55	2.116
7	16	12	.623	3.373	2.750

Since it is common custom to designate different tapers in inches or fractions of an inch to one foot of axial length, instead of in degrees, it is the practice to graduate an arc over which the outer end of the guide-bar swings, so as to give direct readings. Thus if the machinist desires to turn a taper of ½ inch to the foot, he sets the datum line on the end of the guide-bar to the graduation marked ½ on the scale, and so on.

Now if the operator is careful to have his centers ground true and set dead in line, and to set the tool exactly on a level with the center of the work, the taper attachment should save much time in getting exact tapers, provided the graduations for the guide-bar setting are correct. But the usual practice is to graduate the arc in *equal* divisions to correspond to one-half the taper per foot multiplied by the ratio of guide-bar length to 12 inches. That is, if the guide-bar length is 15 inches from pivot to scale, the setting for, say, ¾ taper per foot, would be $\frac{3}{4} \times \frac{1}{2} \times \frac{15}{12} = $ 15-32 inch measured on the arc of the circle. But this is inaccurate since the even graduations expressed by any setting ratio, can only be laid off on the line tangent to the arc at the intersection of the line *CF*, Fig. 1. The taper per foot corresponds to the divisions on the tangents *AB*, which lie at right angles to the axis of the lathe. If, for example, the guide-bar was 12 inches long, the divisions on this line could be laid off in exact inch divisions, being marked for direct reading, of course, just double the actual length. Thus the ¼ inch line from zero would be marked ½, and so on. But, as stated, the graduations are laid off on the arc *DE*, and usually in equal divisions. Now since the equal divisions only properly exist on the tangent scale *AB*, the projections of these divisions must necessarily intercept parts on the arc which vary with the angle subtended by the axis of the guide-bar. When the angle is small the tangent and arc divisions are nearly equal, the differences being very minute, but as the angle increases the differences become marked. The change may be noted by referring to Table I. The lines *CK*, Ck_1, Ck_2, etc., in Fig. 1, indicate the position of the guide-bar for various settings up to 4 inches taper per foot.

Fig. 1. Diagram Illustrating Application of Tangent Scale.

The Bradford Machine Tool Co., of Cincinnati, Ohio, investigated this matter quite thoroughly some time ago, and, becoming convinced of the desirability of more accurate means for setting taper attachments than generally provided, they had "tangent" scales made by the Brown & Sharpe Manufacturing Co., which are now applied to all engine lathes built by them, having taper attachments. These scales are screwed fast to the end of the sector plate, being bent to the arc of the required circle, as indicated in Fig. 2, and are made for the various sizes shown in the same figure. The divisions indicating tapers in even inches are exact, being projected from the inch divisions on the tangent, as already explained in the reference to the tangent *AB*, Fig. 1. The intermediate divisions are equally spaced; that is, the space between two adjacent inch marks are divided into eight equal parts. The error thus introduced is negligible; it is the accumulated error on wide angles that the corrected scale is designed to avoid.

SIZE LATHE	DIMENSIONS	
	A	B
14	10½	2⅞
16	14	4¾
18	15	5
21	14	5½
25	17½	6
28	24	8¼
31	21½	7
32	21½	7

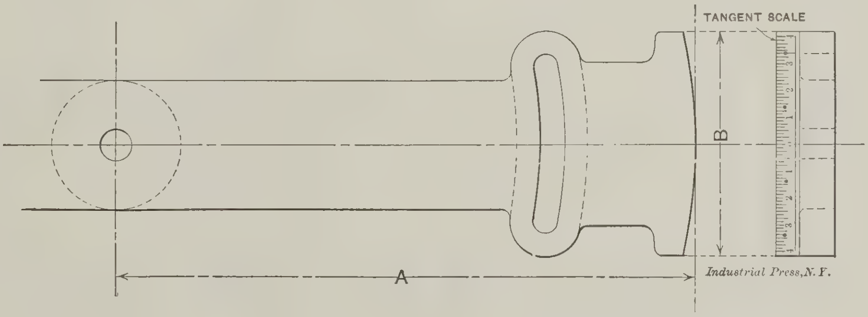

Fig. 2. Application of Tangent Scale to Bradford Lathe Taper Attachment.

The importance of having at hand accurate means for producing tapers on engine lathes to any required taper per foot, or to any angle, scarcely needs to be discussed here—it is too apparent. But as an example of the confusion and trouble that have been perpetuated because of using inaccurate methods in the past, we reproduce a table of Morse taper reamers, provided in blueprint form for use in the Bradford Company's shop, which, of course, they are obliged to follow when boring lathe spindles to Morse tapers. The Morse taper was, we believe, intended to be ⅝ inch (.625) per foot; the variation from this measurement may be noted in Table II. It is but fair, however, to state that the Brown & Sharpe standard taper of ½ inch (.500) per foot, varies in the case of No. 10, the taper in this case being .5161 inch per foot.

In addition to providing the corrected scales on taper attachments the Bradford Company expect soon to also graduate them in degrees, so that angles expressed in taper per foot or in circular measure, may be readily and accurately turned or bored by setting of the guide-bar to direct-reading scales.

* * *

Casehardening is a primitive steel-making process by which the surface of the pieces is enriched with carbon, putting it in condition to be hardened by sudden cooling. For hardening dies of complicated form, or most simple forms for that matter, casehardening usually gives more satisfactory results than plain hardening. Heating a piece of high-carbon steel in an open fire will very likely burn out some of the carbon, leaving it in a poor condition to harden when dipped. The casehardening process, on the contrary, enriches the surface with carbon and insures the maximum hardness at the surface where it is needed. It permits of the use of low-carbon steel which is cheaper and more easily worked. Another feature of the casehardening process that is particularly favorable to getting good results, is that the pieces being packed in a box and slowly heated, the heating is more uniform and the metal is protected from jets of cold air impinging against it, which we all know, is one of the difficult things to avoid in open forge heating.

MACHINE SHOP EQUIPMENT.—5.

EQUIPMENT OF THE IRON FOUNDRY.

OSCAR E. PERRIGO.

The equipment of the iron foundry necessarily differs in many respects from that of the other departments heretofore considered, as to its product, its work, and the necessary arrangements for carrying it on. These requirements, while they have changed much since the earlier plants for this work were established, have not perhaps undergone so great a change in a general way as have those of the machine shop. The early plants were, of course, very crude and primitive affairs, and iron was often melted in crucibles somewhat as brass is melted now. Most of the work done was of the plainest kind and little attention was paid to symmetrical or artistic effect.

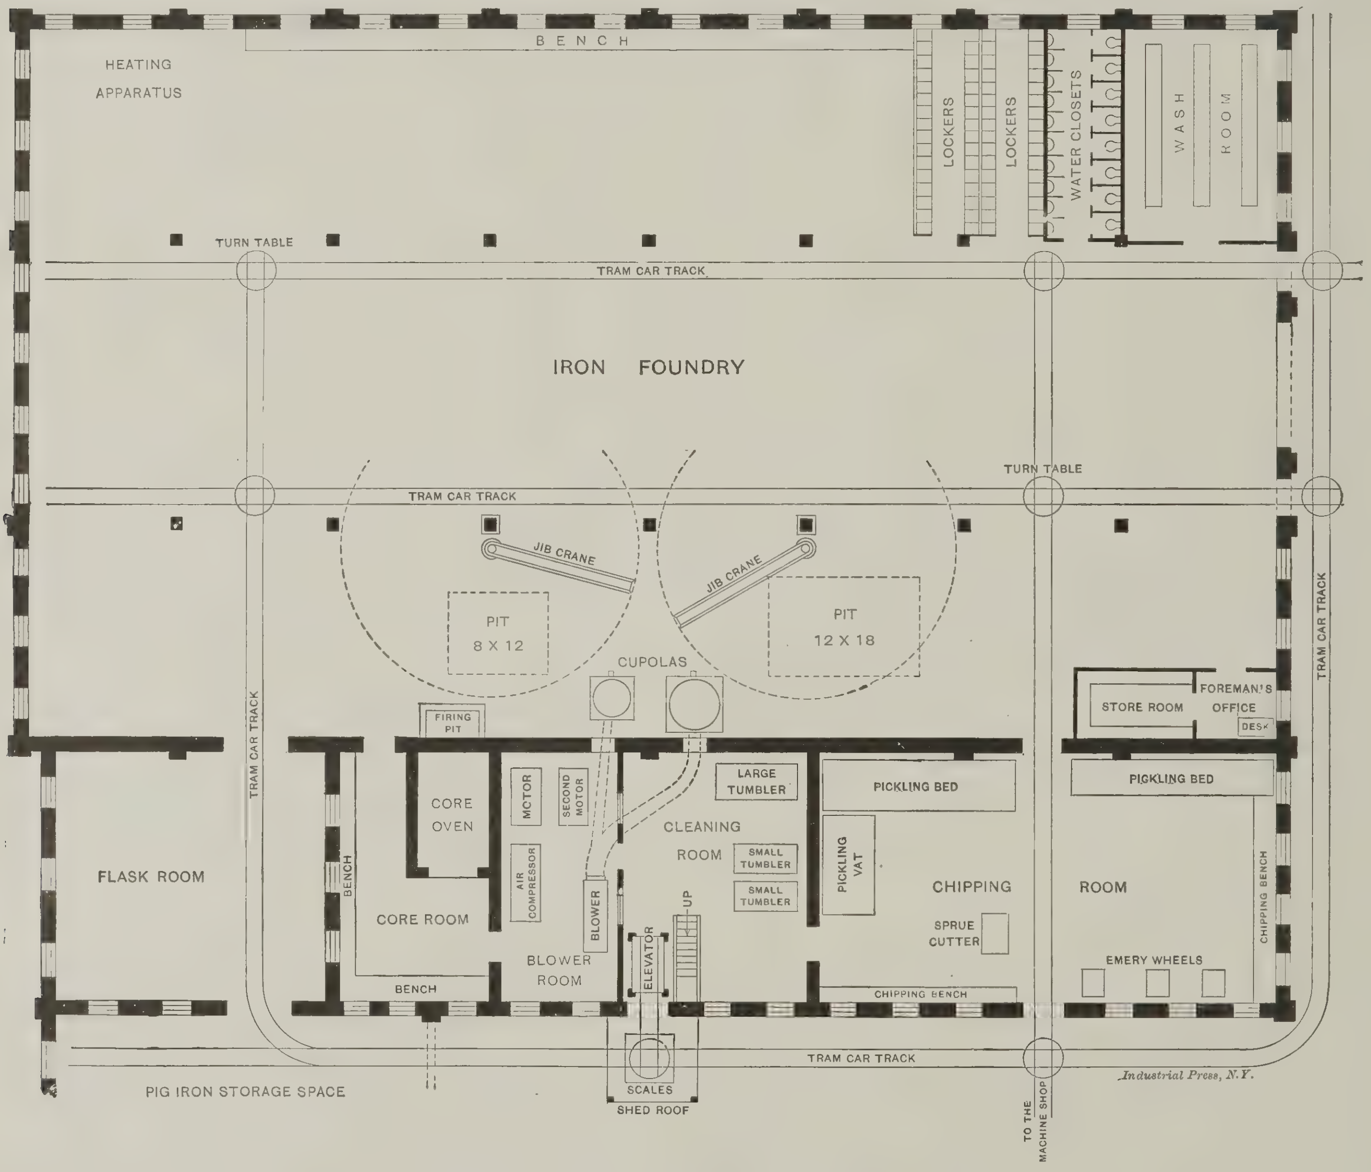

Fig. 1. Plan view of Foundry, showing General Arrangement and Equipment.

Early history shows that the making of iron castings was one of the oldest mechanical industries of the country. In the year 1643 John Winthrop arrived in this country from England, bringing with him the necessary number of skilled workmen for this purpose, and built a small iron foundry in Lynn, Mass., and the fact that the first casting which was made was "a small iron pot holding about a quart," shows the modest capacity of the foundry. The casting is said to have been made "from native ore."

Little progress seems to have been made in enlarging the original scope of the work from its early beginnings, so far as records of the facts are known. In 1735 an iron foundry was established in the little town of Carver, Mass., and a second one was built in the year 1760, wherein the historic Massachusetts Teakettle was cast.

Another foundry was built in 1793, and was burned down in 1841. The proprietors of this foundry were Bowers & Pratt. A relative of the latter partner established a foundry in Wenham, Mass., and his son, at a later date built a foundry in Watertown, Mass., which was the original of the now well-known foundry of the firm of Walker & Pratt, for whom the writer had the privilege of making the first drawings of their heating apparatus to be reproduced by the original photo-engraving process invented by Moss, and operated by the Moss Photo-Engraving Company, on Park Place, New York City. Following the gradual development of the iron founding business from the early times is very interesting, but too long a story for the space of this article.

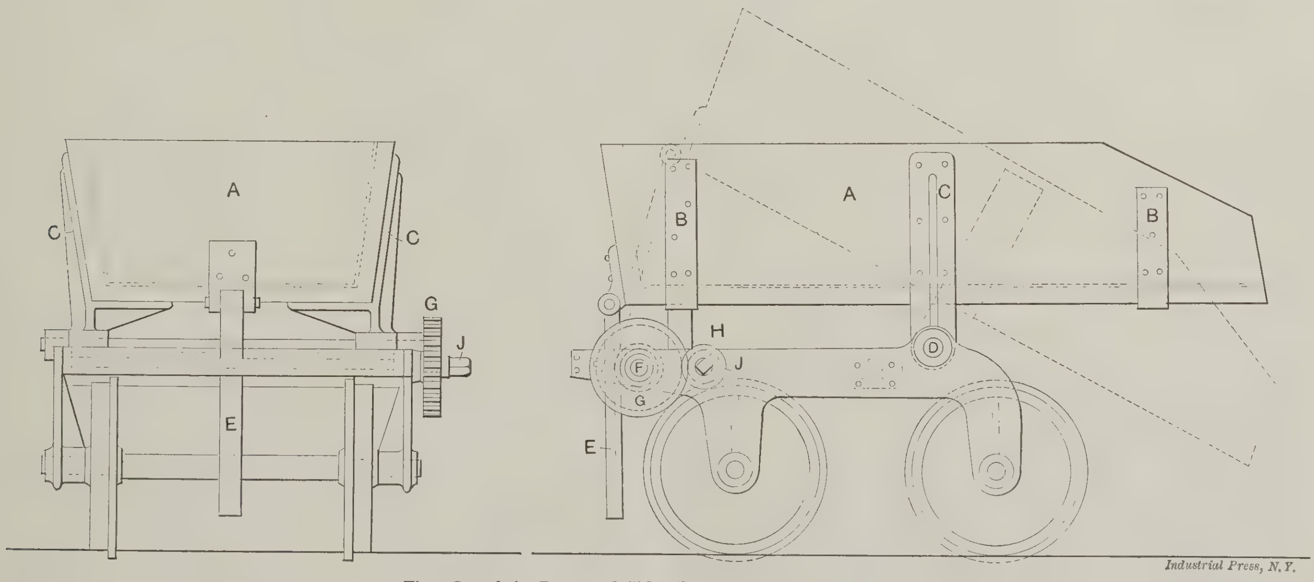
In these later years the addition of the traveling crane, the pneumatic hoist, the application of electricity, the iron flasks, the sand blast system for cleaning castings, and similar improvements have changed many of the older methods, and rendered the work less laborious and the output much larger. At the same time the quality of the work, both in its practical and in its artistic features, has been greatly improved.

The foundry floor has been particularly described in the article on floors in the series on shop construction, MACHINERY, Vol. IX., to which the reader is referred for detailed information on this point.

Fig. 1 shows the general arrangement of the foundry and its equipment. The central portion is provided with a traveling crane, and under this and the two jib cranes shown, the heavy molding and casting are done. Tramcar tracks, located as shown, bring in any stock and material, such as sand, flasks, pig iron, coal, etc., as may be necessary, upon cars specially constructed to adapt them to each class of load to be carried. Turntables are provided at the intersection of the tracks, in preference to curves and switches, as they occupy much less room, do not require any more time to operate, and the cost is nearly the same, for equipment offering like facilities. The special construction of these tracks and their accessories will be particularly described in a future article on shop transportation.

In bringing pig iron, coal, etc., to the cupolas the material is brought on the cars to the turntable scale in front of the elevator, and there it is weighed, then run upon the elevator, raised to the charging floor and the cars run upon the branch tracks, and thence to the cupolas, as shown in Fig. 2. The charging cars are specially constructed for this purpose, and are substantially the same as used by the Vilter Mfg. Company in their foundry in Milwaukee, Wis. A rear elevation of one of these cars is shown in Fig. 3, and a side elevation in Fig. 4. The frame consists of two similar iron castings for sides, held together by cast-iron cross rails bolted to them, as shown. The car body *A* is composed of two-inch planks, lined with sheet iron, and supported by wrought-iron, forged straps *B*, *B*, of U-shaped form, at the back and front, and by cast-iron angle supports *C*, *C*, near the center. Upon these supports are formed downwardly-projecting lugs, by means of which the car body is pivoted by the rod *D* to the frame, as shown in Fig. 4. The greater part of the load is placed back of this pivot, thus holding the car body in a horizontal position. Pivoted to the rear end of the car body is a rack *E*, engaging a pinion on a horizontal shaft *F*, which has fixed upon its front end spur gear *G*, engaging spur pinion *H* on the shaft *J*, which is squared on the front end for the application of a crank, by means of which the rear end of the car body may be raised and the contents of the car dumped. The dumping position is shown by dotted lines in Fig. 4. The car is of very simple construction; the gear and rack teeth are cast, the wheels and gears bored, and the hubs faced, but not turned on the outside. Several of these cars should be provided, so that there may be no waiting on the charging floor for either pig iron, scrap iron, coal or coke, during the progress of a heat, when time is valuable.

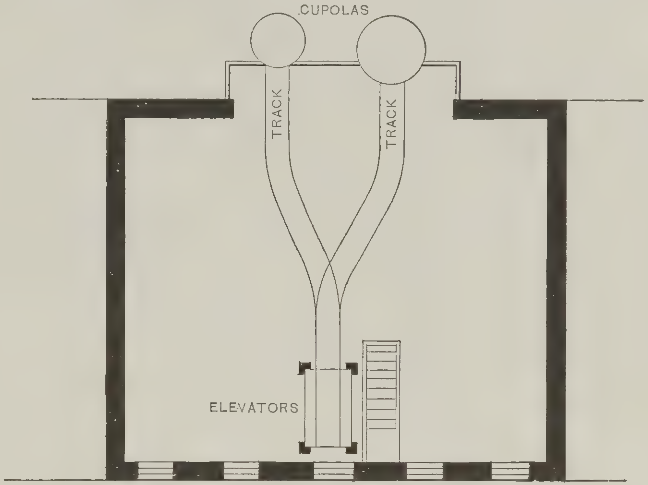
In Fig. 1 the location of the cupolas is shown, and also that of the blower and the blast pipes leading from the latter to the cupolas. A motor is also located in the blower room, which is used to furnish power to run the blower, and also the elevator, the tumbling barrels and the machines in the chipping room. It may be preferred to have two motors, one to be used only for running the blower, and run for a few hours only when a heat is on, and the other constantly, for driving the machinery above mentioned. These motors may be located side by side in the blower room, as shown. The blower may be placed on the floor, but it is often advisable to locate it overhead, out of the way of dirt and dust and more nearly on a level with the tuyeres of the cupolas, so that some of the curves in the blast pipes may be avoided, as this is a very important matter when the amount of air pressure is to be compared to the power necessary to generate it, as in this class of blowers it is considerably more than is generally supposed, even by good mechanics.



Industrial Press, N.Y.

Figs. 3 and 4. Rear and Side Elevation of Charging Cars.

The motor, or one of them, may furnish power to operate the traveling crane by the old system of a square shaft running the length of the building beside it and so providing power at any point in its travel; but this method is a rather clumsy way to transmit power, and it is a much better system to have the traveling crane carry its own motor, the current being supplied to it by flexible, pendant cables near the wall and out of the way. These should be placed on the side of the building opposite the cupolas, where there will be no obstruction to them and where they will be away from the excessive heat.



Industrial Press, N.Y.

Fig. 2. Branch Tracks for Cars to run from Elevator to Cupola.

The general molding floor of the foundry should have its work so arranged that the spaces outside of the supporting columns will be devoted to the lighter floor work and the bench work, where crane service is not needed. A bench is provided along one side as far as the heating apparatus (which occupies the outer front corner), for bench, or snap flask work. Here it will be found very convenient to use the compressed-air hoists for floor work, as it will be in other parts of the plant, as the hoists may be suspended overhead and used not only for drawing the deeper patterns but for turning over flasks, for it is now a demonstrated fact that in compressed air we have a very useful, convenient and efficient power, which may be utilized in the foundry, perhaps to as good or better advantage than in any other department of the modern manufacturing plant. Its uses are many, and the convenience with which it may be carried to any part of the floor for individual use, or for the lifting of quite heavy loads, renders it almost indispensable in the routine work of the foundry. The economy of its use may be readily appreciated when it is remembered that an air compressor provided with a cylinder six inches in diameter, and a storage tank three feet in diameter and five feet long, compressing air to 80 pounds per square inch, will furnish ample supply for a dozen hoists lifting 400 pounds or more each. In drawing patterns, turning small flasks, setting large cores and similar work, these hoists may be suspended in any desired location, the rubber hose attached bringing a supply of compressed air, easily controlled by a simple valve. These hoists may be suspended from a trolley traveling on an overhead beam, so located as to be convenient to the work. Of course, larger hoists may be used when necessary, and they are quite as effective and economical. Roughly speaking, a hoist with a 3-inch piston should lift 450 pounds; with a 4-inch piston, 800 pounds; with a 6-inch piston, 1,850 pounds; and with an 8-inch piston, 3,300 pounds. A supply of compressed air is very useful in the chipping room, where chipping tools may be very efficiently operated with it, and by its use one man may thereby do the work of at least two, and usually more.

An air compressor may be located in the blower room, as indicated in Fig. 1, and operated by the motor situated there. A cylinder 12 inches in diameter will be ample for the ordinary uses of the foundry floor and for operating such tools as are necessary in the chipping room. It will require a tank about 4 feet in diameter and 8 to 10 feet in length. This may be situated over the air compressor so as not to occupy the floor space. Such a tank should, of course, be constructed on the same lines and of like materials as a steam boiler of similar size, and to withstand the same pressure per square inch. It should be remembered that under ordinary circumstances if the air compressor is constructed on the plan of the boiler-feed pump, with a steam cylinder and an air cylinder, with one piston common to both, the proportions will be nearly these, viz.: steam cylinder, 6 x 8 inches, and air cylinder 10 x 8 inches. And also, that 90 pounds steam pressure will give about 65 pounds air pressure, with a piston velocity of 300 feet per minute. These figures are given as nearly correct and easily remembered.

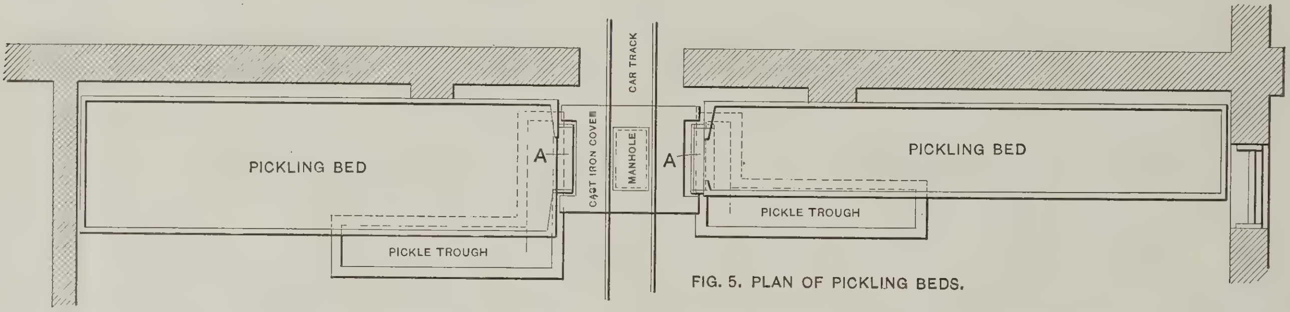


FIG. 5. PLAN OF PICKLING BEDS.

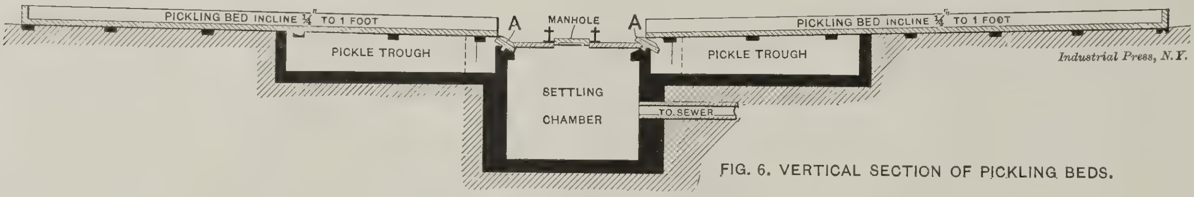

FIG. 6. VERTICAL SECTION OF PICKLING BEDS.

Figs. 5 and 6. Pickling Beds—a new and Efficient Method of Pickling.

A large variety of molding machines are in the market, many of which are admirably designed to turn out a large quantity of work in a day, and to save much of the manual labor usually necessary. They are, of course, employed on comparatively plain work where the tamping of the sand may be easily done by forcing down upon it a comparatively flat surface. They are usually employed upon the lighter kinds of work.

Molding machines are also made for molding the teeth of gear wheels of large dimensions, as well as large segments, and by their use much time is saved and the cost of large and expensive patterns for the gear teeth is avoided. There are also molding machines for pulleys, which are valuable as a part of the foundry equipment, and with a proper supply of rims and spiders this work is much simplified and the costs reduced.

These machines must be selected and provided in accordance with the particular class of work to be done, as their utility will depend almost entirely upon this matter.

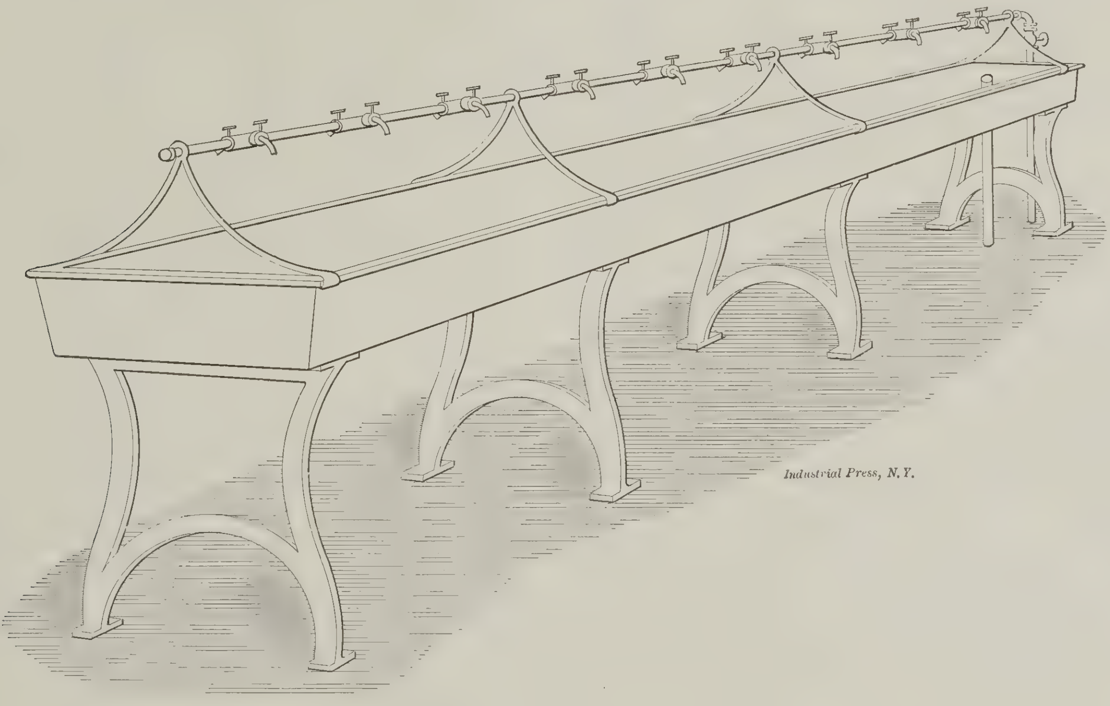
Sand sifters and sand mixers are now made so as to be mounted upon a tram car and are driven by a small electric motor attached to them, the machine being thus rendered complete in itself, and may be easily moved to any part of the foundry desired, and when not in use, run out of the way. They will be found very convenient on nearly all classes of work, and may supersede the usual hand riddles almost entirely, saving much of the molder's time and producing better castings, as more sifted sand is likely to be used if the molder is not obliged to sift it by hand. Besides, being sifted close at hand, it is not so liable to contain foreign matter, as if it is sifted at one point and carried to different parts of the foundry where it may be needed.

The deep molding pits are located as shown by dotted lines in Fig. 1, one, 8 x 12 feet, and the other 12 x 18 feet. These may be of any required depth, but more usually the smaller one would be about 5 feet, and the larger one about 8 feet. All of these dimensions should, of course, be made according to the character, size and the weight of the larger castings to be made. The walls and floors of the pits should be constructed according to the directions given in the article on shop floor construction, which preceded this series. These pits will be found very useful in molding large pieces wherein a very deep nowel flask would be required, and which would necessarily raise them several feet higher on the floor than would be the case where a pit is made use of. Such pieces, which may not be cast on their side, and weighing, say, over 4 tons, will usually be found fit subjects for pit molding.

It will be noticed that the cupolas have been located within the space of the foundry proper. This, of course, will occupy considerable room on the foundry floor. They are so placed in many foundries, this being a more desirable location in several respects. In this case they come nearer to the cranes, which are supported from the main columns, and afford a convenient means of transferring a ladle of melted iron from the cupola front to the cars, and thence by the track to any point in the foundry, or, from the cranes over to the traveling crane and thence to any part of the central space of the floor. The cupolas may be located in the cleaning room and the blower room space, and thereby save about 140 square feet of molding floor space. In this case the cranes will be placed closer to the wall, but yet with sufficient reach to pass ladles of melted iron to the car track, or to the traveling crane. If this disposition is made the location of the tumbling barrels will need to be changed, placing one at the front of the room. If it is found necessary, the motors and the air compressor may be placed on the charging floor, where there is ample room for them. Even the blower may be located there, for the purpose of affording more space on the first floor, a partition dividing them from the charging floor proper. The stairs also may be placed at right angles to their position as shown, for the purpose of affording any specially desired location for the first floor equipment. In case the cupolas are placed in the cleaning room and blower room space, it may be advisable to run a car track immediately in front of them, connecting at each end with the transverse tracks by the usual turntables, and by which means ladles of melted iron may be transferred to the central space under the traveling crane by taking the route either to the right or left, as may be the shorter distance. However, many will prefer the jib crane for this service, as being quick, efficient and safe.

In the back corner of the main part of the foundry proper is the foreman's office, and adjoining it is a store room for the various small articles, tools, etc., necessary for almost daily issue, and which the foreman of a foundry of this size will probably find necessary to have under his personal control; although it will be advisable to have an employee in the office who is conversant with these matters, and to act as a bookkeeper, in order that the foreman's time may not be too much taken up with these matters of routine details.

In the front corner, on the outer side, is located the heating apparatus, which has been previously described in the general article on heating, in the series on shop construction. If preferred, it might as well be located in the corner next to the flask room. This would be convenient if more bench room was required for snap flask work.



Industrial Press, N.Y.

Fig. 7. Cast-iron Washing Sinks, with Individual Supply of Water.

The chipping room is provided with the usual benches, having a sufficient number of vises on them to accommodate the work requiring hand chipping. Sprues are cut off in the sprue cutter where this can be done by such a machine. The three emery wheels will do much of the small finishing on the castings, while the pneumatic chipping tools will do very much of the work on the heavy castings.

Pickling beds are provided for, as shown on the plan, Fig. 1. These should be so constructed that the pickling solution may drain off into a receptacle where it may be saved and used again, while the water used in washing the castings after pickling, and the burned sand and scale coming from the castings, will go into another receptacle, where the sand and scale may be retained and the water flow into the sewer.

A very efficient method of accomplishing these results is in use in the new foundry of the Brown & Sharpe Mfg. Company, Providence, R. I., and with some necessary modification, it is shown on enlarged scale in the plan Fig. 5, and in vertical, longitudinal section in Fig. 6. The pickling beds are built of 2-inch plank, supported on timbers 4 x 6 inches, placed not over 4 feet centers, and have at both sides and at the upper end a plank 8 inches high. This bed is lined with sheet lead of sufficient thickness to not be easily cut through by laying castings upon it. Very heavy castings may rest upon pieces of board laid upon the lead for its protection. The lead should not be thinner than an eighth of an inch for ordinary uses. The pickle bed inclines toward the drainage system a quarter of an inch to the foot. The pickling solution or wash water dripping from the castings upon the pickling bed flows to the lower end, and upon a narrow tilting table *A*, which directs its course as may be desired. In the position shown on the right of the drawing it will run the pickling solution into a transverse conduit, from which it flows into the pickle trough, where it may be dipped up to put on other castings. When the castings are sufficiently pickled and it is desired to wash them, the hose is brought into use and the tilting table *A* is placed in the position shown on the left in Fig. 6, and the wash water flows into the settling chamber. Considerably above the bottom of this chamber a drainage pipe leads to the sewer. All sand or scale which passes down from the washing process drops to the bottom of the settling chamber, from whence it is cleared out as often as necessary through the manhole between the car tracks, as shown. A cast-iron plate covers the settling chamber, supporting the car tracks passing over it, as well as the manhole cover.

Near the pickling beds is located the pickling vat, in which small castings may be immersed until sufficiently pickled, then placed upon the pickling beds to drain and be washed. This is constructed of planks and lined with lead, the same as the pickling beds. Concrete construction may be used if desired.

An overhead trolley and hoist should be placed over the pickling beds, for removing castings from the cars and transferring them to the bed on the right or left, as may be desired, and back to the car when they are finally washed. Another similar overhead trolley should be placed in the center of the room for lifting castings to and from the floor and cars. These two trolley beams may be connected if desired, and run as one system. The hoists may be operated by compressed air, in the same manner as those in the foundry proper. If the sand blast process is to be used for cleaning castings it will be necessary to enclose a space of sufficient size in which to operate it, in order to prevent the disagreeable dust created by its use, provided the high velocity usually used is to be arranged for. There is, however, a sand blast apparatus made in Germany which uses a very coarse sand at a comparatively low velocity, which appears to be a success, and does not require to be operated in a close room.

The core room is provided with benches on two sides, and the usual form of core oven, which is fired from a pit formed in the floor of the foundry proper, by which arrangement the entire height from the core room floor is utilized for the cars upon which the cores are arranged and run into the oven from the floor level. The core oven may have its entire front closed with sheet-iron doors, running up out of the way; and upon the inner sides of the oven walls a series of supporting bars, permitting cars to run in, one above the other, their front ends being suspended on overhead trolley beams when they are drawn out. By this means the upper portions of the core oven may be better utilized and smaller lots of cores may be run in and baked at a time; or, the oven may be divided by a vertical partition and one side used for a large car, filling the entire space, and the other side arranged with shelf-like cars or racks, for small lots of cores. Separate doors should be provided to close each section so as not to expose one section to cold air when cores are to be put in or taken out of the other. By this arrangement much more work may be baked than if the whole front is to be opened at once. The doors may swing upon hinges if there is a lack of height for lifting doors, although the latter, properly balanced, form a very convenient arrangement, and not in the way when the doors are opened.

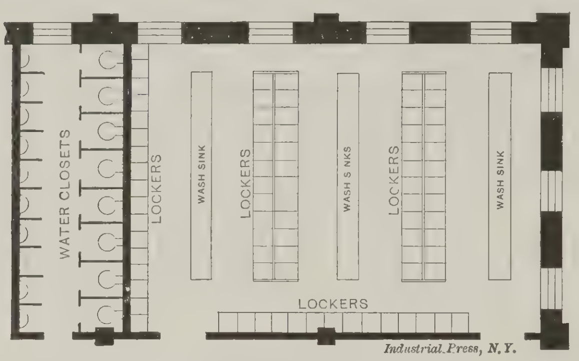


Fig. 8. Showing Arrangement of Wash Room.

The flask room requires no special arrangement or equipment beyond the car track and its cars for carrying flasks to and from the molding floor, unless a very considerable number of the flasks are of small and medium sizes, when they might be conveniently stored upon a gallery floor, which might extend nearly around the room. Flasks could be quickly and conveniently passed to and from this gallery by means of a pneumatic hoist. By this means the storage capacity of the room could be increased at least fifty per cent., perhaps more.

The wash room is located in one of the outer corners of the foundry proper, as shown in Fig. 1, and has adjoining it the water closets, and next to these the lockers for the use of the employees. The washing sinks are of cast-iron and arranged with an individual supply of water from a pipe running along above them. One of these sinks is shown in perspective in Fig. 7. By this method of water supply each man may have clean water, and still the expense of separate wash bowls is avoided. The plentiful supply of fresh water is nearly always appreciated by the men, although the writer once knew of a shop in which a similar arrangement for their cleanliness was made and the men refused to use it, preferring to wash in the common pool of not over-clean water in which all the rest of the force did the same. It has been said that "there is no accounting for taste," and this may be a case in point. Certain it is that the well-meant efforts of shop owners and managers are not always appreciated by the employees.

The water closets are arranged with a row of separate closets on one side, and a row of urinals on the other, the latter having dividing partitions 24 inches wide, while the depth of the closets is 3 feet 6 inches, and each is provided with a swinging door hung with double spring butts. The closets should be arranged so as to flush automatically, and a continual supply of running water provided for the urinals.

The lockers are of expanded metal, and are of the usual dimensions for such use, that is, 12 inches deep, 18 inches wide and 72 inches high. The width might be decreased to 15 inches and still provide ample room. They are placed in rows facing each other, with the two rows in the center back to back, for economy of space. In the plan just described it will be noticed that the lockers, the wash room and the water closets are each separated from the other. In some respects this is not as convenient as it will be to have the lockers arranged in the wash room. Such a plan is shown in Fig. 8. The amount of space and the expense necessary are about the same in either case, but the latter arrangement will probably be preferred by the employees generally, as being more convenient to have their lockers near where they are to wash up, and it will cause less confusion in running back and forth from one to the other, at a time when everyone is in a hurry to wash, dress and get out in the shortest possible time.

* * *

DEEP DRILLING.

FRANK B. KLEINHANS.

It has always been an expensive operation to drill out the interior of a hollow spindle. Indeed, it has not only been an expensive operation, but, on account of the spindle being of high-carbon steel, it has also been a difficult operation. Thus we have placed on the market hollow-drawn tubing, such as the Shelby tubing, which is intended to be furnished at a less price than one can bore out the interior of a solid bar. Of course for some purposes this tubing answers very well. But there are many cases, as in certain kinds of spindles, where such tubing cannot be used. We are obliged, therefore, to bore out this metal as best we can and endure the expense, whatever it may amount to.

Nearly all lathes nowadays must be built with a hollow spindle. This is also true of spindles of boring machines, drill presses, etc., and thus we have a large variety of work on machinery which involves deep drilling. The cost of deep drilling has been greatly reduced recently, by several manufacturers, by means of what may be termed a hollow drill. A strong flow of oil is forced through this drill against the cut, and on its return carries the chips with it, thus performing the double function of keeping the drill cool and clearing out the chips.

A perspective view of one of these drills fitted up complete for work, is indicated in Fig. 1. The body of the drill, *B*, is made of machine steel. The point, *P*, is made tool steel, and is held in position by the taper pin, *T*. A hole, *H*, is drilled in the shank, and from this hole the oil is led to slots, *S*, which are milled along the outside. These slots run the full length of the drill and then shoot down at the ends, as indicated. *F* is a flat spot for holding the drill.

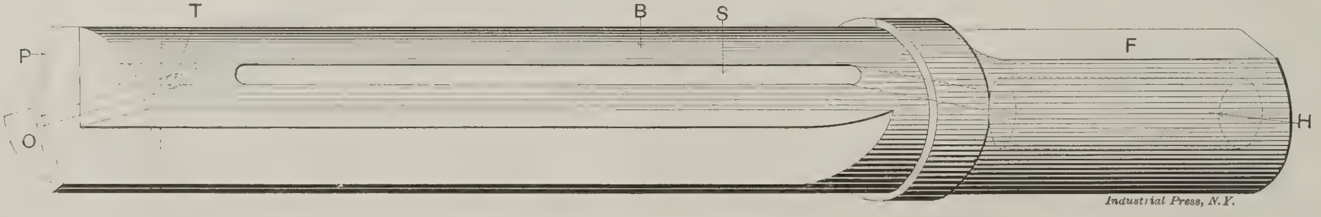

Fig. 1. Oil-tube Drill for Deep Drilling.

A longitudinal sectional view of this drill is shown in Fig. 2, from which the construction of the passageway for the oil is better seen. *H*, again, is the oil inlet hole already referred to. Two small holes, *J*, *J′*, are drilled into it in the manner indicated in this figure. The holes, *K*, *K′*, are then beveled off, and a piece of brass tube is bent in the arc of a circle and the ends are entered into the holes, *J*, *J′* and *K*, *K′*. It is then hammered down into place and the joint is flushed with solder. The slot, *P*, is milled out so as to have a semicircular bottom. Into this slot the cutter of the drill is neatly fitted. These points are best made of Novo steel, as they hold up better than under high speed. They are made as shown in Fig. 3. The hole, *H*, is reamed through the drill, while the cutter is clamped firmly back against its seat at the end of the slot. The angle, *A*, is made about 20 degrees. The cutting edge is nicked at several places, as at *N*, in order to break up the chips, this being done on the corner of an emery wheel. After the drill is put into place, it is ground up accurately to the diameter, *D*.

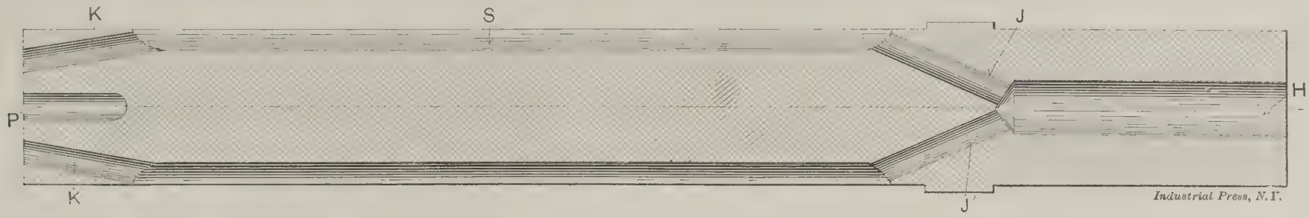

Fig. 2. Section of Drill.

The arrangement of a machine for boring out lathe spindles with this drill is shown in the illustration in Fig. 4. Instead of the long slide and hexagonal turret, a special slide, *A*, is provided, which is shaped up at the end to receive the drills. *B* is a steady-rest and *S* is the spindle. A lathe carrier is screwed into the end of the spindle, as shown, and a plate, *P*, holds the spindle up against the center by means of a few bolts. *C* is a Brown & Sharpe No. 2 pump, which is belted up to run 350 revolutions per minute. This gives an ample supply of oil for drilling a three-inch hole. A flexible tube leads from

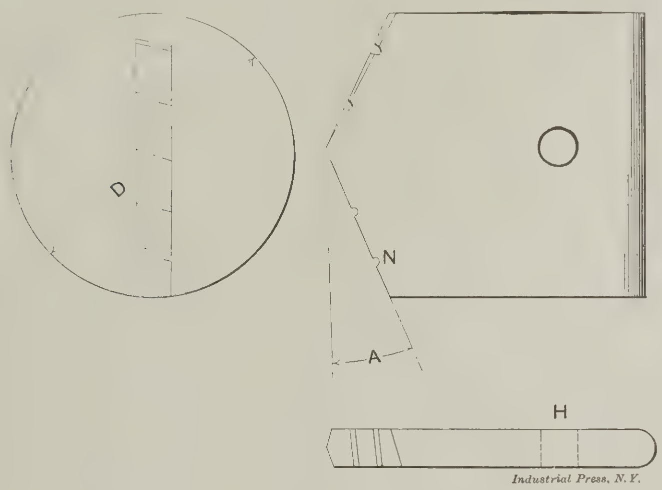

Fig. 3. Steel Cutter for Oil-tube Drill.

the spindle. The trays, *T*, *T*, catch the oil, and from these trays a pipe leads to the suction side of the pump. The drill is made long enough so as to run a short distance beyond the middle of the spindle to be drilled, the spindle being then turned round and drilled from the other end. With a drill made up in the manner explained, it is pos-

the pump to the fitting, *F*, and from thence the oil enters

sible to drill a 1 5-16 diameter hole in a .40 carbon spindle at the rate of 1⅜ inches per minute. The cutting speed would be 60 feet per minute on the longest diameter of the drill. We would thus remove the following amount of metal in a day of ten hours:

$$\frac{1.353 \times 11 \times 60 \times 10 \times .28}{8} = 312.5 \text{ pounds.}$$

By this method, a bar 28 inches in length can be drilled out at less cost than we can obtain the cold-drawn tubing of the same size.

* * *

Most failures of amateurs in machine shop photography arise from insufficient exposure. The result is a thin negative having poor printing qualities. The best thing to do under such conditions, is, of course, to take another picture, giving longer exposure or using a larger stop, but this is not always feasible. In such cases it is possible to improve the printing effect by making a transparency, using plates covered with lantern-slide emulsion, that is, plates that are specially prepared for making lantern slides. The transparency is made with the two plates placed with their faces in contact, and held in a printing frame so that the register may afterward be exactly duplicated. This is simply done by pressing each into the same corner so that a side and end are in contact with the ledges. When the transparency has been developed, fixed and dried, it is used in connection with the negative for making prints, being placed in the printing frame first, followed by the negative which is, of course, disposed in the ordinary manner with reference to the printing paper. The transparency being the exact opposite of the negative, has the effect of reducing the high lights and giving the shadows time to print the fullest possible detail.

Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

JANUARY, 1904.

NET CIRCULATION FOR DECEMBER, 1903,—27,217 COPIES.

MACHINERY is published in three editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages. The Engineering Edition—$2.00 a year—contains all the matter in the Shop Edition, and about 250 pages a year of additional matter, which includes a complete review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering, but is printed on thin paper for transmission abroad.

Mr. George H. Hall has resigned from the editorial department of MACHINERY to again take up the work of constructive engineering. He is to be connected with the Crocker-Wheeler Company, Ampere, N. J., and carries with him the friendship and best wishes of his associates in this office.

PRESIDENT DODGE'S ADDRESS.

Mr. James M. Dodge's presidential address before the American Society of Mechanical Engineers, upon "The Money Value of Technical Training," should make pleasant reading for a young man who is trying to improve his opportunities for self-advancement. It should strengthen his confidence in himself and in his future.

Mr. Dodge believes that education pays. We probably all believe that it pays, provided the education is of the right kind and does not absorb too many of the best years of a young man's life. But the interesting thing about Mr. Dodge's paper is that he backs up his belief by statistics which demonstrate, so far as his investigations have gone, that education pays in dollars and cents. He went at the subject in a business-like manner, by selecting four groups of men, between whom comparisons of progress and advancement were to be made, and his final conclusions were derived from the average attainments of the men in each group. The first group was composed of unskilled workers or laborers; the second of shop-trained mechanics; the third of mechanics trained in schools of mechanic arts; and the fourth of technical graduates.

A statement of the manner in which the data were gathered was purposely omitted by Mr. Dodge so as to divert the discussion of his address from this feature to the more profitable question of actual results accomplished by technical training. The figures were obtained, however, in the main from the records of the Link Belt Engineering Company, Philadelphia, of which Mr. Dodge is president. The statistics of laborers represent the records of about ten years and are the averages of at least 200 men. Those of mechanics who have grown up in the shop cover a like period and were derived from about 150 men. The trade school statistics are based upon the record of 24 men selected at random from about 50 men. Those with regard to technical graduates are based on records of about 80 men who are or have been in the employ of the company. Considerable pains were taken to verify the figures by comparing them with those obtained in other establishments.

Taking the average results from each of these groups, Mr. Dodge has plotted a diagram indicating the rate and extent of advancement of each class of employees, from which we draw the following general conclusions:

The pay of the average laborer rises steadily until at 22 years of age he receives about $10 a week; and there it remains. He apparently has no resources, no initiative, no reserve to draw on to enable him to climb higher.

When we come to the shop-trained mechanic we find that his wages advance in a similar manner, but he rises higher. He has a trade to help him and does not arrive at the stationary period of wages until 24 years old, when he receives $15.80.

The trade school group averages to reach $12 a week at 19 years and $22 at 25 years. From this point on the wages do not remain stationary, as in the other two cases, although the rate of increase is small; but it is enough to indicate that the education of the trade school is of permanent help to a man in securing advancement, while a trade alone, without the education, will not, on the average, provide the means for advancing beyond a certain point.

Finally, the technical group, which advances rather slowly at first, shoots ahead rapidly after a few years and continues to climb—perhaps indefinitely. At 18 years the technical man receives only $4 a week, and at 24 years $18, but at 30 years he receives $41. As a matter of course both the trade school and technical men will at some time reach "high-water mark," beyond which their pay will not rise, but there were no statistics to indicate where these points are and it is doubtful if they could be determined.

The lesson to be learned from Mr. Dodge's address is not that a course of study will enable one to receive a stated sum of money at a certain age, and it would be wrong to assume that a course of technical study would necessarily qualify a man to draw 25 or 30 or 41 dollars a week; or even that he would receive these amounts if he were qualified. Neither is it an argument showing that a shop man may not earn several times 41 dollars a week, without even any education at all, if he has the opportunity and ability. Advancement really depends upon two things: First, outside conditions, such as the state of the labor market, influence of friends, chance opportunities, etc.; and second, the inside conditions, or what the man himself is or what his abilities are. One may and often does secure a position through outside conditions; but it generally requires ability to hold it, and Mr. Dodge has gone one step farther and has shown pretty conclusively that in the long run and on the average it requires not only ability, but knowledge to hold a good position. As he expresses it, "Trained common sense receives the greatest compensation and reaps the greatest reward," and he very aptly says, "Every man pays for the amount or percentage of bossing he requires."

It is to be hoped that other manufacturers, with statistics at their disposal relating to their employees, will have results tabulated, similar to those quoted, so that we may know whether the effects noted by Mr. Dodge in the comparatively small groups observed, actually hold in larger groups, composed of men engaged in varied lines of industry. Such a test would give the surest indication of the commercial value of education.

* * *

The manufacture of metal planers presents an almost ideal example of planer work—the platen. Naturally the tool builders making planers present a first-class showing on planer work in their own shops. Two tools working on a platen as large as that of the machine planing it, is an impressive sight, as is also the pile of cast iron chips removed in a regular day's work. In the shop of the Cincinnati Planer Company the platens are first roughed top and bottom and on the sides, and the T-slots are also roughed at the same time.

The platens are then taken to the drill press and the holes drilled for the stakes, using Novo steel twist drills running at high speed, the speed for a 1-inch drill being about 280 turns per minute. Drilling the platens before the finishing is done gives the internal stresses in the castings a chance to readjust themselves, thus preventing final changes after the finishing cuts are taken. After the finishing cuts have been planed the ways are scraped and fitted to the Vees and lastly the final finishing cut of a platen is taken on its own bed, driven by its own mechanism when being tested.

NOTES AND COMMENT.

A treatise has recently been issued, called "Technical Mechanics." The Standard Dictionary defines the word technical as "specially or exclusively pertaining to some particular art, science, trade, occupation, or the like." Mechanics is at least a branch of science, if not a science itself; so, What would non-technical mechanics be? Now let us have a treatise on medical pharmaceutics.

A number of manufacturing concerns in this country now provide their employees with a warm lunch at noon, or furnish dining room facilities where they can eat lunches brought from home in comfortable surroundings and add to the *menu* certain items like soup or coffee supplied by the company at nominal prices. This is not done as an act of charity, but is a matter of good business policy. The increased energy and better health resulting from a warm substantial noonday meal, especially with female help, has been found to more than pay the cost of such undertakings. The well-known National Cash Register Works at Dayton, Ohio, now feed about 550 girls daily, and it is their plan to eventually provide dining facilities for all their employees, who number about 4,700, during the busy season. A big catering job, that!

Notwithstanding all the arguments in favor of the worm gear, the fact remains that it is much more likely to be abused than spur gearing. The latter *can* run without oil, and, of course, in almost every instance it is better for it to do so, but worm gearing must have oil, or it will soon wear out. While it may be argued that anyone in charge of worm gearing, would run it in a bath of oil if he had any mechanical sense at all, the fact remains that machines of this type have been ruined simply by not being properly oiled. We well remember a large worm-driven butting machine installed in a structural iron works for facing off the end of cast iron columns. A pan beneath the worm, forming part of the machine, was a mute appeal for plenty of that which lubricates, but the machine was run at a period of about six months with "nary" a drop of oil in the pan, and only an occasional drizzle on the gearing, with the result that the wormwheel was nearly worn out in that period.

A not unusual procedure and perhaps the most common method of setting a gear cutting machine, is to do so by making a trial cut and measuring the height of the tooth with a gear tooth caliper. The result by this method may be right if the outside diameter of the blank is right, but if it varies a few thousandths from the correct diameter, the variation may make a noisy running gear. Again it is not the easiest matter in the world to get a correct setting in this way, even with a correctly sized blank. The Cincinnati Planer Company provide cast iron blanks, mounted on permanent arbors, for setting their gear cutting machines, which are carefully ground to the correct root diameter of the required gear. The operator places the setting blank upon the index centers and raises the cutter until it just skims the surface, which has been covered with a light coating of red lead. The setting made in this manner is very accurate, being easily within a limit of one-half thousandth inch. If the operator happens to score the surface of the setting blank it is not ruined since obviously any untouched portion of its surface can be used for setting purposes.

There are two ways of handling mechanical difficulties—one by surmounting them, the other by going around them. A well-known mechanical engineer says that sorrow and vexation of spirit is almost invariably the lot of the engineer who attempts the first mode of solution and that the easiest, and usually the best way, is to solve them by not solving them, that is, by using some other expedient equally as good, but free from the objection of the other. A case in point is that of the Manhattan Elevated Railway in New York, now a portion of the Interborough system, in regard to the third-rail difficulties in snow and sleet storms. The officials are trying to surmount the difficulty by removing the accumulations of sleet by scrapers, etc. One device of this nature is now being tried and has been found moderately successful. But its action is accompanied by a distracting screech, and it is quite doubtful if it will work successfully under severe weather conditions. The device does *not* remove the difficulty permanently—it works Sisyphus-like at a never-ending task so long as sleet is falling. The logical way of handling this problem is by preventing all accumulation of sleet on the third rail. A hooded construction presents a simple and readily built protection which has been found to successfully cope with the snow and sleet trouble in a location far worse than that of New York City.

MACHINE WORK VS. FORGING.

One of the largest steel companies in the country is employing high-speed steel for reducing forgings in a way to open the eyes even of those conversant with the rapid lathe work done in many of our machine shops. This steel company has special lathes for reducing rough forgings to the rough-turned size suitable for shipping to customers, and we are reliably informed that these lathes are of sufficient power and can carry enough cutting tools for simultaneous turning, to remove what is estimated to be thirty times the weight of metal that an ordinary heavy lathe of the same swing would be capable of turning off. The use of such massive and powerful tools, and the introduction of high-speed steels, have brought about a new condition in the production of these high-grade forgings, in that after being roughly formed from the ingot they can be reduced to approximate size more rapidly and far more cheaply by turning in a heavy forged lathe than by forging down to size under the hammer or hydraulic press. An instance has been cited to us of a forging that was reduced from 36 to 28 inches in diameter by one man working at the lathe for two days, where a gang of workmen would have been required for perhaps a day at the forge and hammer by the old method. And not only would the labor cost have been greater, but the forge and hammer would have been tied up during this time and a great quantity of fuel would have been wasted.

ELECTRICITY DIRECT FROM FUEL.

Ever since, and even before, the period when the potential force of electricity was generally recognized as a factor of great commercial value the dream of the engineer was to generate it direct from fuel without recourse to the present cumbersome and wasteful process. With the steam boiler, engine and dynamo the fuel must be fed into a furnace, where, if it is not already in a gaseous condition, it gasifies and burns at a high temperature—the higher the better, the average firebox temperature being from 2,200 to 2,500 degrees F. or more. The heat thus produced is transmitted through the shell and tubes of the boiler to the contained water which is changed into steam under pressure. By virtue of its latent heat and pressure the steam impels the piston and its energy is converted into rotary motion. Still another conversion is made in the dynamo to supply the electric current. All this is costly and inefficient, as we all know only too well. The best stationary steam plants that we know of cannot show an efficiency of one indicated horse power per pound of coal per hour, although some closely approach it. But this figure is absurdly wasteful, the thermal efficiency being only about 19 per cent., and with the best gas engines it does not appear possible to show an average efficiency of much more than 25 per cent. The efficiency of the average commercial steam plant is said to be only about 8½ per cent., and perhaps this figure is high. It is not surprising, therefore, that many of the best inventive minds have been working on the problem of direct heat conversion, the theoretical possibility of which has generally been conceded, but which has presented most formidable and baffling difficulties to a practical solution.

* * *

In a recent number N. C. B. contributed a note about different coatings for a shaft when it is necessary to pour a solid babbitt bearing around it. Mr. J. C. Green, Hackettstown, N. J., writes that he has used a simple method for years past. It is simply to rub the shaft sparingly with hard soap before pouring the bearing. He has found this plan very successful.

MEASURING EXTERNAL THREAD DIAMETERS.

METHOD OF THREAD MEASUREMENT BY MEANS OF WIRES AND MICROMETERS.

JOSEPH M. STABEL.

No doubt many mechanics who have to do with the making of taps, thread plugs and rings, often find it difficult to get accurate fits by using the tops of V-threads as points from which to obtain their measurements. Errors are almost sure to exist when measuring from the tops of the threads—points which in one sense of the word have no value at all. As is well known, the bearing of a thread is on its side and that is where a perfect fit is required. Some take it for granted that if the measurement over the tops of the threads, and that at the root, are correct the thread cannot help being a perfect fit, and no doubt they are right provided the root diameter is measured properly and the sides of the teeth are cut at exactly the right angle.

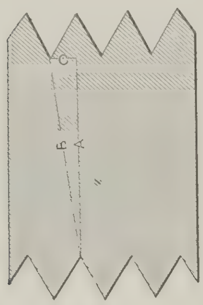

Fig. 1.

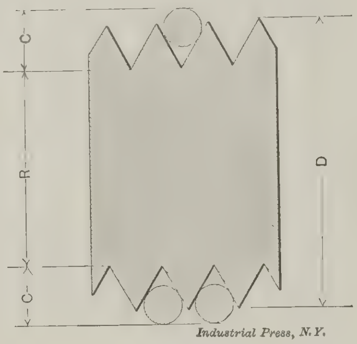


Industrial Press, N.Y.

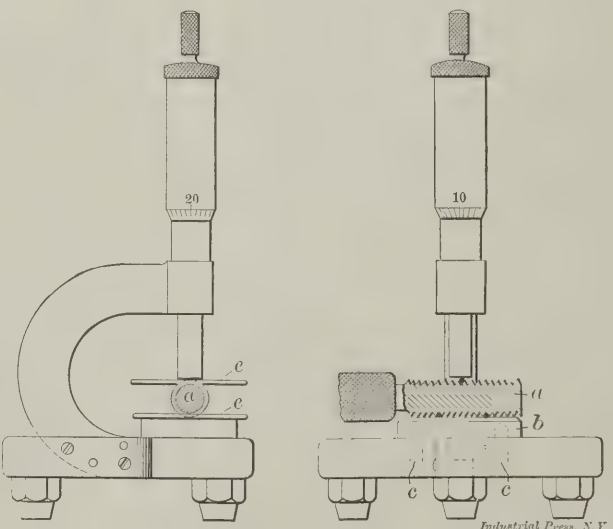
Fig. 3.

In obtaining the root diameter it is customary to divide the constant 1.732 by the pitch of the thread, and this gives the diameter of the cylinder upon which the threads are formed, but it is impossible to measure this diameter directly, as will be seen in Fig. 1. If this is a ½ inch 12 thread screw the core diameter will be $\frac{1.732}{12} = .1443 +$ and $.500 - .1443 = .3557$, which is a measurement that must be made at right angles with the center line of the screw; an impossibility unless a pilot is turned on each piece that is to be threaded, and the thread then cut down until it comes in contact with the pilot. This, however, is not a practical method, and can seldom be followed. As will be seen in the figure the line *B* indicates the angle at which the calipers would be set in measuring this thread and it will be easily seen to be longer than the line *A*, which indicates the actual core diameter. Should the core diameter be measured on the line *B* it would be equal .3582. So when measuring the root diameter of any screw, as on the line *B*, we would have to discard the constant 1.732 and use the formula $B = \sqrt{A^2 + C^2}$.

Measuring at the top and root of the thread, however, does not always insure an accurate size of screw, as the sides of the threads may be convex or concave, thereby giving a thread that is thicker or thinner than it should be. In such a case the screw would not fit the female threaded ring properly even though the external and root diameters were accurate in size. So the method here described has been found a much more satisfactory way of measuring screw threads than by the method of measuring the apexes of the thread diameters. The measurements are accomplished by the aid of short pieces of round wire, different diameters being employed for the various pitches of threads. Fig. 2 shows the method in use and illustrates a neat fixture that is adapted to the purpose. It is composed of a regular micrometer with its anvil cut off and the frame fixed into a base plate which, in turn, rests upon three hardened legs. Great care should be taken when milling the slots into the base plate to receive the frame of the micrometer, as it must stand perfectly perpendicular with the base to insure accuracy. Upon this base plate rests the plate *b*, which serves as the anvil of the micrometer. It should be hardened, ground, and lapped on its sides perfectly parallel and is held in position by the two screws, *cc*, which fit blind holes, so that the anvil surface will be free from any obstructions. The wires are shown in position at *eee*. It is not really necessary to have this fixture as an ordinary pair of micrometers may often answer—especially for measuring fine pitch screws—but it can be easily seen that the fixture makes the work very much easier to handle.

Table No. 1 has been computed by the writer for use in connection with this method of measuring threads. It gives the measurements that are obtained by using certain sizes of wires for the certain pitch threads, both V. and U. S. Standard. It not only gives the sizes for standard threads but for numerous others with their corresponding diameters. As an illustration of the use of these tables let us suppose that a 10 pitch, ⅝-inch V-thread tap is to be cut. Following down the first column (marked diameter of screw) we come to ⅝. The next column shows the threads per inch, which in this case is 10; the third column gives the distance from center to center of adjacent threads, or .1. The fourth column gives the diameter of the wire that is to be used and then, following on to the right, the next three columns are the properties of a V-thread, and the last four of the U. S. Standard thread, giving the diameter of core, flat on threads and also the diameter of the screw at its apex of the thread angles, or in other words, the diameter that would result if the flats were omitted and the sides ran to a point; see diameter *A* in the cut. The last column is the diameter measured over the wires. As the tap is a V-thread, the fourth column shows that a .07 wire is to be used and the seventh column gives the actual size that is to be measured over the wires; which in this case is .6618, Had our tap had U. S. S. threads the size of wire would have been the same but the over-wire measurement would have been .68344.

It may be desired to measure some thread that is not found in Table 1, and for this purpose reference is made to Table 2, which gives the constants used in connection with certain sized wires on 60-degree threads. This table covers nearly all threads used, and with it the diameter required for the measurement may be easily obtained. In the first column are the threads per inch, ranging from 2 to 100, and any intermediate thread measurement can be obtained. In the upper column, running horizontally from left to right, are the different diameters of wires that may be used and under the different sizes appear the constants in line with the pitches to which they apply. The rule for the use of this table is as follows: Divide the constant 1.732 by the pitch and this gives the double depth of the thread. Subtract this from the diameter of the screw, and to the remainder add the constant selected from the table, the result being the diameter that is to be measured over the wires. The constants in this table are equal to twice the distance from the root of a 60-degree V-thread to the top of its relative size wires, as will be seen in Fig. 3, in which *CC* represent the constant, *R* the root diameter and *D* the diameter of the screw.



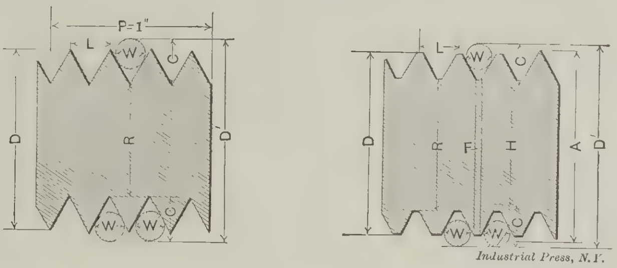
Industrial Press, N. Y.

Fig. 2. Micrometer for Measuring Threads with Wires.

For example, we will suppose that a ⅝-inch, 10-thread tap is to be made by the use of Table No. 2. As diameters are not given in this table we look up 10 pitch, in the first column, and following this along to the right we come to the constant .180, and at the head of this column we note that this constant is to be used with a wire .06 inch in diameter. If we have not this size at hand we can select from three other sizes, or in other words, a ten-pitch thread can be measured with either an .060, .070, .080 or .090 wire. Having an .080 wire at hand we select the constant for this wire which in this case is .240. Following our rule we then have $\frac{1.732}{10}$ .1732 and diameter of screw equals .625 — .1732 = .4518, which is the core diameter of the screw. Then .4518 + .240 = .6918, which is the size that is to be measured over the tops of the .080 wires.

The foregoing example was for a V-thread screw but the table may be used equally well for a U. S. S. thread, the only difference being that we must consider the threads of the screw continued up to an apex thus giving a larger diameter for a certain size of screw, as will be seen in column eight

TABLES FOR MEASURING V AND U. S. S. THREADS WITH THE AID OF STEEL WIRES.



Industrial Press, N.Y.

D = Diam. of Screw.	P = Threads per inch.	L = Distance from Center to Center.	W = Diam. of Wire used.	V Threads.			U. S. Standard Threads.			
				R = Diam. of Core.	Double Depth of Thread.	D¹ = Diam. over Wires.	R = Diam. of Core.	F = Flat on Threads.	A = Diam. of Apex of 60° Angle.	D¹ = Diam. over Wires.

Table No. 1.

of Table 1. The diameter of a ⅝-inch 60-degree U. S. S. thread with the sides of the threads brought up to an apex would equal .6466. Then we proceed as with the V-thread, by taking this as the diameter and from it subtracting the double depth of the thread and adding the constant from the table. Thus: $\frac{1.732}{10} = .1732$ and $.6466 - .1732 = .4734$, which added to the constant for the .080 wire equals $.4734 + .240 = .7134$, which is the diameter which is to be measured over the tops of the wires for a U. S. S. thread.

Table No. 3 furnishes the data for measuring Acme standard screw threads of the pitches most commonly used on that style of thread. In the first column is given the number of threads per inch; in the second the double depth of the threads, by means of which the core diameter may be obtained; while the third column shows the size of wire that is to be used, which equals one-half the pitch, or nearly so. In the fourth column we find the amount that is to be added to the core diameter to find the measurement over the wires, and the last column gives the amount that is to be added to the largest diameter of the screw to obtain the same measurement. The convenience of this last column lies in its making it unnecessary to find the core diameter of the screw in order to measure the thread. For example: Should it be desired to cut a one-inch screw with six threads per inch, the only computation necessary would be to add the value found in the last column to the outside diameter of the screw, or $1.000 + .00898 = 1.00898$, which is the size that is to be measured over wires .083 inches in diameter for this size and pitch of Acme thread.

The nickel-steel alloy known as "invar," which has a coefficient of expansion of nearly zero (about 0.00000073 for 1 deg. F.) is being used to some extent by the United States Geodetic Survey in the construction of transits, but its use for measuring tapes is as yet made difficult by the fact that all nickel-steel alloys having a large percentage of nickel, are too soft to allow their use in the field for measuring purposes. It is hoped that this difficulty will soon be overcome, since promising results in that direction have been accomplished in France already. It is a consummation to be hoped for in the interests of exact measurements of base lines —the present method of using an iced bar, is very expensive and cumbersome.

TWENTY-FOURTH ANNUAL MEETING

OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

The annual meeting of the American Society of Mechanical Engineers was held from December 1 to December 4, inclusive, and was characterized by an unusually large attendance. The opening session, at which the retiring president delivered the annual address, was held at the society house, which was crowded to its utmost capacity. The subsequent sessions were held at Mendelssohn Hall, New York City, and Stevens Institute of Technology, Hoboken, as the society's hall is entirely inadequate to accommodate the large number who attend the annual meetings. Social entertainment was well provided for. Besides the usual reception, one afternoon was devoted to an inspection of the immense power plants of the New York Edison Company, the Manhattan Railway Company and the Metropolitan Street Railway Company. On another afternoon Prof. Goldschmidt gave his interesting lecture upon "Alumino-Thermics," reviewed in these columns last month. The afternoon of the last day was utilized by an excursion to the works of the De Laval Steam Turbine Company, Trenton, N. J.

At the business session the report of the council was presented, covering the affairs of the society, and showing, among other things, that there was a net deficit for the year of over $1,100. In connection with this report Mr. C. W. Hunt made a statement concerning the Engineering Building project. He said that last year Mr. Carnegie attended a meeting of the Electrical Engineers and was much interested in the enthusiasm aroused by an address by Mr. Scott, the president, upon the necessity for co-operation of the different engineering societies. Finding the several great engineering societies of the country to be in good financial condition, with substantial resources, he suggested that they join forces and buy land, upon which he promised to erect a Union society house. The several organizations have since taken action upon Mr. Carnegie's proposed gift, and through funds advanced by Mr. Carnegie, have purchased a plot of ground on 59th Street, and it is now held, pending action by the several bodies.

The Mechanical Engineers have not only adopted resolutions favorable to the Union building, but have individually signed the resolutions, to emphasize the importance of the event. The Electrical Engineers and Engineers' Club have also fully adopted the scheme. The Mining Engineers, by their peculiar by-laws, were obliged to hold a letter vote, resulting in only 13 votes against the plan out of a total of 1,600 replies. The Civil Engineers were also unable to act immediately, but have had the gift under discussion and it will be voted upon in February.

To advance matters to a definite point an architect has made preliminary plans, which prove the plot of land ample for all requirements. But the estimated cost showed the million dollars to be given by Mr. Carnegie inadequate for so large a structure, and he was accordingly approached upon the subject and willingly agreed to furnish one and a quarter millions, or as much as might be necessary.

The next business was the report of the tellers to count the ballots on the amendments to the constitution and rules previously proposed, which were declared adopted.

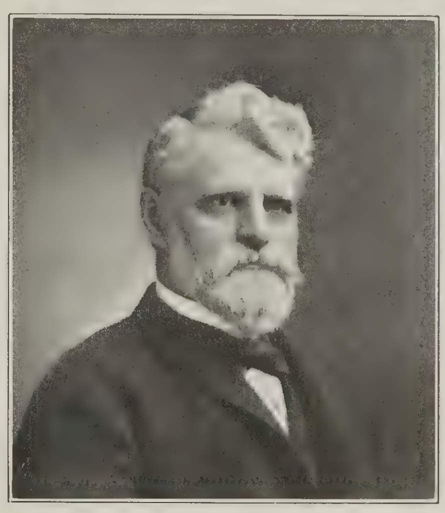
The President-elect then took the chair and in his brief remarks alluded to the formation of the society in 1880 and of a visit he then received from Prof. Sweet when the latter told him of the new society and its great advantages, and of its possibilities in the way of development.

Mr. Henry Harrison Suplee brought to the attention of the meeting the approaching twenty-fifth anniversary of the society and proposed that a historical record be prepared upon its organization, growth, books, pictures, relics, etc., and the president appointed Messrs. Suplee, Sweet and Hunt a committee for the purpose.

At the business meeting, also, the question of specifications for certain grades of steel was discussed, in view of the report of a committee appointed to confer with the American Society for Testing Materials. Mr. Henning, and Profs. Carpenter, Lanza and several others offered criticisms, chiefly against the proposal that the "yield point" be omitted from specifications.

The President for the Coming Year.

Ambrose Swasey, the newly elected president of the American Society of Mechanical Engineers, was born at Exeter, N. H., and spent his younger days in New England. His father and grandfather lived on the farm where he was raised and reached the venerable ages of 91 and 94 years, respectively. Mr. Swasey stills owns this farm and occasionally visits it in the summer time. At the age of 18 he left the old homestead and went to Hartford, Conn., to learn the machinist's trade at the Pratt & Whitney shops. He was accompanied by W. R. Warner, his boyhood chum, and now his business partner in the Warner & Swasey Company, Cleveland, O. While with Pratt & Whitney Mr. Swasey advanced to a position where he had much important work to do, particularly in the department of gearing. He developed, among other things, the machine used by this company for the production of true epicyclic curves and later his own generating and cutting machine, which is in use at the works at Cleveland. In 1880 the firm of Warner & Swasey was started, and while they have primarily been machine tool builders, they are better known to the public as builders of mountings and mechanism for astronomical instruments, particularly the telescopes at the Lick and Yerkes observatories and the naval observatory at Washington. Mr. Warner is a past president of the American Society of Mechanical Engineers, and it is highly complimentary to the firm that both its members have been able to honor the society by serving in this capacity.



Ambrose Swasey.

The Professional Papers.

In the last number of MACHINERY was published a complete list of the titles of papers presented at the New York meeting, and from these we have selected several for review in this number. Brief abstracts of these, and of the discussions upon the papers, follow:

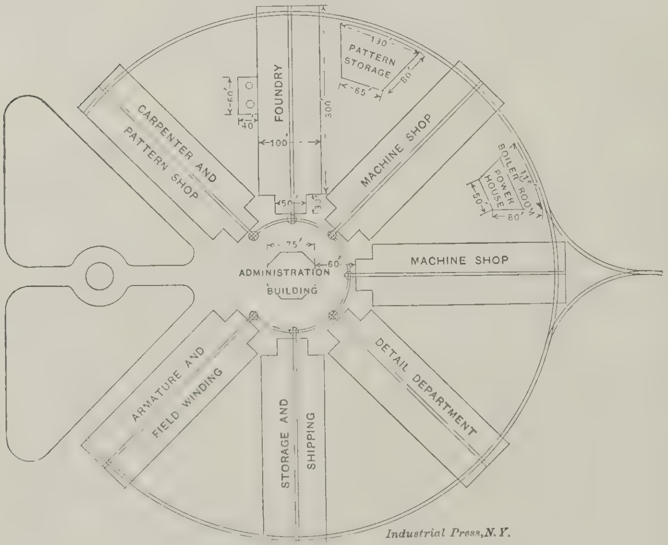
Tests have been made upon air motors and pneumatic hammers at the Aurora, Ill., laboratory of the C. B. and Q. R. R., and a paper by Max H. Wickhorst describes the apparatus used and gives the results of the tests. Those of the greatest interest relate to the power of a Vulcan pneumatic hammer, weighing 22 pounds, with a plunger weighing one pound and having an 8-inch stroke. The hammer was so placed that it would strike upward against a weight of 120 pounds, so connected with an autographic recording apparatus that any vertical movement of the weight was multiplied 8 times on the record. Tests were made with air pressures of 60, 80, 100 and 120 pounds and the distances the weight was raised by the hammer blows under the different pressures were, respectively, .004, .0052, .006 and .0065 feet. The corresponding foot-pounds per blow were accordingly, .48, .624, .72 and .7818. The strokes per minute were 834, 892, 964 and 1,000, and the horse power, found by multiplying the foot-pounds by blows per minute, and dividing by 33,000 is, for the different air pressures, .0122, .0168, .021 and .0236.

The Construction and Efficiency of a Four-valve Engine, by Benj. T. Allen, related to a type of engine in which four Corliss valves are used for each cylinder, but are positively operated by a shaft governor. Engines of this class are usually operated at medium speed, not exceeding, say 200 revolutions per minute. The particular engine under description was built by the Harrisburg Foundry and Machine Company, and is tandem-compound, direct-connected to an electric generator. The cylinders are of the ratio 1 to 7.33, after the style advocated by Mr. Geo. I. Rockwood, high pressure cylinder 15 inches diameter, low pressure cylinder 40½ inches and stroke 27 inches. There is a reheating receiver between the cylinders. The engine runs condensing at 150 revolutions per minute. The boiler pressure varied during the tests from 90 to 153 pounds per square inch and tests were conducted with loads at 1-6, 5-8, 7-10, and 1 1-10 full load. The steam consumptions per I. H. P. per hour at these several loads were, respectively, 14.42, 13.59, 12.33, 12.66 and 12.73. These results indicate a remarkably small variation in steam consumption for different loads, representing a curve of economy closely approaching a straight line.

In the discussion Prof. Carpenter questioned the value of comparisons of tests where the boiler pressure changed so greatly. He also said that while the efficiency curve, found by plotting the total steam consumption in relation to the horse power, would become a straight line in the case of a throttling engine, which runs at fixed cut off, he had never known of an instance where it would be other than curved in the case of an automatic cut-off engine.

Mr. Rockwood, however, corroborated the "straight line" performance and said that in reality this engine, while actually an automatic engine, would throttle the steam at short cut-offs, tending to make the efficiency curve a straight line. He also testified to the excellent results with other "high-ratio compound" engines, and quoted tests giving results similar to the Harrisburg engine. The author of the paper said that as the steam was throttled in any case by the action of the valve at small loads, the low boiler pressure during certain of the tests introduced no error.

Suggestions for Shop Construction, by F. A. Scheffler, outlined the layout for a manufacturing plant, on the hub-and-spoke plan. In the center of the space available for buildings is located an administration building, constituting the business, accounting and sales offices; and on the second story, the drafting room. This building is octagonal, or hexagonal, whichever may be found to be most suitable for the purpose. In this case, it has been designed with a view of accommodating seven buildings, which radiate from each side of the octagon, and has one side reserved for the main entrance through the building. The end of each shop which is nearest to the administration building has its individual office for the foremen and shop clerks.



Industrial Press, N.Y.

Novel Arrangement of Manufacturing Plant.

The general arrangement gives each shop plenty of yard room, which is also very essential; and traveling cranes, either worked by hand or power, could be located in the yard room between any two of the shops, for handling raw or finished material.

A circular track around the administration building connected in front of each shop building by means of suitable turntables, worked by hand or power, makes the distribution of material between the buildings very easy, and it will be noticed that the distance the material will have to travel from any one building to another is comparatively short.

At the extreme outer end of each building is another circular track, primarily to be used for shipping purposes, and the distributing of such material as may come in or go out over the connecting railroad lines. This track runs through the end of each building; and in such buildings where the machinery, castings or other goods are to be handled, the heavier traveling crane in that particular building which should run the length of the shop, can easily unload or load the cars. This arrangement makes it possible to go into every shop without having a multiplicity of tracks and switches, thus cutting up the available yard room, as is usually the case in ordinary plants. It is also possible, if there is sufficient ground available, to extend any one or all of the buildings, and still retain the best features of the design.

In commenting on this construction, Mr. Suplee mentioned a penitentiary in Pennsylvania built on this plan, the guard house being at the center. A series of mirrors near the central portion of the guard house made it possible for an attendant sitting in a certain position to see what was transpiring in any of the radiating corridors without leaving his post or even changing his position.

"A compact Gas Engine, Beam Type," was the subject of a paper by C. H. Morgan. This engine is now being built and is designed in a way to minimize the lateral pressure of the piston on the cylinder walls. We shall not attempt to illustrate this engine at present, but there were several interesting points brought out in the discussion which will be referred to.

Prof. Sidney A. Reeve said there is a false impression that a blow is struck in a gas engine cylinder by the combustion of the gas. On the contrary, this is not so much the case as in the steam engine, considering the pressure at which the engine operates. In designing a steam engine for a steam pressure of 400 pounds per square inch, the pressure at which a gas engine works, there would be more trouble than in a gas engine, because with the former steam is admitted full pressure at the beginning of the stroke. He showed pressure diagrams, indicating the pressures sustained by the pins and bearings of gas and steam engines.

Mr. Thwait, the English engineer and gas engine expert, also corroborated this statement. Mr. E. A. Uehling presented data upon blast furnace gas. Above the requirements of the blast furnace and the heating of the blast there are 840 horse power per ton of iron produced available for outside purposes. In one plant 20,000 horse power answered requirements for blast furnaces, and there might be 18,000 horse power for sale in addition. While the amount of available power from different plants varies, in no case had he found it less than 800 horse power per ton of iron manufactured per hour. Though blast furnace gas is a lean gas, it is a very valuable gas for power purposes. When illuminating gas is used in a gas engine, there must be added 9 times the quantity of air while with blast furnace gas air need be added only about in the ratio of 1 to 1. In blast furnace gas there is only about 25 per cent. of combustible as against nearly 100 per cent. in illuminating gas; but when it comes to the final mixture of gas and air the illuminating gas will be found to have nearly 80 per cent. of nitrogen mixed with it and there will be more inert gas than with the blast furnace mixture. Besides the illuminating gas cannot be compressed to so high a pressure and is not so economical to use on this account.

In some respects the most important paper of the meetings was the report of a test by Prof. D. S. Jacobus upon a Rice and Sargent steam engine, using superheated steam. This is the first American-built engine of importance upon which tests have been conducted and reported before the society.

The high pressure cylinder of the engine has double-beat poppet valves and the low pressure cylinder, Corliss valves. The inlet and exhaust valves of each cylinder are operated by separate eccentrics. The inlet valves are closed by vacuum dash pots and the exhaust by a positive motion. A portion of the highly superheated steam furnished to the engine passes through a coil in the receiver between the high and low pressure cylinders. The cylinders are 16 and 28 by 42 inches. The steam is superheated in an independently-fired Schmidt superheater. With superheated steam the water consumption per horse power hour was 9.76 pounds at 474.5 horse power, 9.56 pounds at 420.4 horse power and 9.70 pounds at 276.8 horse power. The pressure of the steam at the engine throttle was slightly over 140 pounds per square inch, and the superheating from about 350 degrees to 400 degrees Fahr. The vacuum measured near the engine ranged from about 25 to 26 inches of mercury.

With saturated steam the water consumption was 13.84 pounds per hour per horse power at 406.7 horse power. In this test the vacuum was poorer than in any of the others, being 24.5 inches. It must also be borne in mind that the engine was built for superheated steam, and the cylinder ratio was not what would be used for saturated steam.

The coal consumption per hour per indicated horse power for superheated steam was 1.265 pounds at 475.5 horse power, 1.257 pounds at 420.4 horse power, and 1.288 pounds at 276.8 horse power. For the test with saturated steam the coal consumption was 1.497 pounds per hour at 406.7 horse power.

The coal consumption forms the most accurate basis for comparing the efficiencies of engines using saturated and superheated steam, because when the coal consumption is obtained it allows for any difference in the economy of the combined boiler and superheater from that of an ordinary boiler.

In the test with saturated steam the coal consumption was about 19 per cent. greater than that obtained at the same power with superheated steam. This does not form a proper basis of comparison, however, for the two reasons already stated, which are that the engine was not built for saturated steam and that the vacuum in the test was not as high as it should have been. An engine of the same general type built for saturated steam, but of about twice the power, was tested by the author and the results were embodied in a paper presented by him at the Saratoga meeting. The vacuum in this case was exceptionally high, being over 28 inches. If the vacuum had been about 26 inches, as in the present tests, it is probable that the coal consumption on the basis already given would have been 1.42 pounds per hour per horse power. As the minimum coal consumption with superheated steam was 1.257 pounds per hour per horse power there is a gain in favor of using superheated steam of .163 pounds per hour per horse power, or the larger steam engine using saturated steam is about 13 per cent. less economical than the smaller one using superheated steam.

Mr. Rice, of the firm which built the engine, called attention to some of the details of construction. The poppet-valve seats are surrounded by live steam to avoid trouble from difference of expansion of valve and seat. The stuffing-boxes are on long necks, to remove them further from the heat of the steam. The valve-gear is of the Corliss type, but with independent linkage to give full closing and avoid slamming.

The cylinder ratio of this engine was the subject of some discussion. The ratio of high pressure to low pressure cylinder volume is about 3 to 1, which ratio was copied from European practice in superheated steam engines. Professor Jacobus stated that it might be found that lower cylinder ratios need to be used with superheated than with saturated steam, but that there is yet no definite knowledge on this matter.

"What are the New Machine Tools to be?" was the title of a paper by Prof. John E. Sweet, which we reprint in full. In the discussion, Mr. Howard P. Fairfield reported the results of work of students at Worcester Polytechnic Institute with high-speed steel. Tools of certain brands of this steel were given students to use in 14-inch and 16-inch lathes. They were told to first break down the tools, if possible, and then reduce the speed and feed until a desirable balance was reached. On diameters of about 2 inches the lathes were not able to make good. The trouble seemed to be confined entirely to the headstock and carriage and most of the trouble seemed to be due to lack of material in the headstock itself. At the diameters turned a high speed was needed to give the necessary surface speed. He finally put on a heavy faceplate of large diameter to prevent tearing the headstock to pieces. The faceplate absorbed much of the jar and vibration due to the heavy cut. Mr. Fairfield suggested that the engine lathe needs more material in its headstock, broad surfaces in its carriage, which should be nicely gibbed, a positive drive to its feed works, a less number of steps on its cone and wider belts, and a massive faceplate.

* * *

WHAT ARE THE NEW MACHINE TOOLS TO BE?

A. S. M. E. PAPER BY PROF. JOHN E. SWEET.

It is a fact quite apparent to users of machine tools (and first among them are the machine tool builders themselves) that the new high-speed tool steel calls for a redesigning of our machines if we are to get even a fair share of the ultimate possibilities which the new steel offers.

I expect the machine tool builders have already the reply formulated as follows: "You just keep on building engines and leave the machine tool business to us." But that will not quite do. If no one but the engine builders had mixed in the engine business, we would have had no turbine engines, and many of the standard machine tools were originally devised by those who had use for them, rather than by the man who devised things to sell.

I think the machine tool builders will admit that the machines must be redesigned; but to the most of them will this mean anything but just to make the driving elements more powerful and the machines stronger, which is as much as to say everything has been all right, and all we need to do is to change the strength and power. But have they been all right or half right?

It can be shown by figures, I suppose (I know it to be a fact by a trial with models), that a complete box is thirteen times more rigid against torsion and four times more rigid against bending than the same amount of material is in the form of side plates and thin cross girts. It is probably from four to eight times more rigid than the cross girt plan in any form, and yet in the case of lathes, the whole business of whose beds is to resist torsion, only one or two builders have had the courage or audacity to adopt the box form.

All planer beds can just as well be box beds with half the cost in patterns and foundry work, and so, too, the tables which are sprung by bolting down work can just as well be box tables four times as strong with the same material, and with a saving of half the cost in patterns and something in the foundry.

The whole tendency of the cut is to slide the work endwise of the planer bed; but who has ever tried putting the slots crosswise in a way to offer the greater resistance and prevent the bending of the bed by the peening of the upper surface, as now occurs, which, with the springing by bolting down the work, are the primary causes of cut ways.

Some planer and boring mill cross rails are of box section in the center, but are thinned down at the ends when fastened to the housings. The most of them are three sides of a box only, or one-tenth the strength of a box, where a plain square box straight through is infinitely better and cheaper. Of course the boxes are not to be proportioned from what is in use now, but from what is to be made to meet the new conditions. To select enough material to meet the new demands and then put the material so that it will be four times more rigid will be something like it. Housings of box section will be just as rigid fore and aft and much more rigid against side strain.

Milling machines of the planer style are constructed like planing machines, seemingly without a thought but that the conditions are identical, while they are not. If the bed of a planing machine and the table were of the same length, the weight of the table and the load overrunning the end of the bed would soon wear the top of the bed crowning and the under side of the table concave to fit, and it is to counteract this tendency of gravity to wear them out of true that the beds are made longer than the tables. With the milling machine the load is less, more of it in the middle of the table, because there is less gained by putting on small pieces end to end, and the down pressure of the big cutter always in the middle partially, if not wholly, neutralizes the tendency to wear out of true by gravity. When such a machine has side cutters or a vertical spindle, the pressure is always in the middle, first in one direction and then the other, exactly the reverse from the gravity action, and instead of the side guide of the bed being longer than the table it should be shorter, by just about the same amount as the bed of a planer needs to be longer.

Many times the sliding piece and its guides can be the same length and keep straight. The things which do not tend to wear out of true do not wear much, and the things which do wear out of true and have to be refitted are never just right except when new and when so refitted. Where a short block slides on a long guide, if the scraper marks wear out sooner along the middle than at the ends, the ends of the guide need cutting off, however much overrun it gives to the sliding block.

The draftsman dare not make a drawing of an engine crosshead overrunning the guide one-third of its length at each end; the builder would hardly dare to build it if he did, and no user has the courage to take out the guides and cut them off or cut away the surface even when he knows it would be money in his pocket, but it is the thing to do. We find that in the case of a slipper guide, owing to the effect of inertia and momentum giving a twisting action to the crosshead, it is necessary to cut away the guide so that the crosshead will overrun very nearly one-half its length before the scraper marks will show uniform wear. This, of course, is subject to modification according as the center of gravity is higher or lower, or the speed of the engine is greater or less. We are building engines with the cross-heads overrunning that way and people buy them.

To get the best out of machines, they not only want to be rigid and true, but the drive needs to be powerful. In this respect a worm gear is about as perfect as can be, or cutting spur gear teeth spiral accomplishes about the same result. What appears as an objection to spiral teeth is end thrust against the shoulders, which does not amount to much, and when the shaft runs in reverse directions and end play in the journals is permissible, the journals keep in much better condition. The mention of a worm gear is like the flaunting of a red rag to some people, but it has its place and a good many more places than it has been used in. The claimed objection is excessive friction and loss of power, but the results do not seem to justify the claim.

The most perfect worm gear we have (theoretically) is a screw and nut, and they do waste enormously in friction, and in proportion to what they do they wear out the most of any piece of mechanism. The most imperfect worm gear we have (theoretically) is the Sellers planing machine drive, and yet they never wear out, and hence cannot lose much in friction.

In the writer's opinion two of the things which never need to have been invented are the Hindley worm gear and a machine for hobbing worm gear. Experience convinces the writer that a liberal pitch worm skewed round so as to properly mesh with a plain spur gear, or one with the teeth at such an angle as to skew the worm a little more, will run more easily and last longer than the other sort. A machine driven with the worm is positive, and if there is any chatter it comes from elasticity in the spindle or the work itself. The value of lathes, particularly those used for face plate work, is considerably improved by having large and short main bearings. They should be large to resist torsion and short to resist bending, and the ordinary face plates are ridiculously frail. To get the best of a face plate it should be box section and as large as will swing in the lathe.

Owing to the rapid wear of screws the writer is convinced that a precision screw in any lathe used in manufacturing is of no special value over a fairly good one. Wearing the screw in one place while threading a few hundred pieces destroys the precision in a way which no future use will ever correct.

If the designer will analyze every detail he will find that many of the old features were not right to meet the old conditions and are not half right for the new.

While manufacturing is going to call for many more simple machines—that is, machines to do one thing rapidly and well—the machines which will do a variety of work will be still in demand, for the sparsely settled sections of the country and the colonies will call for the country machine shop as of old.

It is the hope of the writer that this tirade will bring out an interesting discussion on machine design and the capabilities of the high-speed steel, for that is the object of its presentation.

THE REID PROCESS FOR PRODUCING ELECTRICITY FROM FUEL.

There have been many types of apparatus devised for producing electricity direct from fuel, either by the thermo-electric process, such as by the use of the thermopile, or by an electrolytic process, in which some form of battery is employed. All have so far been commercial failures, but it will nevertheless be of interest to describe a new apparatus for this purpose, a demonstration of which was recently made at Newark, N. J., before a party of engineers and representatives of the press. The apparatus is the invention of Mr. James H. Reid, of Newark, and apparently the demonstration was successful; but not until a test has been made by expert and disinterested engineers, which Mr. Reid promises will be done in the near future, can any prediction be made as to the merits of the process. The following description is in accordance with the statement given us by the inventor.

The Reid process of generating electricity from fuel is electrolytic, the apparatus being essentially a gas battery in which hydrocarbon gas is oxidized. The oxidation takes place in an alkaline electrolyte between carbon and iron electrodes, and sets up an electromotive force of 9-10 volt per cell. The temperature of oxidation is low compared with that of a firebox, being only about 392 degrees F., and the action is comparatively slow. "Minute subdivision and slow oxidation" expresses a fundamental principle of the process. When the fuel is converted into a gaseous state it is, of course, minutely subdivided, and since the oxidation takes place at a low temperature, it takes place slowly.

When ordinary illuminating gas, containing, say, 650 B. T. U. per cubic foot, is used, it is diluted with about 40 parts of air to one part of gas, so as to always maintain an excess of oxygen. The mixture is forced through the electrolyte under a slight pressure, about 4 pounds per square inch being used for the demonstration. Since so poor a mixture is used it is at once apparent that producer or blast furnace gases can be used. All in fact are too rich and must be diluted with air for use. An evanescent gas like producer or blast-furnace gas is said to be better than the more stable illuminating gas. The electrolyte, as stated, is alkaline, being composed mainly of sodium hydrate (caustic soda), a small quantity of iron oxide, and a little calcium chloride to absorb moisture.

Referring to Figs. 1 and 2, which show end and side sectional views of an apparatus after which substantially the commercial machines will be patterned, *A* shows the lower part of the shell, and *B* the upper part. These parts are separated by insulation and form the positive and negative poles, the connection for the wires being shown at *A'* and *B'*. The lower part *A* forms a trough containing the alkaline electrolyte and the iron electrodes *I*, *I*, *I*, etc., and from *B* are suspended the carbon electrodes *C*, *C*, *C*, etc. The carbon electrodes are made in the form of hollow plates having porous walls through which the gas entering the holes in the tops, from the chamber *D*, may filter and mingle with the electrolyte. A top view of a carbon plate, showing the holes for entrance of gas, appears at *H*, and a bottom view at *G*. As the carbon and hydrogen of the gas combine with the oxygen of the electrolyte, the latter begins to froth or foam and rise in the pipe *O*, from which it passes through the space *P*. (This portion of the cut is diagrammatic. The free air inlet *K*, and exhaust for uncombined gas *J*, are actually one, strange as it may seem. The interchange takes place through a diaphragm, *R*, *R'*, composed of alternate layers of canvas and iron wire cloth.) Here the electrolyte is said to take in some oxygen to replenish its exhausted supply. The most of the necessary oxygen is supplied with the gas, however. The iron oxide acts as an oxygen carrier in much the same manner as the red corpuscles of the blood. In fact Mr. Reid points out that his process is a mechanical parallel to that which takes place in animal bodies, i. e., carbon is oxidized at a low temperature in the lungs, the blood acting as an oxygen carrier. The chamber *P* and diaphragms in a measure correspond to the lungs, and the electrolyte to the blood. The circulation of the electrolyte is in the direction of the arrows, passing down through the pipe or passage *Q*. The gaseous products of oxidation and the unconsumed gas escape at *J*, but are not wasted in the commercial apparatus.

The pipe shown at *F* is primarily for admitting water to flush the apparatus when cleaning out; it is also used for admitting a small quantity of water when first starting it into purpose. The gas retort is not shown in Figs. 1 and 2. When the machine is generating electricity, that is, when gas is admitted, the oxidation process forms CO_2 and H_2O, the latter being water in the form of steam, which helps to keep the balance of water required in the electrolyte, but water is added from time to time.

As already stated, the electromotive force generated is 9-10 volt per cell: to get 9 volts ten cells must be connected in series. From this it is apparent that, commercially, it will not be feasible to generate high voltages direct; but any voltage can, of course, be obtained with circuit breakers and static transformers in the case of alternating current; and rotary converters for direct current. The amperage depends upon the extent of carbon surface. One ampere is generated for each five square inches of carbon surface.

Two views of the experimental apparatus with which the demonstration was made are shown in Figs. 3 and 4. *A A'* are the generating cells; *B*, small gas generator; *C*, small steam boiler; *D*, air tank; *E*, voltmeter; *F*, ammeter; *G G'*, connecting wires or cables; *H*, one of four burners for each cell to warm the electrolyte; and *J J'*, diaphragms composed of alternate layers of iron wire cloth and canvas, to prevent escape of electrolyte and to allow the ingress of free air and the escape of waste gases. The cells, in this instance, are circular, and the carbon electrodes are round hollow rods, about 1½ inch diameter and 10 inches long, making the total carbon surface of each cell about 300 square inches. The carbons are each surrounded by an iron pipe electrode, perforated with holes. The space between the pipe and the carbon is about 3-16-inch all around. The cells were connected in series and developed a current of 1.8 volts and about 45 amperes,

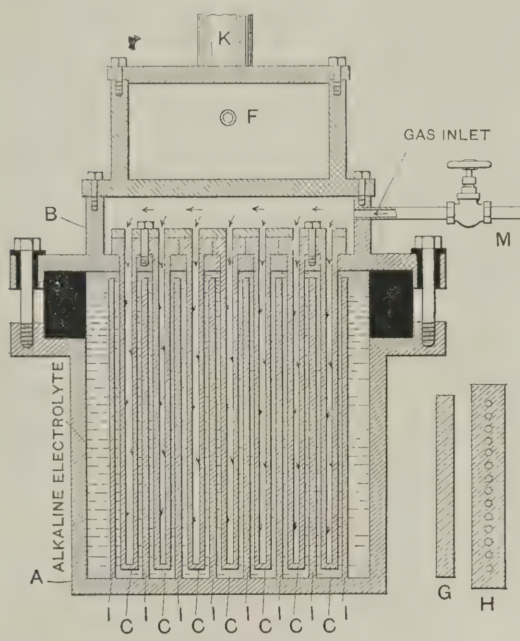

Fig. 1.

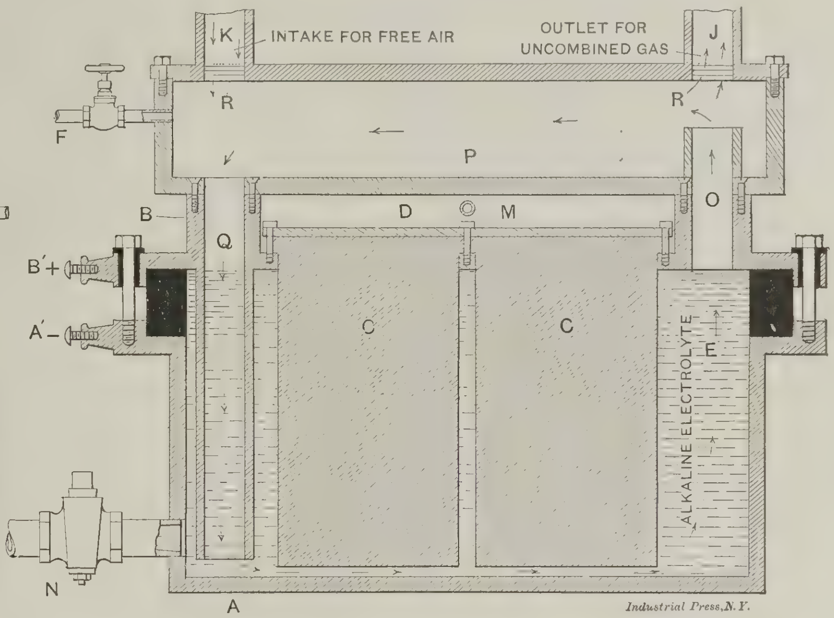

Fig. 2.

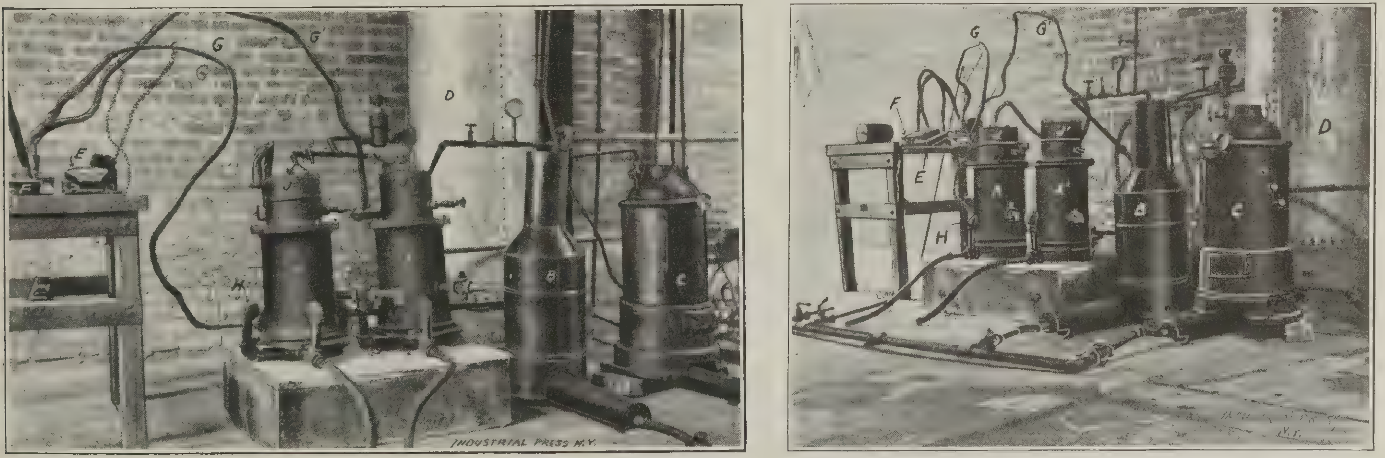

Fig. 3. Fig. 4.

Experimental Electrolytic Apparatus for Producing Electric Power.

operation, to take the place of that evaporated from the electrolyte by the application of external heat. The application of external heat has not yet been described. This is necessary to maintain the electrolyte at the proper temperature, viz.: 392 degrees F. The internal work or waste effort of a cell, even on short circuit, is by no means sufficient to maintain the required temperature. So in the commercial machines the gas retorts will be placed in close connection with the electric generating apparatus in order to use the radiated heat for this equivalent to about 1-10 electrical horse power. The gas connections are made at the bottom from the back. The pipe connections shown in front are for gas to maintain the temperature of the electrolyte, and terminate in four burners for each cell, one being indicated at *H*. In operation a casing covers the body of each cell so as to retain the heat.

It should be understood that the application of external heat in this manner is very wasteful, and that the gas used for the purpose is not charged against the efficiency of the cells, but only that used within them. As already stated, the temperature of the electrolyte is maintained in the commercial machines by the heat radiated from the gas retorts. This is indicated in the diagram, Fig. 5. The consumption of gas per electrical horse power is said to be 5 cubic feet of 650 B. T. U. gas per hour, and the commercial efficiency as being over 45 per cent. of the total heat units in the coal.

WHY THE BUILT-IN MOTORS FAILED.

Editor MACHINERY:

On page 183 of the December number of MACHINERY an article from an exchange is commented upon editorially under the heading, "Hitching the Motor." It seems incredible that the author of this article should be so ignorant of the facts relating to the manufacture of electrical machines as to hold opinions such as are here expressed. Having designed most of the motors which are referred to as having been built in the headstocks of lathes, I have been in a position to watch their operation and would like to tell the real reason why they were superseded by standard motors geared to the lathes.

When the electrical firm referred to took up the matter of motor drive for machine tools, it received no co-operation at all from the tool builders, as the latter absolutely refused to make any change whatever in the design of their tools. In designing the first motors, therefore, it was simply a question of building a motor that would go into a rather limited space with a comparatively large hollow spindle through the center of the armature, to run at a certain speed and give the maximum horse power possible under these conditions. At that time the whole range of speed was obtained by the use of armature resistance and shunt field resistance. These first motors were failures, it must be admitted, but during the eight years that these motors have been in service, not one armature has had to be rewound on account of burn-outs, as stated. Some of them were rewound when the shop voltage was changed from 120 to 250 volts, but these motors served a most valuable purpose in demonstrating the utter impracticability of the use of armature resistance as a means of motor speed control when applied to machine tools. It was not until this same firm introduced the now well-known multiple voltage system into its own shop that a satisfactory method of controlling the speed of these motors was secured. But the real reason for discarding these old motors did not arise until about three years ago, when the introduction of new kinds of tool steel, allowing both higher cutting speeds and cuts of greater cross-section, necessitated the use of motors of larger capacity. As stated before, these motors had been squeezed into a certain given space, and by no possible means could they be made to run at the desired speed and give the torque required to remove the amount of metal that the new tool steels were capable of cutting off. It became a question of abandoning the motors or of using these lathes on a class of work for which they were not intended. The former plan was adopted and motors of ample capacity were attached to these lathes. That these motors should be of standard design was as natural as that a man when using a bolt should use one of standard dimensions; the advantages of using standard parts are as great in one case as in the other.

In order to show that the introduction of motor drive is not being retarded by the fear of "burnt-out" armatures, I would refer to the publishers of most of the large daily newspapers. The necessity of having no breakdowns in the printing press equipment when getting out the regular editions of a large daily is evident. The same firm that built the lathe motors referred to has built most of the newspaper press motors now in use in New York City, and of all of those installed I know of none that has burnt out.

It is true that electric motors often need repairing, but the primary cause of these repairs is almost invariably neglect. Other parts of the machine tool are constantly cleaned and oiled, but the motor is required to run with practically no attention and the dirt that accumulates sooner or later causes trouble. An electric motor, when properly used, is the equal of any other mechanical device now on the market, and, when one considers the amount of abuse it will stand, it surpasses most machines in durability as well as in satisfactory operation.

A. G. WESSLING.

While Mr. Wessling appears to take exceptions to our editorial comment, he substantially supports the dominant idea therein, viz.: "In the present state of the art it is bad design to make an electric motor an integral part of a machine tool." Why? Because such a motor is special; it costs more and cannot be readily replaced, since it is not of standard type. As our correspondent says, it is as natural that motors should be of standard design as that a man using a bolt should use one of standard dimensions.

Of the merits of the case in question, we know nothing, save what was learned casually, and in our comments in the last number did not intentionally, at least, lay the degree of stress upon the burning out of motor armatures that our correspondent seems to think; for it is of secondary importance whether a motor or its armature has to be replaced from this cause or from some other. But as a matter of fact, motors do burn out and must burn out when subjected to great overloads. While our correspondent informs us that the motors referred to did not actually burn out, it is safe to say they would have done so had it been attempted to make them carry the loads that the motors now in use have to carry.

We believe the best practice demands that the motor shall be so located that the whole motor, or any part of it, can be easily replaced by another of standard design, regardless of whether the change is necessary because of the advance in machine shop practice or because of repairs that are required from whatever cause. And we further believe that our correspondent agrees with us in this respect.—Editor.

* * *

The largest lifting machine in the world is said to be the 150-revolving jib crane at Howaldt's Works, Kiel, Germany. The height of the traveler rails from the ground is 154 feet 8 inches, and the length of the jib on which the traveler works is 146 feet 11 inches. A weight of 150 tons is lifted at the rate of 3 feet 3 inches per minute, and one of 15 tons at the rate of 31 feet 2 inches. The speed traveling along the jib is uniform, the rate being of 26 feet 3 inches per minute, and complete rotation of the jib is effected in 10 minutes. The traveler carries two capstans for winding up the steel wire lifting rope which are jointly driven by a 70 horse power alternating current motor. The wire rope is 2.36 inches diameter and is wound eight times around the lifting pulley. The rope for traversing the carriage or traveler has a thickness of 1.81 inches. Both its drum and the two capstan drums are rotated when traversing, but then the two capstan drums turn in opposite directions so that the height of the load is not altered.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

The Houille Blanche (white coal) Congress, which recently met in France, brought out some interesting facts regarding the possibilities of developing power from the mountain streams of the Alps and Pyrenees. It is said that the potential power of the waters formed by the melting of snow and ice in these mountain ranges is not less than 10,000,000 horse power, and that 500,000 horse power is already being utilized. France, as is well known, is a country practically destitute of extensive coal beds, and nearly all her coal has to be imported. It is estimated that the saving resulting from the utilization of mountain streams will be not less than $40,000,000 yearly. The economical development of mountain water power as found here is, of course, only made possible by the efficient long distance transmission by the high-tension alternating current.

A Jersey City firm has completed a "battery van" for the United States Government, which in reality is an automobile machine shop designed to go under its own power anywhere that a battery can go, and to be in readiness to make any repairs which may be necessary to the field guns. It has a speed of ten miles an hour and is supplied with two winches and a cable by means of which it can extricate itself from any morass or hole which it might be thrown into while in service. When loaded for the march it will weigh five tons. This will include four thousand pounds of miscellaneous equipment for the batteries which it is following. Six men can be accommodated on the vehicle. This outfit will be assigned to duty with one of the light field batteries and sent on a tour, during which all sorts of demands will be made on it and its conduct under all circumstances will be made the subject of a report.

INSURANCE OF MACHINERY AGAINST ACCIDENTS.

Stahl und Eisen, July 15, 1903, p. 850.

A prospectus has been issued by the *Stuttgarter Mit-und Ruckversicherungs-Aktiengesellschaft*, for the insurance of machinery against damages inflicted as the result of awkwardness or carelessness of the workman as well as from maliciousness. This insurance also proposes to cover such failures of material composing the machinery that may occur after the expiration of the builder's guarantee. Finally such insurance is to include not only the machinery of an establishment but also all that used for transmission purposes such as belting, wire, rope and cable, and, of course, hangers and shafting.

G. L. F.

COMPARATIVE COST OF GAS AND ELECTRIC POWER.

The *Scientific American* recently published the report of a very interesting test which was made in a printing establishment in New York City to determine the comparative cost of power obtained from gas engine and electric motor. The test was made with a 15-horse power gas engine and a 25-horse power electric motor, the average load carried being about 10 horse power. The comparison lasted over a period of two months, during which the gas engine alone was used, and two other months when the electric motor alone was in service. Gas was taken from the city illuminating mains at a cost of $1.05 per 1,000 cubic feet. The engine was run a total of 697 hours and the gas consumed cost $106.68, or an average of 15.3 cents per hour, which is about 1½ cents per horse power hour. Electric current was taken from the Edison mains, and the amount used during the 686 hours of operation of the motor cost $250.30, or an average of 36.5 cents per hour, which is about 3½ cents per horse power hour. Although this test certainly indicates a great advantage of the gas engine over the electric motor, the advocates of the gas engine should not be too sanguinary over the results, since it will be noticed that the motor was operated at but 40 per cent. of its rated capacity and consequently its efficiency was much below that which would have been obtained had it been run at full load.

ELECTRIC LOCOMOTIVES.

The New York Central Railroad has placed a contract with the General Electric Company for thirty electric locomotives to be built by that company in conjunction with the American Locomotive Company of Schenectady. It is said that the electric locomotives are to be of a new design and will weigh 85 tons each, of which 67 tons will be on the drivers. The rated power is 2,200 horse power each, and it is expected that the new locomotives will be capable of hauling a 500-ton train at the rate of 60 miles per hour. It is stated that the officials do not expect that the electric locomotives will show so great a saving of fuel as of maintenance. The fuel consumption of a steam locomotive running 60 miles per hour, is placed at 5 pounds of bituminous coal per horse power hour; with the electric motors, the losses of transmission will make it about 4 pounds at the axles. It is expected that at least 50 miles of each of the New York Central's branches out of New York, and of the New York, New Haven & Hartford Railroad will be operated electrically. The suburban trains will be operated by the multiple-unit system, each car having its own motors, but all under control of one motorman. The longer distance and heavier trains will be drawn by the electric locomotives. With the order for the locomotives, another was placed with the General Electric Company for eight four-stage, vertical Curtis turbo-generators of 7,500 horse power each for the power station.

In commenting on this *The Electrical World and Engineer* says: "It constitutes one of the most important events which have occurred in the history of electric traction since the equipment of the West End Railway, of Boston, in 1888 and 1899. That installation marked the confidence of the largest street railway company in the world at that time in what was then a new motive power. The contracts awarded by the New York Central & Hudson River Railroad, coupled with the adoption of electricity for its New York tunnel by the Pennsylvania Railroad Company, prove in an equally conclusive manner the confidence of steam railroad owners in what has been up to the present a comparatively untried motive power for heavy traffic conditions. The notable feature of the proposed New York Central installation is that electricity has been adopted not only for the tunnel section but as well for the service extending for a radius of about 50 miles on the main line and branches; in other words, for the entire suburban business."

HOW A LOCOMOTIVE WORKED ITS WAY ON THE OHIO RIVER.

Railway and Locomotive Engineering, December, 1903.

The story is told of the firm of Smith & Porter, which later became the well-known H. K. Porter Company. The original firm in 1868 built a locomotive for a small railroad running out of Greenup, Ky. This town is 333 miles below Pittsburg, Pa., on the Ohio River, and at about the time the delivery was to be made none of the towboats appear to have been available, the river being very low owing to a long drought, and other transportation facilities were not to be had. It was, however, decided by Smith & Porter that the engine should be delivered at the specified time. Mr. Smith obtained a suitable flat boat, and placed the machine aboard, and with the help of several men the locomotive was arranged to propel the boat.

The main driving wheels were at the rear, and the side-rod extended forward, as in many of our modern 4-4-2 engines. The front ends of the side-rods were uncoupled and the rods thrown back so that they extended out behind the engine as far as the leading wheels were ahead of the main drivers. The projecting ends of the side-rods were coupled to a temporary crank shaft, arranged for the purpose, and on the ends of this shaft were two paddle-wheels. The main drivers were jacked clear of the rail and the boiler was fired up.

In action the locomotive presented a strange appearance, standing on the deck of a scow, its leading drivers hanging motionless, its main driver slowly turning and its reversed side-rods working a crank shaft which made a pair of dripping paddles revolve, while the engine solemnly puffed its way down stream. This novel locomotive-steamboat made the voyage successfully, and furnishes a good example of what men of enterprise could do to overcome difficulties thirty-five years ago.

THE USE OF RIVETS INSTEAD OF BOLTS IN LOCOMOTIVE CONSTRUCTION.

Railway and Engineering Review, November 14, 1903.

The engine truck of a locomotive generally presents considerable opportunity for improvement both in design and in the matter of construction and repair. It is an axiom that with locomotives the nearer a construction approaches one single piece the more perfect it is. The length of wheel base on the present sizes of power has required the general use of a swinging center casting, which adds to the number of necessary separate parts. But contemplation of either a two or four-wheeled type will bring out in all cases several points wherein the construction could be somewhat simplified. The cradle or transom arrangement is often made in more separate parts than is necessary and in these days of steel castings a superior design of cradle in a particular case could, by the use of this metal, often be obtained. A consideration of the pedestal jaws in connection with the upper framing of the trucks reveals no adequate reason either of service, machinery or wheel changing work standing in the way of making these jaws integral with the frames themselves. Such integral construction would materially diminish the jarring which causes the binder bolts to always be loose. The use of bolts in other places than on these binders is unnecessary—rivets are certainly preferable, for the reaming of holes and machine fitting of the bolts are avoided and there are no nuts to work loose, while there is no occasion for removing such rivets except once a year in the back shop. In fact we know of lines where this plan has been standard for years and their roundhouse work books are not littered with requests to supply missing nuts to engine parts.

INDUCTION MOTOR FOR CRANES.

George L. Hoxie, in Journal Franklin Institute, November, 1903, p. 351.

The induction motor would probably not be used upon cranes and similar classes of work, except for the great desirability of polyphase motors for other work and the inconvenience of maintaining two separate systems of electrical supply. These considerations have, however, led to the use of the induction-crane motor in many cases. The motors, if of squirrel-cage construction, are built with high resistance end rings, and while they give, therefore, a large torque they are not very efficient machines. The efficiency of a direct-current machine is considerably the better through its entire range, and it has a wide range of operation over which its efficiency is quite good. An induction motor, on the other hand, reaches its maximum efficiency very abruptly.

Speed variation in a motor of this sort is accomplished by the use of a special compensator that provides varying impressed pressures. This is not an efficient means of regulation, since the torque of such a motor varies with the square of the impressed pressure. Crane motors with wound secondaries may be made to give a variable speed by the variation of a resistance in series with the secondary. This again is inefficient, though it provides a highly satisfactory torque curve. The motor is not so desirable mechanically since this method of control is considerably more complex. The motor with squirrel-cage secondary is probably the more desirable, on the whole, for this class of work.

RAISING WATER FROM DEEP WELLS BY COMPRESSED AIR.

Extract from Paper read by William H. Maxwell before the Bolton Meeting of the British Association of Waterworks Engineers.

The experiments carried out in the United States by Dr. Pohlé, of Arizona, who for some years past has been engaged in the application and development of the "air lift" system for raising water, oil and other liquids from underground sources, have proved that the main principle upon which the system operates is the following: Air under the necessary pressure, and of suitable volume, is admitted to the bottom of a pipe immersed in the water to be lifted in the manner shown in Fig. 1 of the sketch. By this means alternate bands or columns of air and water are formed in the water-pipe or "rising main," and the air does not, as might perhaps have been anticipated, pass through the mass of water. The result of this is that the aggregate weight of the water in the rising main is insufficient to balance the column of water in the boring, and the pressure of the latter therefore produces an upward movement of the air and water column in the rising main. As the force lifting this column is the head of water at *A* it follows that the height to which the water can be lifted depends upon the depth to which the pipe is immersed below the pumping level of the water in the boring; thus the higher the "lift" required the deeper must be the point at which the air is injected relatively to the normal water level therein, and so the height to which the water has to be raised determines the minimum depth to which the boring must be driven.

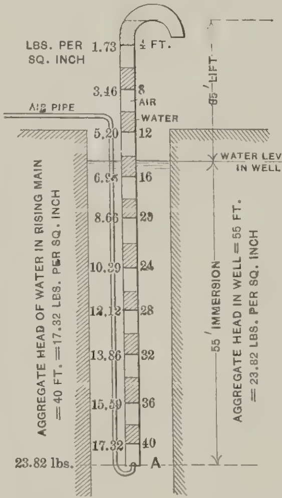

Fig. 1.

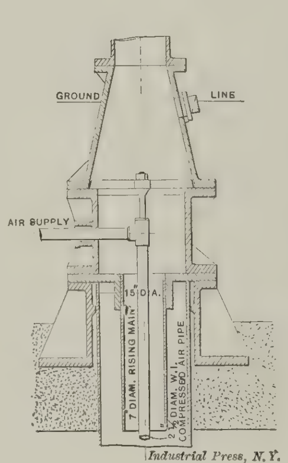

Industrial Press, N.Y.

Fig. 2.

With regard to the best proportion between the immersion of the air nozzle and the "lift" of the water, opinions vary, but the author found that in his case the most economical result was obtained when the ratio was 3 (of immersion) to 1 (of lift) at the start, and 2.2 to one at the finish of the test. Under these conditions the efficiency worked out at 36.8 per cent. calculated from the steam diagram, and at 46 per cent. calculated from the compressor diagram, the volumes of air used and water lifted being in the proportion of 2.69 of the former to 1 of the latter.

From the results of his own tests and those of others, the author prepared the following, showing the approximate horse power required to compress one cubic foot of free air to different pressures per square inch:

	Pressure per sq. in.	H. P. per cu. ft. Free Air.
1. Solvay Works, Saaralben	176	0.434
2. Brostowe Estate, near Friedheim	140	0.376
3. Tunbridge Bridge Waterworks..	100	0.201

With regard to the quantity of air required to lift a given volume of water to any specified height, the author found the following formula to give results in accordance with his own experience:

$x =$ cubic feet of free air per minute;
$A =$ gallons of water required per minute;
$B =$ "lift" of water in feet;

$$x = \frac{A \times B}{125}$$

From this formula it is, of course, a simple matter to ascertain the quantity of water that can be lifted to any given height by a given quantity of air. The diameter of the air pipe should be such that the velocity of the escaping air shall not exceed 20 feet per second. In a boring 350 feet deep, with the rest level of the water 96 feet below the surface and the pumping level 120 feet from the surface, with a discharge of 32,000 gallons per hour, an air pressure of 91 pounds per square inch was used. The rising main was 7 inches diameter and the air pipe was 2½ inches diameter. See Fig. 2.

EMERY WHEEL PRACTICE IN FOUNDRIES.

Extract from Paper read by Mr. Charles G. Smith before the Pittsburg Foundrymen's Association.

In iron foundry work there can be very little grinding done with economy on heavy castings, unless the iron is hard, in which case the swing frame machine with about 20 x 2½ inch wheel, running at 1,200 revolutions per minute, will grind considerably faster than it can be chipped. The amount of gain in grinding will, of course, depend on the hardness and ductility of the iron. I have seen castings so hard that it took two men one and three quarter hours to chip the gate and fin from one side. In such cases as this two men could have ground this gate and fin with a swing frame machine in a very little over fifteen minutes. But on soft iron the advantage is in favor of the chipping, as in this case the iron spalls before the chisel, and a man with one blow of the hammer can remove considerable of the gate and fin, which gives a great advantage in favor of the chipping. In a great many foundries I have noticed that the grinding on light castings has been done on light machines, using small wheels, and in almost every case the machine has been set without any regard to its stability.

The user will invariably be reimbursed if, in buying an emery grinding machine, he purchases a heavy stand with long bearings and large diameter of spindle, and places it on a concrete foundation. The machine will vibrate less than if it was standing on the floor. The wheels will become out of true less quickly than if they were set so that there may be vibration in the spindle. This will cause considerably less dressing of the wheel, and as it is always necessary to dress the wheel to the lower point when it has become out of true, the user will receive more than reasonable interest on the investment in the foundation in the amount of emery that is saved in truing the wheel. Then it is often the case that wheels too small have been used to accomplish satisfactory results. The largest diameter wheel practicable should always be used for doing any kind of grinding. For instance, a wheel 24 inches in diameter will do more work per dollar invested down to 18 inches in diameter than an 18-inch wheel will do. Another point to be regarded is the belt power furnished to drive the wheel. It is very necessary that the machine have belt capacity to keep the wheels up to speed while they are under duty, as the speed of a wheel when running idle will have no effect on the work if it is not kept up to this speed when it is doing the work. Neglect in the above-mentioned points has caused many to abandon the practice of grinding their castings with emery wheels.

For grinding any castings in a foundry where the man can lift the casting up to the machine it will be found that the most economical and satisfactory results can be obtained by having a heavy machine with 24 x 3-inch wheel driven with 5-inch belt, the wheel speeded at 1,000 revolutions per minute. This gives wheels heavy enough to resist the pressure of the work forced against them, and the power transmitted by the belt will force the wheels to cut instead of shrinking from duty and becoming out of true. This condition invariably occurs where the belt power is insufficient, and the man forcing the work with uneven pressure will bring the wheel to slacken its speed at intervals.

In steel foundry practice the emery wheel has been found to be quite a success, and is as far ahead of any other method that is commonly in use to a large scale on both heavy and light work, as is the case in malleable iron foundries. I have seen a gate ground with an emery wheel on a swing frame grinder by two men in less than 15 minutes. This same gate would have required about two and a half hours to remove on the planer or shaper.

MARINE TURBINES.

Journal of the American Society of Naval Engineers, November, 1903, p. 1241.

The following is an abstract of a report of a board appointed by the Navy Department to investigate the performance of the Steamer *Revolution*, which is equipped with Curtis steam turbines, and was built for experimental purposes. In view of the fact that turbines are now being considered by the Navy Department for use on naval vessels, and are about to be adopted for two Atlantic liners, the report is of timely interest.

The turbines are of the Curtis two-stage, compound, marine type, reversible and condensing. They are two in number, directly connected to the thrust and propeller shafting, each set of turbines driving one screw of about 4 feet 6 inches in diameter and 3 feet 4 inches pitch.

Aside from the ordinary advantages claimed for the steam turbine, the most noticeable feature observed was the almost entire absence of vibration or disturbing noises usually attending the running of fast-moving reciprocating engines, and the slight care and attention needed while in operation. These turbine engines were easily started, stopped and reversed, the time required for each operation being only that necessary for the opening and closing of a set of valves connecting the turbine casings with the main steam pipes. Five seconds was the maximum time consumed for the operation of reversing the motors from full speed ahead to full speed back, with two men handling the gear, one to each turbine. This may, however, be done by one man at a slightly increased expenditure of time. Various runs with corresponding stopping, backing and turning of the ship, were made at different speeds of rotation, the maximum speed of engines being about 650 R. P. M., and the minimum about 250. At full speed ahead the vessel turned readily either to starboard or to port in about thrice her length. Dead in the water, and starting one propeller full speed ahead and the other full speed astern, the vessel turned in her own length. Dead in the water, and with the helm hard to starboard, and then going ahead on the port propeller, the vessel turned readily to port, due to the action of the propeller race upon the rudder. Under these latter conditions it was noticed, however, that the vessel ceased to turn when the wind was well on the port beam.

Running full speed ahead with both screws, and then suddenly reversing the engines, the ship was brought to a standstill in about 32 seconds; the same conditions with one screw, required about 38 seconds. Similar operations were repeated with the vessel running at lower speeds, and about the same amount of time for reversing was required.

In a report on these turbines by Prof. Jas. E. Denton it is stated that at 672 R. P. M. an equivalent power of about 1,800 I. H. P. was developed by both turbines at a steam consumption equal to 18.14 pounds per equivalent I. H. P. This is, however, believed to be excessive, owing to the use of the steam in two stages only. With four-stage turbines the consumption of steam per I. H. P. should be reduced well within the margin of prevailing averages for marine engines.

The clearance spaces between the stationary and running blades on the revolving drum being made extremely small (from .02 inch to .06 inch), the amount of which is ascertained by a small, simple, micrometer attachment, and there being no flexible coupling arranged for between the turbine shaft and the thrust shaft, the bearing of the latter was provided with a handwheel mechanism actuating a yoke, so arranged as to maintain the original clearances by sliding the thrust-block on its sole plate, propeller, shafting and turbine drum all moving together. The wear on the thrust-block being very slight, this adjustment is only rarely resorted to.

The turbine shaft bearings, one at each end of the casing, run in oil, which is continuously circulated and cooled by water coils connected with the oil pump, no water circulation being used direct on the journals; water circulation is however, used in the thrust bearing. The exhaust from each turbine issues from the casing of the upper half of the secondary stage through a 20-inch pipe into the condenser.

The main turbines consist principally of the casings, nozzles and revolving drums containing the bucket wheels and shafts. The steam enters at a pressure of 250 pounds through four steam nozzles, each of which supplies one-fourth of the full power of the turbine, and acts consecutively upon a series of bucket wheels constituting the "first stage," in which the steam expands down from 265 pounds absolute to about 16 pounds absolute. It then flows through four other nozzles, to act upon another set of bucket wheels, which form the "second stage," and there expands from 16 pounds absolute to less than 1 pound absolute, with condenser vacuum of 28 inches, the work done by the steam upon the buckets being thereby nearly equalized.

Reversing is made possible in a very simple manner by placing vanes on the outer rim pointing oppositely to the ahead buckets, all enclosed in the casing of the secondary stage. A separate steam pipe leads to this part of the casing and the steam is admitted by a separate valve.

The general ease with which the machines in question are cared for and handled is undoubtedly due to the great simplicity of the mechanism when compared with the reciprocating engine. As an engine it requires but little previous "warming up;" no cylinder drains to be opened nor any general filling up of oil boxes, sight feeds and wick cups, the turning on or the shutting off of the main steam supply being the principal and almost the only operation remaining. It might be here incidentally mentioned that the above points are not features peculiar only to the turbines of which this report treats, but hold in common for steam turbine machinery of the various designs and makes. The space occupied, judged in the light of a casual observation, is no less, but rather more, than that required by engines of the torpedo-boat class; but, as there is not the same amount of overhauling necessary, the extra space can well be spared. The weights of the turbines proper in this case are alleged to be 8¾ pounds per equivalent I. H. P., and are thus less than those of torpedo-boat engines, which run about 11½ pounds per I. H. P. The attention required and the amount of oil used are extremely small, owing to the entire absence of any internal or external oiling except the main bearings, which are automatically oiled. No frequent adjustments are required, as there are no rubbing surfaces, which may best be illustrated by the fact that the turbines in question have never been apart since first put up, covering a period equal to one and one-half years.

The points in conjecture with regard to these machines being their efficiency and their capacity to compete in economy with the best marine engines, should be ascertained by more accurate tests, both on land and on board ship, where this is possible.

Additional fore-and-aft space will be required for any efficient installation of turbines as compared with the reciprocating engine installation, and particularly will this be found in torpedo boats. This fact should be well recognized and be given due consideration, so that all parts of the mechanism, but particularly the condenser and other auxiliaries, may be installed in such manner as will permit frequent and necessary overhauling from the engine room.

As the turbine is more dependent upon a high vacuum than is the case with a reciprocating engine, it is essential that the main condensers and main air pumps must be favorably placed in the ship for ready examination and overhauling.

RESPONSIBILITIES OF INVENTORS.

E. P. Thompson in Stevens Indicator, October, 1903, p. 411.

How unfortunate for inventors, manufacturers, and other owners of patent rights, including corporations of enormous capital, that the value of a patent does not necessarily depend alone upon the value of an invention, nor upon any power that the inventor or other owner is supposed to possess. The inventor might be literary, a great scientist, an engineer, and an electrical expert, and might be able to explain an invention that he had made better than anybody else; and yet, if the description were not according to form, and especially if the solicitor should not have sufficient skill to word the claims to properly protect the invention, the invention would practically be given to the public.

My object is to show the principle underlying the difference between a properly broad claim and a narrow one, so that an inventor, in writing a description of the invention for his solicitor, may define his invention after the manner of a sufficiently broad claim. Electrical inventors are, in the present age, highly educated and should be perfectly competent to define their invention from a broad standpoint, and then the solicitor can improve the wording and form, and supplement applicant's claims by subordinate and perhaps by a slightly broader claim. I do not propose to take your valuable space by a lecture on the general principles of claims, but to show this one point by examples, by studying which, your readers will be competent to see that their claims are about what they should be.

Their inclination is to leave all to the solicitor, but this is not advisable, because however expert he is he is not infallible. As the whole value of the patent depends upon the scope of the claim, and as the inventor is the one who is best acquainted with the device and with the department of art to which the invention belongs, he must not leave the matter entirely to the solicitor; and the solicitor who refuses aid and suggestions from his client is more concerned with his own conceit than with his client's interests. The attorney is superior on all formal matters, but the client is superior on the merits. The solicitor should acquire as much as possible of the technical points, and the client should have a fundamental knowledge of the nature of claims.

A few examples will suffice to explain.

A few years ago there was an inventor who was the first to invent a new rheostat element adapted to be varied. His claim on this feature reads:

"The combination, with a box or case, of a pile of thin sheet-metal resistance plates therein, and a screw for regulating the pressure upon said plates, substantially as specified."

An inventor should not only make the invention in one form, but think of several ways of carrying out the device, and then formulate a definition to cover all the devices. All such devices could, I think, be covered by a claim reading:

"A variable electric resistance, consisting of the combination of a pile of electrical resistance plates, and means for varying the pressure upon said plates."

It is held that it would be easy for pirates to get around the patent claim, but difficult to avoid infringement of the proposed substitute claim, which may be possible of still further improvement.

Another case is that of a photometer for measuring mean spherical candle-power. The method consists in revolving two mirrors about an axis passing through the source of light under such conditions that the light from the source is reflected in different successive angles of a single plane upon the screen of a photometer, and also transmitted in this reflected passage according to a certain simple harmonic law. For our purpose, it is immaterial to explain what law this is, as too much space would be necessary. The broadest combination claim reads:

"In an apparatus for measuring the mean spherical luminous intensity of a source of light, the combination of two revolving mirrors, and means for varying the intensity transmitted to the photometer according to a simple harmonic law."

Why limit the protection to mirrors, leaving a loophole for another inventor to use refraction? Why confine the scope to a simple harmonic law, when the inventors are entitled to broad protection upon any arrangement of reflecting or refracting devices for securing the same result?

The claim could have been as broad as the following:

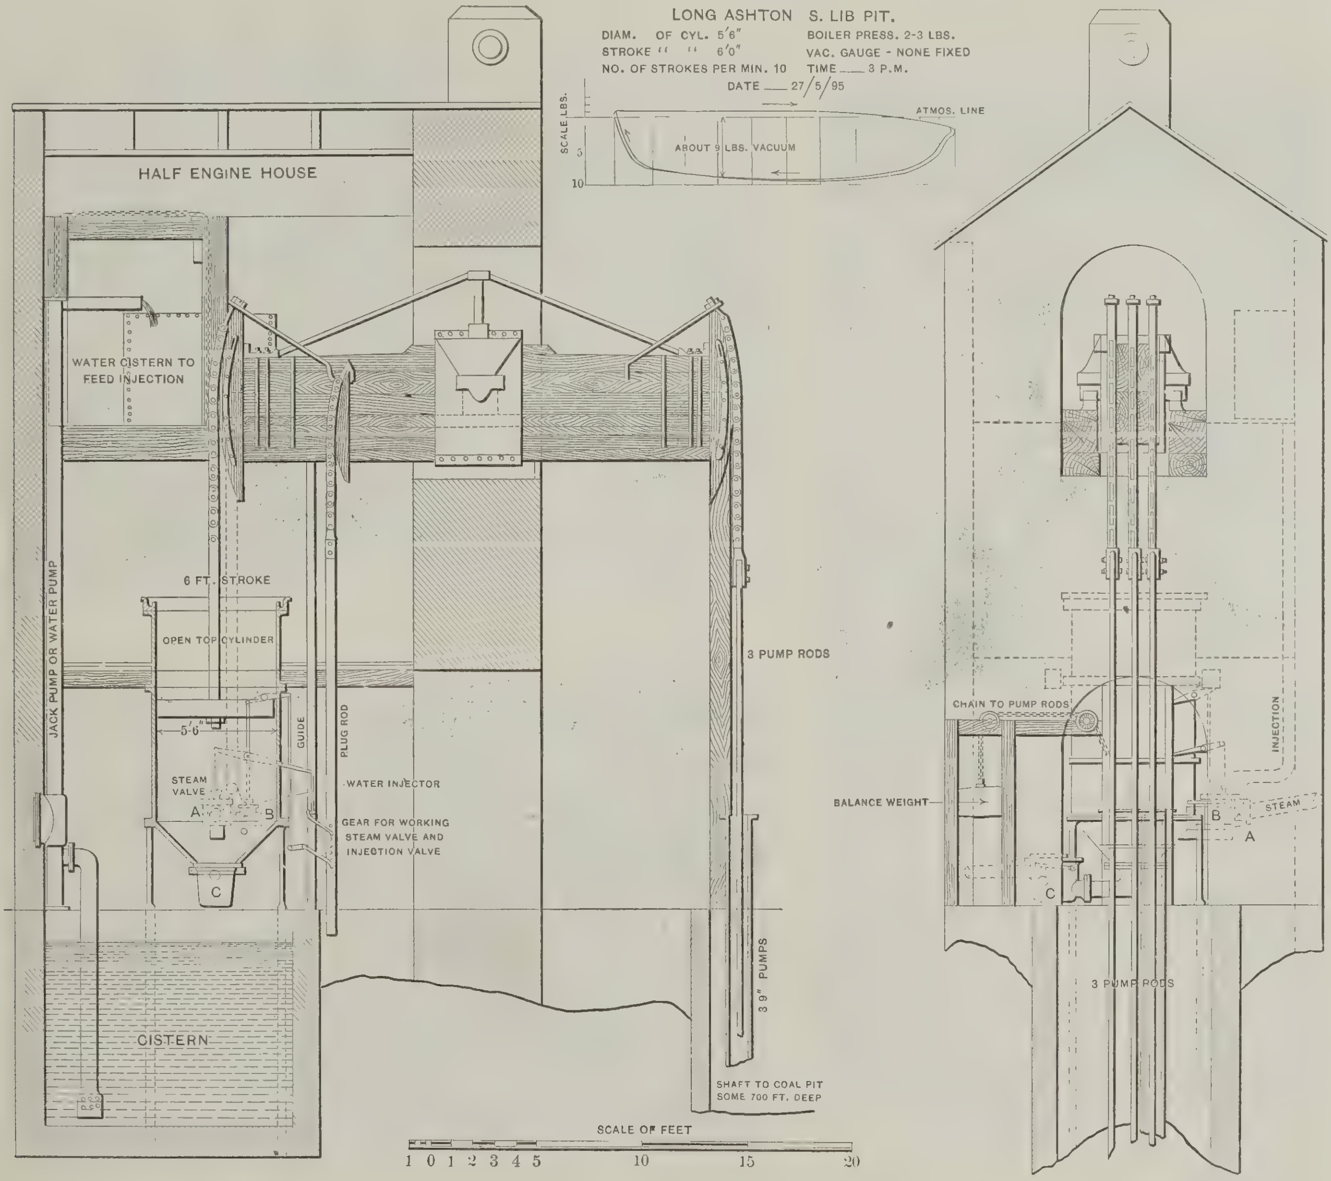
"In an apparatus for measuring the mean spherical luminous intensity of a source of light, the combination of a photometer, and revolvable devices so disposed as to illuminate said photometer proportionally to the mean spherical candle-power of said source."

This claim would have protected the invention, whether on the principle of a simple harmonic law, or some other law. The patent claim is also faulty in the narrow term "two revolving mirrors." Other means could easily be invented, and infringement avoided. If the scope is not defined by a proper wording of the claim, the patent is about as valuable as a house standing on a lot having a defective title.

NEWCOMEN ENGINE AT THE ASHTON VALE IRON WORKS*

From Paper read by Mr. Henry Davey before the Institute of Mechanical Engineers, October 16, 1903.

The earliest instance of a pumping engine for colliery purposes, which had come under the writer's notice, was that of the Newcomen engine at the South Liberty Colliery of the Ashton Vale Iron Company, near Bristol. As is well known, Thomas Newcomen, of Devonshire, invented, in 1705, the first successful cylinder and piston engines, and this example is considered one of the early large engines built by him, possibly about the year 1746-50.† The drawing, Figs. 1 and 2, shows the general arrangement of the engine, and has been prepared from a sketch the writer had made in September, 1895, when he had occasion to take some particulars on the spot for illustrating this old relic. The drawing, together with three photographs, Figs, 3, 4 and 5, will convey to readers the rude though successful working structure of Newcomen's age, with its trussed oak beam with circular ends and open-topped cylinder. The cylinder was 5 feet 6 inches in diameter, and had clearance enough to allow of working 8 foot stroke if required (the cylinder is 10 feet long). The piston was packed with rope ends and loaded with pig iron to help balance the indoor stroke, and was worked with a covering of water on the top, so that if the packing was not quite tight, water only passed through and helped to maintain the vacuum. The valves fitted to the cylinders consisted of a circular lift steam-valve for admission of steam (marked *A* in drawing), a slide-valve, *B*, for admitting injection water to condense the steam for forming the vacuum, and a flap-valve, *C*, kept closed by a weighted lever) for the escape of the condensed water. The Newcomen engine was utterly dependent on manually-worked valves, until that eminent youth Humphrey Potter devised self-acting catches, whereby the working beam was made to supplement the opening and closing of the valve.‡ This led to the introduction of the plug-frame fitted with catches to act on the valve levers—first put on a Newcomen engine by Henry Beighton in 1718. The engine was at first supplied with steam from a haystack boiler, but was latterly supplied with steam from the boilers working the winding engine, which was passed through a reducing valve into a receiver down to a pressure of 2½ pounds to the square inch, at which pressure it entered the cylinder. The beam was built of oak timber, trussed with rods 24 feet long and 4 feet deep, and had V-shaped gudgeons of cast-iron (bolted to the beam



Figs. 1 and 2. From a Sketch of an Old Newcomen Engine.

Industrial Press, N.Y.

---

* Compiled by the writer from particulars taken by him from the engine itself at the South Liberty Colliery in 1895, at which date the engine was in regular work. It has since been dismantled. There is at South Kensington a photograph of this engine, taken many years ago, when it was in a more perfect condition than it was in 1895.

† Mr. W. G. Norris writes that he has little doubt that the castings for this engine were made at Coalbrookdale, about the year 1760, or perhaps a few years earlier; no castings so large could have been obtained much earlier than this date.

‡ Mr. Davey discredits the story of the Humphrey-Potter invention. The contrivance said to have been invented by Potter is described in the following: "In some engines there is a catch held by a chain fixed to the great beam, and this catch holds the eff from falling back and opening the cold-water cock, till the rising of the beam pulls the catch up by the chain and then the eff falls." The story probably arose from calling cock-buoy cock-boy, a buoy being used for opening and closing the cocks.

in the form of a collar) rocking in cast-iron gudgeon-blocks. Its weight with the gudgeons, trusses, etc., was about 5 tons. The engine made from ten to eleven motor strokes per minute.

The pumps, which were three in number, were bucket lifts, and 9¾ inches in diameter, and were worked from the end of the beam by chains secured to the beam and passing over the wooden arcs at ends of beam (as shown on the drawing) and thence down to the rods of pumps, which were of wood bolted together, with side straps. The pumps were in three lifts, and delivered one into the other from the bottom of the shaft, which was 750 feet deep. There was a jack-pump attached to the engine, which lifted water into a cistern at the level of the beam floor, to supply the injection water to the cylinder. It may, perhaps, be interesting to describe its mode of action. A vacuum was formed on the under side of the piston by the admission of steam, which was then condensed by the admission of the injection water, and the top of cylinder being open to the atmosphere, the atmospheric pressure exerted itself on top of piston, causing it to descend with an energy due to the perfection of the vacuum formed, and so producing the indoor stroke which lifted the pump rods at the other end of the beam, thereby actuating the buckets of pumps and lifting the water from the bottom of the shaft. The outdoor, or descending stroke, of the pumps was made chiefly by the weights of the rods, etc., and thus the double stroke was completed.

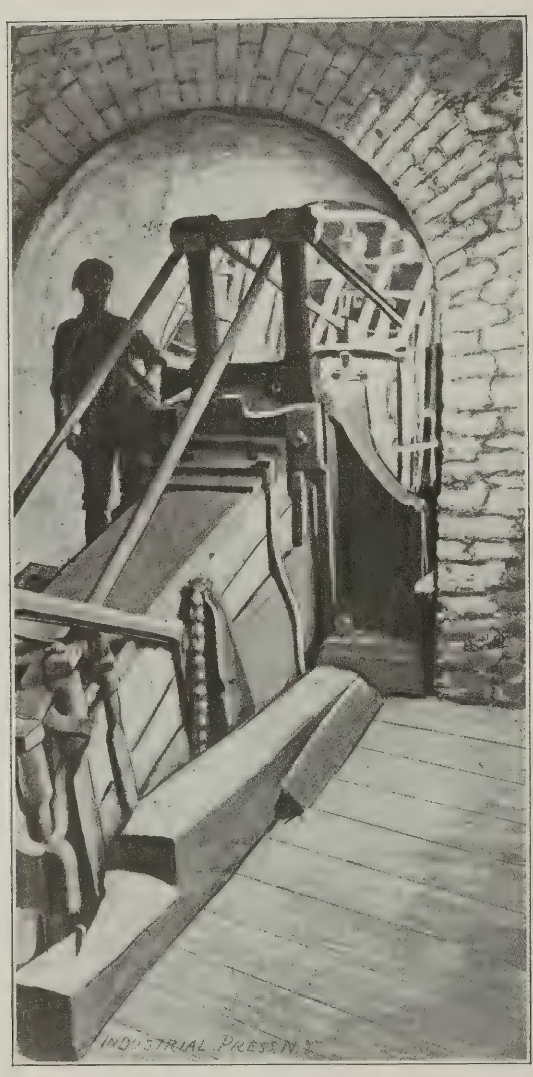


Fig. 3. View of Old Walking Beam.

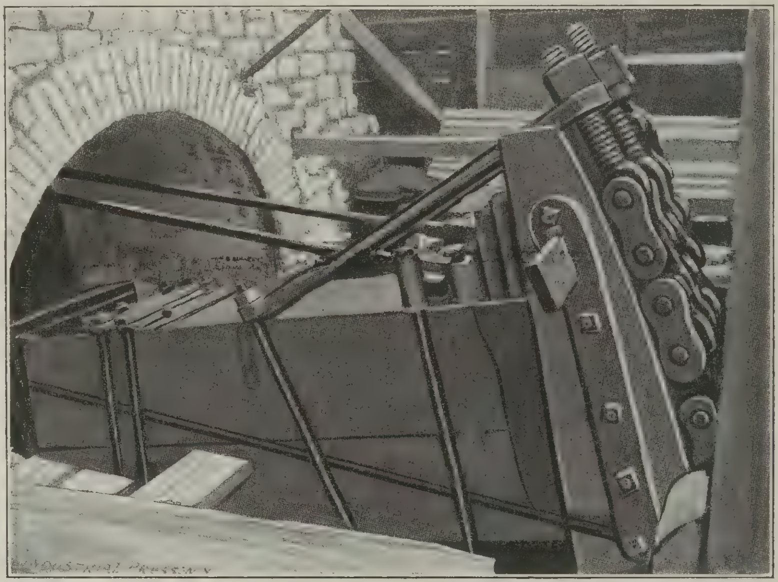

Fig. 4. Point of Attachment of Chains to Walking Beam.

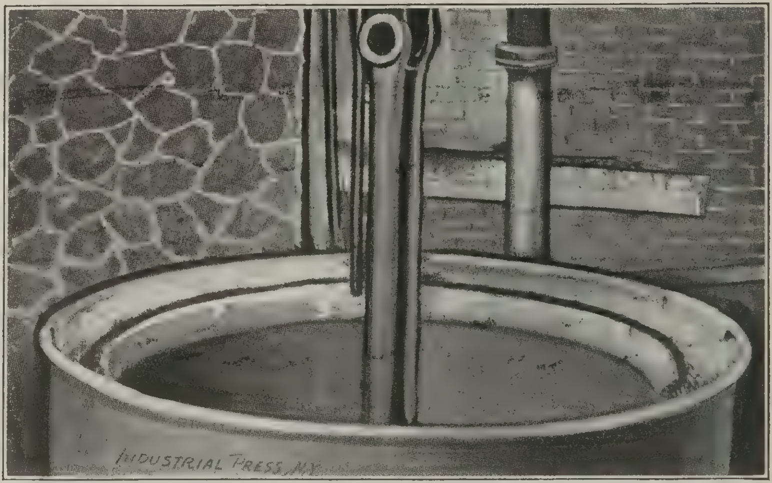

Fig. 5. View of the Open-top Atmospheric Cylinder.

No indicator diagrams had ever been taken from the cylinder until the writer took some in 1895, for which purpose the cylinder had to be drilled and indicator connections and gear fitted. The diagram, shown with Figs. 1 and 2, represents the indicator cards showing the amount of vacuum to be between 9 pounds and 10 pounds. This diagram, at a speed of 10 strokes per minute, gives about 52 horse power. The old man, seen in Fig. 3, near the gudgeon-blocks, worked the engine up to the time of its being dismounted in 1900, and had driven it since he was a boy; his father and grandfather had worked the engine before him.

* * *

The property of calcium carbide of rapidly developing acetylene gas, when brought in contact with water, has led to its use as a means for raising and sinking submarine boats. The boat is supplied with an ordinary gas generator and a water tank, whose contents serve as ballast. The upper part of the tank is connected with the gas reservoir of the generator by a pipe so that gas can escape into the tank. The tank and the generator have pipes at the bottom opening into the sea water. The upper parts have vertical pipes for the escape of the gas. If the reservoirs are filled with water, the boat sinks.

After the introduction of a carbide cartridge into the gas generator gas is formed at once, which forces the water through the lower pipe into the sea. After opening the cock in the connecting pipe, the gas enters the tank and fills it by forcing out the water. The boat now rises to the surface, remaining there until the gas is allowed to escape from both reservoirs, which causes them to be again filled by sea water. If the boat has sunk deeper than desired, the introduction of a sufficiently large carbide cartridge into the generator will make the boat rise to the proper level. The apparatus is quite simple and works reliably, doing away with air and water pumps.

TOOL MAKING.—2.

REAMERS (Continued).

E. R. MARKHAM.

It is the intention of the writer to explain in a brief yet thorough manner the methods usually employed when making the various tools used in machine shop work; and he trusts that the skilled mechanic who has at his tongue's end the various methods here explained will patiently consider that it is for the many who have not been so fortunate as he that these articles are written. An article that would tell the skillful workman many things he does not already know would be of little benefit to those who are anxious to get the fundamental principles on which to build an experience that will be of value to them. Now a certain principle that may be fully explained under the heading of reamers may apply to similar operations as applied to other tools; but in cases of this kind the explanation will not be repeated, as under such circumstances the series would have no ending. For this reason we request that the reader who is anxious to learn as much as possible will try to impress on his mind the methods here given and apply them to other articles where the description is omitted.

In our last article we stated that it was formerly considered necessary to give *fluted* reamers an uneven number of cutting teeth to avoid chattering when the tool was in use, but that experience had proved that a reamer having an even number of teeth *unevenly* spaced worked as well and was easier to make. It could be ground to size at less expense, because the teeth were directly opposite each other, which made it possible to gage the size by means of a micrometer without removing the work from the cutters of the grinding machine—the unevenness of spacing being between adjoining teeth.

In cutting the teeth an uneven distance apart we move the index pin a different number of holes for each adjoining pair of teeth. The variation from even spacing, as before stated, should be from 2 to 4 degrees. To illustrate the method referred to of getting the irregularity we will take as an example a reamer to be cut with ten teeth. Supposing the milling machine to be used has an index head which requires 40 turns of the index pin lever for one revolution of the spindle. Then with the index pin set to the circle on the dial containing 18 holes we find that in making one revolution of the index-head spindle—which is, of course, equivalent to one revolution of the reamer being cut—the index pin must pass 40 × 18 holes = 720. As there are 360 degrees in every circle we divide 720 by 360 = 2. It is apparent that a movement of two holes, with the index pin in the 18 row of holes, moves the work being operated on through one degree of space. If we were to mill 10 equally spaced grooves in the reamer then we would make a movement of four revolutions of the index pin each time, which would give us a movement of 4 × 18 = 72 holes or 36 degrees, which is exactly one-tenth of a circle. As we have the teeth unevenly spaced we first cut a tooth, then revolve on index head one-half revolution by revolving the index pin 20 revolutions and cut the second tooth—as shown in Fig. 1, directly opposite the first. We next move the index pin 64 holes and cut the next tooth; then revolve the head one-half revolution and cut the opposite groove. As a movement of 72 holes would give an equal distance between cutting edges it is apparent that moving 64 holes would cause an irregularity of spacing of 8 holes, and as each hole represents ½ degree the irregularity would amount to 4 degrees. Our next move will be 68 holes, which will require 3 entire revolutions of the index pin and an additional movement of 14 holes. As our previous move was 64 holes and this is 68, we have a variation of 4 holes, or 2 degrees. We next move 76 holes, then 80 holes for the last groove, and we find it would require a movement of 72 holes to carry us to our first groove. Now if we add the different number of holes moved to cut the various grooves we find we have moved the sum of 64 68, 76, 80 and 72 holes, which is 360 holes or 180 degrees, which is one-half circle. And as we cut the two teeth opposite each other every time we made an irregular spacing we would pass through an entire revolution of a circle—360 degrees or 720 holes.

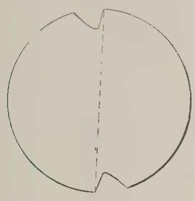

Fig. 1.

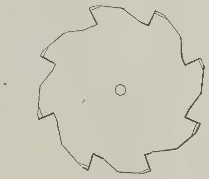


Industrial Press, N.Y.

Fig. 9.

Thickness of Land. When cutting the flutes of reamers with the form of reamer cutter mentioned in Article 1 the depth should be so gaged that the land will be about 1-5 the average distance from one cutting edge to the next. This will necessitate cutting some of the grooves deeper than others, as the irregularity of spacing causes an unequal distance between adjoining cutting edges. If the flutes are cut deeper than mentioned the lands will be thin and weak, and will spring when in use; and if they spring out into the work being cut they will stick and break. If they are cut much shallower they do not form a sufficiently large receptacle for chips.

Hardening Reamers. Extreme care should be exercised when hardening reamers, to avoid springing. Tools of this character should *never be overheated,* as it leaves the cutting edges brittle and unfit for use. If the necessary facilities are at hand the best results will be obtained if the reamer is hardened by the process known as "pack hardening;" but if this is not feasible we must heat very carefully and harden in the usual manner. With a muffle furnace at hand a uniform heat may be obtained very easily; but if obliged to use a blacksmith's forge the reamer should be placed in a piece of gas pipe, or tube, to prevent the fire from coming in contact with it. This method also prevents the air from the blast from striking the edges and causing them to crack. It is necessary to frequently turn the pieces that are being heated.

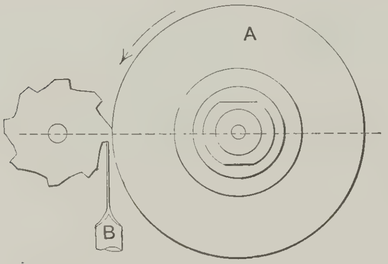
When uniformly heated to the desired temperature the reamer may be taken and plunged into a bath of water, or brine, from which the chill has been removed. It should be in as nearly a vertical position as possible, to avoid springing; when pieces are dipped at an angle the bath acts unequally on the opposite sides and consequently these contract unequally, which causes them to crook. The pieces should also be worked up and down in the bath somewhat, as this prevents the steam generated by the contact of the red-hot steel and water from forming a cushion around the reamer and keeping the water from it. If the reamer is larger than ⅞ inch diameter it should be held over the fire immediately after being taken from the bath, to remove strains set up by the hardening. Another method consists in removing the reamer from the water bath when it stops "singing" and immediately plunging in a bath of oil, allowing it to stay there until it is reduced to the temperature of the oil. The temper should be drawn to a straw color.

Should the reamer spring when hardening it may be straightened by applying pressure to the convex side after heating, the reamer being held between the centers of the lathe. This method of straightening hardened work will be more fully explained in the article on counterbores.

Grinding Reamers. When articles having centers in the ends are hardened, scale and dirt collect in the centers, and in order to get satisfactory results when grinding it is necessary to clean the center holes. This may be done by grinding a three-cornered file to a point at the end and using it as a scraper. Should the article be ground while dirt and scale are in the center holes it would in all probability run out so badly that it would not be possible to "clean" it when grinding. But should there be plenty of stock to allow of truing, some of the dirt might become loosened when the piece was being ground, and either change its location or fall out, and in either case it would cause the piece to again run out of true.

When possible it is advisable to grind work in a machine having two *dead* centers. All universal grinders are made this way. When a piece of work is ground in a lathe or other machine having one *live* center, there is a liability of the center not running true, or of the spindle which contains the center being out of round, in which case it will duplicate its shape on the article being ground. Then again the irregular draw of the belt does not affect the shape of the piece when the spindle is *not revolving*.

Be sure the centers of the grinding machine are in good shape, and to gage. The reamer should first be ground to run true; and to accomplish this place the dog on the cutting end of the reamer and grind the shank to size, then place the dog on the shank end and grind the body to within .001 or .002 inch of finish size. Small reamers are given the less amount and large reamers the greater. Having ground the body to the dimension mentioned, we proceed to back off the cutting edges for clearance; and to make the clearance as straight as possible we use as large an emery as can be used without striking the cutting edge of the tooth next to the one being ground. In order to get the correct clearance we rest the face of the tooth being ground on the guide finger, which can be adjusted to give any desired amount of clearance. Fig. 2 shows an end view of a fluted reamer being ground for clearance. *A* represents the emery wheel, which should be run in the direction of the arrow, so that the tooth of the reamer may be pressed down on the finger *B*. Should it be run in the opposite direction it would tend to draw the tooth up from the finger and cut away the cutting edge—thereby spoiling the reamer. However, when using a dry grinder—that is, one where water is not run on the emery wheel—the danger of heating the tooth and drawing the temper is greater when the wheel is run in the direction shown in Fig. 2; but if the face of the wheel is kept free from glaze, and ordinary care is exercised, there is little danger of starting the temper, provided we use a free cutting wheel that is not too fine. To give the tooth the proper clearance the finger is adjusted to bring the cutting edge below the line of centers, the dotted line denoting this. Do not attempt to remove too great an amount of stock at a cut; rather, take more cuts, going way around the reamer each time the adjustment is altered.



Industrial Press, N.Y.

Fig. 2.

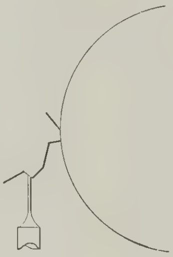


Fig. 3.

When grinding reamers for clearance it is absolutely necessary to rest the face of the *tooth being ground* on the finger, otherwise the teeth, being irregularly spaced, would not be ground with an equal amount of clearance. Neither would the cutting edges be the same distance from the center were we to rest on the tooth next to the one being ground, as shown in Fig. 3, as is done sometimes when work is being ground that has evenly-spaced cutting teeth. But in any case it is not advisable to rest on any tooth face but the one being operated on.

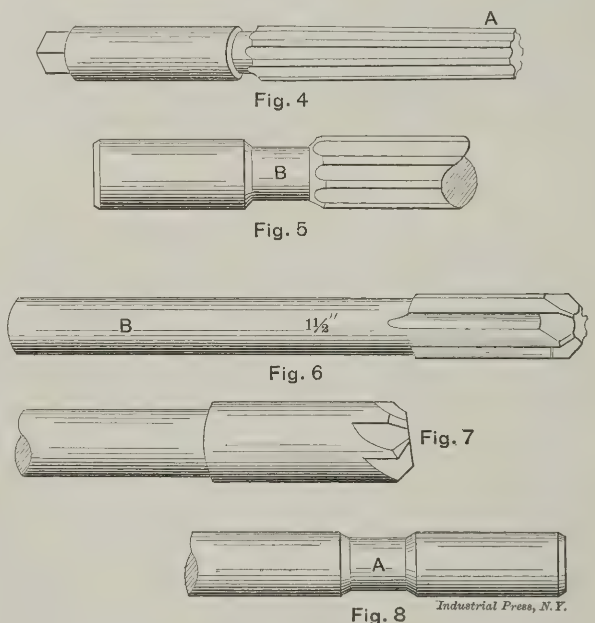
To insure fluted reamers maintaining their size when in use the clearance should not be ground to the edge of the teeth, as though it were a milling machine cutter; it should be ground to within .01 or .015 inch of the edge, the amount left depending on the size of the reamer. However, if the reamer be very small it is best not to leave more than one-half the first amount mentioned. To bring the clearance to the edge use an oil stone. It is necessary during this operation to stone to the desired size, which may appear to some a slow and costly way, but if a free cutting stone of medium grade is used for removing the stock, it can be accomplished in short order. In order to get an edge that will produce a smooth hole and stand up, use a fine stone for finishing. Do not, under any circumstance, use the stone dry; neither should it be allowed to glaze. The face of the stone being used should be flat, and free from indentation of any sort if satisfactory results are desired. It may be trued up by grinding on a wet grinder.

Do not give the cutting edges of a fluted reamer any more clearance than is necessary to insure its cutting freely. Too much clearance makes a weak edge, which chatters and soon loses its size.

As fluted reamers differ from rose reamers in that the latter cut on the end, it is necessary to taper them somewhat for a distance from the end in order that they may enter the hole to be reamed. This taper is represented at *A* in Fig. 4. As this form of reamer is not intended for removing much stock the taper should be very slight. This portion is, of course, given clearance the same as the balance of the tooth. When stoning the point where the taper and straight part of tooth join, it should be slightly rounded so as to avoid making a mark in the hole being reamed. This should be very slight, yet enough to break the abrupt end of taper and commencement of the straight portions.

While the instructions just given relate to fluted hand reamers, they apply in principle to fluted chucking reamers. The shanks of the latter, however, may be turned to size before hardening without leaving any allowance for grinding unless they are to be held in chucks of some form of holder. In this case they must be left somewhat large, and be finished to size after hardening, to insure their running true when in use.

When fluted reamers are intended for use in the lathe, and are not to be held in a chuck or any style of reamer holder, they are ordinarily made of the form illustrated in Fig. 4. When they are to be held in a holder as when used in a drill press, screw machine or chucking machine, they are made as shown in Fig. 5. In this style of reamer the portion to be placed in the holder should be ground after the reamer is hardened, to insure its running true; and on this account it should be left .010 to .015 inch larger than finish size. The portion necked below the body and shank, which is marked *B*, may be turned to the size called for on the drawing, and finished. The size of the reamer and any distinguishing marks needed may be stamped on this portion, care being exercised, however, not to spring it by this operation.



Figs. 4 to 8. Fluted and Rose Reamers

Reamers that are held rigidly at the end of shank are, for several reasons, liable to cut holes somewhat larger than their own size. For this reason in many shops all reamers used for chucking purposes are made somewhat smaller than the hole to be reamed for finish, and after running these through the hole, "standard" hand reamers are used to produce the finished hole. Many mechanics claim this precaution is unnecessary, contending that any hole which must be of exact size should be left a trifle small and lapped to size. However, as this is a matter of opinion, and must be determined by circumstances, we will not discuss it, but will give the required amount to leave for the hand reamer, if it is thought necessary to finish the hole with this rather than with the chucking reamer. The amount of stock to leave for the hand fluted reamer varies according to the custom and notions in the individual shop, and the tool maker must be governed by the ideas of those in whose employ he may happen to be. But in order that he may have some idea of the amount necessary we will give the custom in a shop using many reamers on all classes of work: For reamers under ½ inch .002 inch is allowed; between ½ and ¾ inch .003 inch; between ¾ and 1 inch .004 inch; between 1 and 2 inches .006 inch. For reamers larger than 2 inches diameter .008 inch is allowed. As these amounts are not considered proper to produce good results in other shops no exact amounts can be stated arbitrarily, but the conditions existing in each shop, the stock to be cut, etc., must determine how much stock the finish-reamer must remove. However, if we are to take out only the small amounts mentioned for the small reamers, the holes will have to be smooth and in good condition before we ream them, or we shall not be able to correct any imperfections that may have existed.

Rose Reamers.

The form of reamer known as "rose reamer," Fig. 6, has its cutting edges on the end, as shown. The grooves which are cut the entire length of the body serve the purpose of reducing the amount of bearing surface in the reamed hole, and also furnish ways to conduct the oil or other lubricant to the cutting portion. Rose reamers were formerly made without the grooves, as shown in Fig. 7; the body of the reamer was solid, with the exception of the cuts made to form the teeth at the end, and for this reason they caused a vast amount of annoyance by "wringing up" the stock in the hole of the piece being reamed. This trouble has been done away with, however, by the reduction of frictional bearing effected by cutting the grooves.

Reamers of this character will cut a hole that is nearer parallel than is a fluted reamer, when there are blowholes or other irregularities of surface in the walls of the hole being reamed.

In some shops it is customary to use a rose reamer a few thousandths of an inch smaller than finish size, before using a fluted reamer, thus insuring the proper amount of stock to remove with the fluted reamer, which does not work well if it has too much stock to remove when cutting.

Small rose reamers for use in an emergency are oftentimes made from a piece of drill rod of the right size. This is cut to the proper length, placed in a chuck on the lathe and the end is beveled the proper amount for the cutting lips. The grooves may be filed with a three-cornered or round-edge file, the cutting edges backed off, and it is then ready for hardening. It is advisable to harden up for a distance as great as the reamer is to enter the work, or it will "rough up" when in use. If the reamer is to be used in reaming *long* holes it is advisable to neck down a short distance back from the cutting edges as shown at *A* in Fig. 8, and have the hardening end in this necking, as a peculiarity of drill rod is that it apparently expands at the point where the hardening stops, and if it stops in the smaller part it will not bind in the reamed hole. These remarks of course apply to reamers that are not to be ground to size after hardening.

When making the ordinary form of rose chucking reamer shown in Fig. 6 we select stock enough larger than finish size to allow the removal of all the decarbonized portion. After turning a roughing chip all over the piece, the shank *B* may be turned to finish size, unless the reamer when in use is to be held in a chuck or other holder, in which case there should be sufficient stock left to true by grinding after the reamer is hardened. When rose reamers are to be used for reaming holes that must be exact as to size they must be ground to correct size after they are hardened. To prevent them from binding in the hole being reamed it is advisable to grind them a trifle tapering, making the body 1-4000 inch smaller on the end next to the shank. A greater amount of taper would not do, as the reamer would not be sufficiently supported in the hole when in use, and might run.

When rose reamers are made from drill rod and are *not* to be ground after hardening, the necessary clearance to give the cutting edges may be obtained by filing. Make sure that the clearance goes to the edge, as otherwise the tooth will not cut. Care must be exercised also not to file too much. This would reduce the length of the tooth, as one tooth would be shorter than the others and would not do its share of work. Cutting tools having more than one cutting edge should be constructed so that each edge does its proportional amount of work. If reamers are ground to size the cutting edges should be given clearance by grinding also, thus insuring teeth whose lengths are exactly alike. The bevel given the corner produces a point where it meets the straight part of the body, Fig. 6, and this point it would produce a scratch in the hole being reamed; so this sharp corner must be removed by means of an oilstone, to insure smooth walls in the hole.

Large rose reamers, and those to be used in reaming brass and the various other alloys of copper, should have the lands of about the width of fluted reamers. The bearing surface of the lands must also be reduced, which may be accomplished by filing, commencing at the heel of the land and filing a clearance to within a short distance of the opposite edge. The distance left untouched varies with the character of the work to be reamed, but for most purposes 1-32 inch would be about right. The neatest method of giving the land the clearance mentioned, however, would be by grinding, leaving it as shown in Fig. 9. The amount of clearance in this sketch is exaggerated, so as to illustrate the principle. It need be only sufficient to insure the reduction of frictional resistance, which is very pronounced when reaming the softer metals.

Industrial Press, N.Y.

Figs. 10 to 13. Forms of Reamer Holders.

Reamer Holders. When reamers are operated by hand they are held in a reamer or tap wrench. When used in an engine lathe they are sometimes held with a wrench, and at other times, placed in a drill chuck. When used in a drill press they are held either in a chuck or a collet having a hole in the end the exact size of the reamer shank. The shank must fit exactly in the hole, and the hole must be true with the collet. We might carry this line of reasoning still further and say that the spindle of the press must be true, but this is outside the intended scope of these articles.

When reamers are used in the screw machine, or chucking machine, they are held in reamer holders. Of these there are several styles, the simplest of which is shown in Fig. 10. It is ordinarily made from machine steel, one end of which is turned to fit the hole in the turret while the opposite end is turned to finish size. A hole is bored in the end to receive the reamer shank, the reamer being held in place by a setscrew. When fitting tools of this character to holes in the turret it is advisable to test the holes for size. If there is any variation, fit to the proper hole, then mark the holder to correspond with the hole it is fitted to.

A second form is shown in Figs. 11 and 12. In this holder the reamer is held by closing the sides of the holder onto the shank. These jaws are closed in Fig. 11 by means of the collar and setscrew, while in Fig. 12 the ends of the jaws are tapered and a nut with a tapered hole forces the jaws together. A third form is shown in Fig. 13 and is generally termed a "floating" reamer holder, because the reamer is not held rigidly in position. The object attained in using a holder of this form is that, should the turret holes not line perfectly with the head spindle, the reamer is free to adjust itself to proper alignment, thus doing away with the tendency to ream a hole somewhat larger than its own size at the outer end of the hole.

When making the holder shown in Fig. 10, a piece of machine steel somewhat larger than finish size is used. After turning a roughing chip over the piece one end is fitted into the hole in the screw machine turret, the other end turned to size and the large end run in the back rest of the lathe, while the opposite end is strapped back against the live center. The hole in the end that receives the reamer is drilled and bored to size. Previous to strapping the work against the center, test the center to make sure that it runs true. If it does not, it should be trued before proceeding, for the hole bored in the end would not be true if the center were not true. Care must be taken when fastening the piece back against the center not to draw it to one side by careless methods of strapping; this would also cause the hole to be bored out of true.

If the hole to be made in the end that is to receive the reamer is sufficiently large it should be bored to size with a boring tool rather than attempting to ream it, as a hole more accurate as to size and concentricity will thus be produced, unless we are certain that our lathe spindles are in perfect alignment and the reamer we are using is exactly straight. Many times we find lathes that have been in use for some time have not remained in line, and in fact we occasionally find a new lathe whose spindles are not in line with each other. Now, if the head and tail spindles of a lathe do not line with each other—that is, if one is lower than the other—by moving the tail block in or out we can compensate for the amount the spindles are out of alignment and turn a piece of work straight; but if we attempt to ream a hole in a piece attached to the head spindle by placing the center in the shank end of the reamer on the dead center, when the two spindles are not in alignment, the results will not be satisfactory.

If it is found by trial that the spindles are perfectly aligned, and it is considered advisable to ream the hole, first drill it somewhat small, then by means of a boring tool, bore it to within a few thousandths of an inch of size, to insure its running true. It would not be safe to drill a hole to reaming size, and then ream it without boring, as the drill is almost sure to run somewhat, no matter how much care may be exercised. There is no assurance that steel or iron is perfectly homogeneous, and a soft or hard spot in the stock would cause the drill to run out; for this reason it is always necessary to bore the hole with an inside turning (boring) tool, to make it concentric with the outside of the piece.

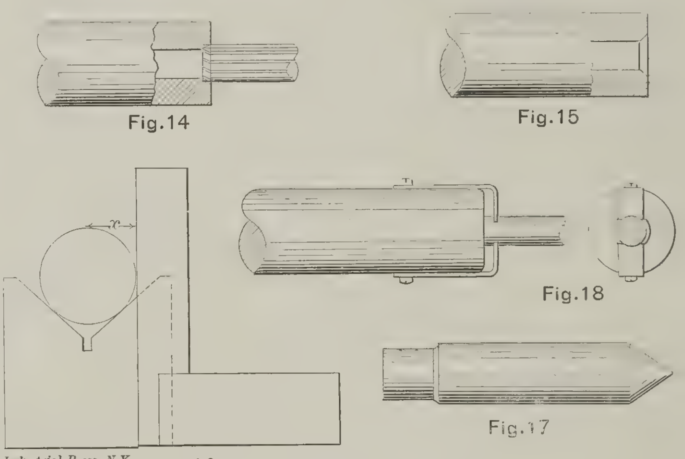
When reaming holes that must run true many mechanics take the precaution to bore the hole to a size at the end—1-16 inch or so—that allows the reamer to be wrung in, as shown in Fig. 14, thus insuring its starting true; and if a rose reamer is *started* true there is every reason to think it will produce a true hole, provided the reamer is straight and in good condition and the spindles are in alignment. Other mechanics who are perhaps equally skillful do not consider it necessary to let the reamer in with the boring tool, but by means of a tool held in the toolpost of the lathe they chamfer the end of the hole, as shown in Fig. 15, to an angle that corresponds to the angle of the cutting edges of the reamer.

A rose reamer will, as a rule, make a hole true to size. If started true the liability of its "running" is reduced to a minimum on account of the large bearing surface it has on its lands which, not being backed off, fill the hole and steady it. This overcomes in a great measure the reamer's tendency to run when it strikes a hard or soft spot, as is the case with a fluted reamer or a drill, which are not supported by the lands—at least not to any considerable degree.

After the hole has been brought to size the holder may be removed from the lathe and the hole for the setscrew drilled and tapped. The burrs are then removed, and when the setscrew is in place it is ready for use. As the pressure of the setscrew is all in one direction the shank of the reamer must fit very nicely in the hole in the holder; the holder must also fit well in the hole in the turret.

To overcome the tendency of the setscrew to throw the reamer to one side, unless the fit be perfect, holders are often made as shown in Fig. 11. The same general instructions given for the other form apply to this except that instead of using a setscrew we drill a hole, *a*, and split the holder as shown. It is quite necessary that the drilling of the hole and cutting of the slots be as nearly central as possible in order that the holder close in a manner that will bring the reamer central. Should the hole *a* be nearer one side of the holder than the other, one side would offer less resistance than the other and the reamer would not be concentric with the holder. Should both sides of the holder not close equally this style of holder is no better than the one using the setscrew to hold the tool.

There are several methods employed when drilling the hole and sawing the slots in holders of this character. The more common way is to center-punch on one side and then drill it in a speed- or engine-lathe, holding the piece in the V-center. The result of using this method would in all probability be a hole drilled to one side of the center of the piece. A better method would be to clamp the holder in a pair of V-blocks on the drill press table, as shown in Fig. 16, locating the punch mark so it is equi-distant from the sides. This can be accomplished by measuring from a square blade placed against the work, as shown, measuring the distance from the blade to the punch mark and setting it so that it measures the same from each side. First drill with a small drill, then follow with a larger one; although a surer way would be to follow with a counterbore. But even with the utmost care the drill is liable to "run" and produce a hole that is not central; so the safest way to drill the hole is to put it between the centers on the milling machine, and drill it by means of a drill held in a chuck, or a collet in the spindle of the machine. The point of the drill should be set at the height of the point of the centers, and when starting to drill, should be set well back in the chuck, having not more than one-half inch of the straight part projecting beyond the jaws. This is to prevent it running when "spotting the work," or in other words, when locating the hole. The work is fed to the drill by means of the cross feed screw handle. Having drilled the hole deep enough to allow the body of the drill to enter the work, withdraw the work and revolve the centers one-half revolution and "spot" the opposite side. The drill is then set out from the chuck and the hole drilled through the walls of the holder, each side being drilled separately from the outside toward the center.



Industrial Press, N.Y.

Figs. 14 to 18. Making a Reamer Holder.

In order that the slots which allow the holder to close together may appear well, hold the piece in the centers, using a metal slitting saw. Set the saw in center of the drilled hole, cut one slot and then revolve the center-head one half revolution and cut the other slot. If this slot were not in the center it would not affect the accuracy of the holder, but how much more mechanical such a piece of work looks when it presents a favorable appearance, and, as a rule, a workman who is slack regarding the appearance of his work is not careful as to essentials. Moreover, as it takes no longer, generally speaking, to do a thing right than to do it in a "slip-shod" manner, it is advisable to cultivate carefulness, not only as to accuracy but as to appearance.

The collar containing the screw used in closing the holder needs no description or explanation as to its construction, as any one can readily see how it is made. Put the small screw shown in cut, in the collar, tapping it into the holder.

This holds the collar in place and prevents its being lost when the holder is laid away if the tension be removed from the setscrew.

When making the form of holder shown in Fig. 12 the same general instructions should be observed, when turning the outside, as with the holder shown in Fig. 11, with the exception of the tapered end and the threaded portion to receive the cap nut used in closing the jaws of the holder. The nut, which is generally made from machine steel, should be made and casehardened before cutting the thread and turning the tapered portion. Caseharden work of this character by dipping in oil rather than water, as the liability of change of shape is then greatly reduced, and the nut will be much stronger.

When possible turn the necessary tapers on this class of work on a lathe having a taper attachment, or a compound rest—preferably the former; the setting over of the dead center is liable to cause the center of the piece being machined to become distorted, thereby throwing the work out of true, i. e., causing one portion to be out of truth with another portion. When there is but one taper to turn on a piece of work it can be accomplished very nicely by setting the dead center over and turning the taper before the straight portion is turned. Then when the centers are placed in line, test the tapered portion before turning the straight portion, and should it prove to be out, the center in the end may be scraped with a three-cornered scraper until the portion runs true. The straight portion may then be turned, and the two will be true one with the other. But where two tapered portions are to be turned on the same piece of work trouble may be experienced unless extreme care is used and the condition of the piece is noted after each operation. Work of this character can be done on lathes having no taper attachment or compound rest, and done in a satisfactory manner, but greater care must be exercised, and the work must be tested after each operation of taper turning.

For the style of holder shown in Fig. 13 we proceed the same as for Fig. 10, when turning the outside portions. The hole in the holder, however, should be somewhat larger than the reamer shank, as shown, but should be concentric with the outside in order that the point of the center may be true with the holder. The center is made from tool steel—a cheaper grade will answer as well as the better quality. It should be turned to a size .010 to .015 inch larger than finish size, and should then be back-rested and the point turned. After this it may be hardened and the temper drawn to a brown color. Harden the entire length of bevel; the angle can then be gaged much more readily when grinding. If it were hard for a part and soft the balance of the taper, the emery wheel would not act alike on the hard and soft portions.

When turning in the lathe it is advisable, when allowable, to turn a portion of one end slightly smaller than finish size, as shown in Fig. 17. When grinding the straight portion to size the dog may be placed on this portion and the straight part ground the entire length. Use a female center for the pointed end, when grinding the straight portion, and after grinding this straight portion, the piece may be back-rested in the grinding machine and the beveled end ground to its proper angle, true with the straight portion.

Now the center may be placed in the holder as shown and a hole drilled through the holder and center and a pin driven in to prevent the center being pressed back, from the force used to cause the reamer to cut. The center, when ground, should be a close fit in the hole; in fact it should be necessary to use gentle blows of a babbitt hammer to drive it to place.

A pin should be driven tightly into a hole in the holder to keep the reamer from turning. The hole in the reamer through which it passes should be considerably larger than the pin; if the pin is ¼ inch diameter the hole should be at least 9-32 inch. For larger size pins the hole should be corresponding above size.

Coil springs are used to keep the reamer central with the holder so that it may readily enter the hole to be reamed. These springs are placed in holes which are tapped to receive screws to give the springs the desired tension. Some mechanics object to the coil springs, claiming that fine chips in the form of grit find their way into the holder, and prevent the springs acting properly. They claim best results with springs made as shown in Fig. 18, which being fastened to the outside of the holder on opposite sides pass over the end and engage with the reamer.

There are other styles of holders in use but those shown give an idea of the operation necessary in making most forms.

ITEMS OF MECHANICAL INTEREST.

A SPECIAL SHAPER JOB–INSULATING COUPLING–MARINE ENGINE MODEL–DRIVING SCREW SPIKES.

In the operation of New York's electric surface railways, it has been found that the electrical power for propulsion costs less than seven per cent of the total operating expenses.

Twist drills hardened in a water bath should be plunged deep enough to harden a short distance on the shank. Water cracks are apt to occur if the drills are held almost stationary in the water. If the drills are soft, directly back of the water cracks, it is proof that this portion was held at the water line or so close to it that they did not go into the bath deep enough to harden.—*Sparks from the Anvil.*

A SPECIAL USE FOR THE SHAPER.

The accompanying illustration shows the adaptation of one of Gould & Eberhardt's shapers, to work which had previously been considered a milling-machine job.

The machine was designed for cutting the grooves in composition trolley ears, such as are used for suspending trolley wires, and sample ears are shown on top of the vise in the illustration. The machine was gotten out for a large manufacturer, who had been using a milling machine, but wanted to increase his output. With the shaper he has been able to almost treble the output of his milling machine.

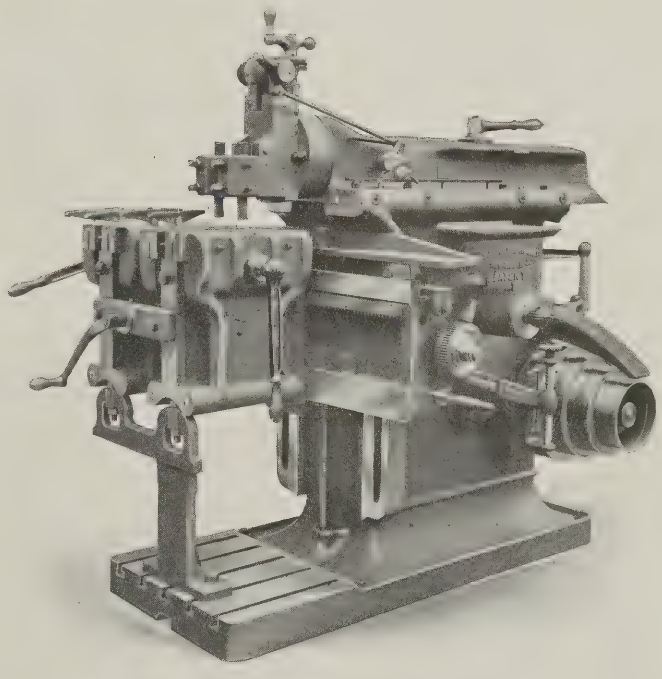

Fig. 1. Cutting Grooves in Trolley Ears.

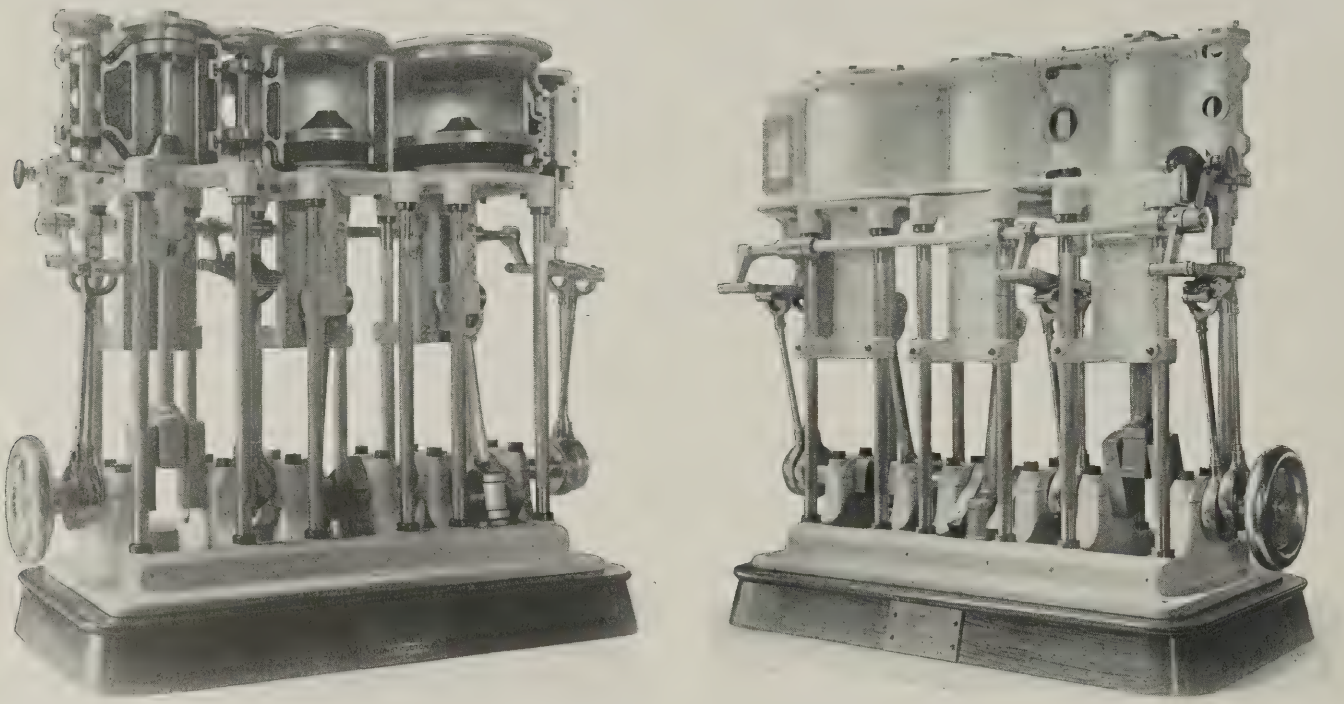
The shaper is a standard machine, with a special table and tool head. These can be replaced by the regular table and head, and the machine used for ordinary shaper work when required. There are two sets of two vises, four in all, for holding the ears, the jaws of the vises conforming to the shape of the ear. The grooves in two of the ears are planed at one time, the machine being provided with a double tool holder. While this operation is going on the operator removes the ears from the other set of vises and replaces them with blank castings. The tool head has an automatic depth stop, and instantaneous return. As soon as the grooves are planed in the two ears the operator moves the other set of vises over in position, by means of the crank handle on the front, which operates a pinion and rack. The table is provided with a stop at each end which insures its being located centrally under the tools when moved. In the meantime the tool head has commenced to feed down, but there are a sufficient number of strokes allowed for the operator to move the vise over before the tool reaches the work. This machine will plane grooves ⅜-inch wide by 17-32-inch deep and 15 inches long, from the solid casting, at the rate of one every forty seconds.



Figs. 2 and 3. Front and Rear View of Marine Engine Model.

INSULATING COUPLERS FOR MOTOR GENERATORS.

In a description of the transforming and distributing station of the Montreal Light, Heat & Power Co., published in the *Canadian Electrical News*, an insulating and flexible coupling for motor generators is illustrated. It consists of the steel castings *AA′* keyed upon the shafts *CC′* to be coupled. Each casting has eight ears which engage those of the opposite casting through the medium of the rubber rolls *BB*, etc., which are interposed to prevent metallic contact, but which have strength sufficient to transmit the torque. The sides of the ears are grooved to the arc of the rolls and nearly encircle them. Plates over the ends retain them in the recesses and give further support to the rubber rolls. There is of course little flexibility to this coupling, the chief aim being to secure the insulating effect.

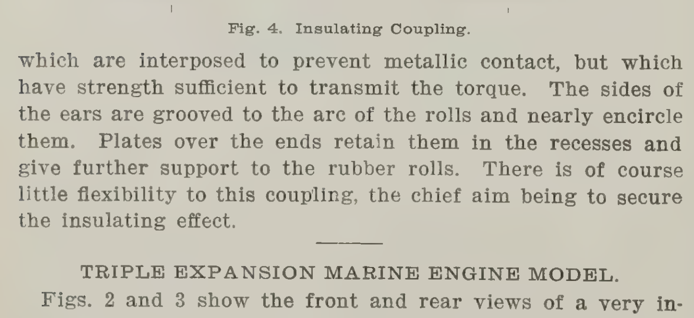


Fig. 4. Insulating Coupling.

TRIPLE EXPANSION MARINE ENGINE MODEL.

Figs. 2 and 3 show the front and rear views of a very interesting model of a triple expansion engine, of the marine type, which was recently furnished the Japanese government for use in the Japanese Naval College. The model represents, to a reduced scale, an engine having cylinders 24, 39 and 60 inches in diameter by 39 inch stroke, and this has been reduced to one-twelfth, giving cylinders 2, 3¼ and 5 inches in diameter by 3¼ inch stroke. The three cylinders and their steam chests are cut open on the front so that their relative movements may be observed as the crank shaft is turned by the hand wheel at the left. The Stephenson link motion is employed for reversing and is operated by a hand lever and knob at the rear of the cylinders. The entire model is about 30 inches in height and is mounted on a neat wooden base. The materials of construction are in nearly all cases the same that would be used in actual practice. All of the steel work is polished and the external cast-iron parts are coated with white enamel paint, so that the engine presents an exceedingly neat appearance as well as affording a correct model for instruction. It was designed by the Gardner Engineering Co., New York City, and built by the Grant Mfg. & Machine Co., Bridgeport, Conn.

MACHINE FOR DRIVING SCREW SPIKES.

Two interesting machines have been built at the Washburn Shops of the Worcester Polytechnic Institute during the last few months under the direction of the United States Bureau of Forestry. These machines are designed for driving screw spikes into railroad ties, and were designed at the Worcester Polytechnic Institute by Alton L. Smith, professor of machine design. The screw spikes are designed to replace the spike ordinarily used by railroad companies, and an effort will be made by the Bureau of Forestry to introduce their use into this country. They are already extensively used in France, Belgium, Germany and other European countries. The advantage of the screw spike lies in the fact that it will allow the use of softer wood for railroad ties than is possible where the ordinary form of spike is employed. The holding power of the latter depends entirely upon the resilience of the wood into which it is driven, and the pounding action caused by the passage of heavy trains over the rails will in a short time loosen the spikes unless the wood employed is firm and close-grained. Of late years the demand for chestnut, oak and other high-grade woods for railroad tie purposes has been so great that railroads have been confronted with a steadily rising price for their tie supplies, and they have been compelled to cast about for something to take their place. In this they have been assisted by the Forestry Department of the Government, which has been, and still is, engaged in an extensive series of experiments along these lines. If the machines which have just been built are successful it is expected that many of the softer kinds of wood, such as spruce and poplar, can be employed for railroad ties. With the old form of spike, experiment has shown that the life of one of these ties did not exceed six or eight months, but with the screw spike it is expected that they will last for some years. One of the machines in question was built for the New York Central, and the other for the Pennsylvania Railroad Company.

HOW AND WHY.

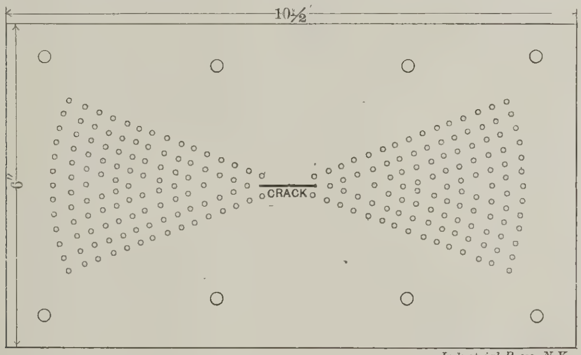
A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

14. W.—1. In hardening tools made of the new process steels, is an air blast employed or are the tools simply left to cool off in the atmosphere? 2. How can tools made of these steels be annealed?

A.—1. Tools of the new process steels should be hardened either in an air blast or in oil. Generally the former method is used for such tools as lathe and planer tools, while the oil bath is used for such tools as milling cutters, taps, etc.. For air hardening, bring the tool to a white welding heat and place it at once in a strong blast, holding it a few inches from the outlet. Do not remove the tool until it is quite cold. For oil hardening, bring the tool to a white pimpling heat, then lay it on the anvil or floor and allow it to cool down to a black heat, showing a dull red in shadow or dark place. Brush the tool off and place in the oil bath. Precaution should be taken in placing it in the oil, for if too hot the steel is liable to crack. 2. To anneal these steels, heat slowly but thoroughly to a yellow color and pack at once in a steel box or tube with dry fire clay so that the air cannot come in contact with the steel. Lime, charcoal and sea sand are recommended for use in place of fire clay, and if one of these substances does not give satisfactory results with any particular brand of steel, it is well to try one of the others. If an air-tight box or receptacle is available the steel may be annealed by heating it in this box and then allowing it to cool off slowly. It is a good plan to let the box containing the steel remain in the furnace while the fire is dying out.

15. D. M. M.—The accompanying sketch shows a perforating die that I made with very poor results. The die was 6 by 10½ inches by one inch thick, and cracked in hardening. The holes were 1-16 inch diameter and spaced ¼ inch. The die cracked at the point marked, and I am at a loss to know why it cracked at the heaviest place. I heated it in a charcoal fire to a cherry red and dipped it, side up. The bath was a large tub of clean water, with a half pail of salt in it. Any information that you can give me will be appreciated.



Industrial Press, N.Y.

Answered by E. R. Markham.

The crack was the result, undoubtedly, of unequal contraction, there being a greater volume of stock between the point where the crack occurred and the sides of the die than at any other portion, and the contraction was not only greater, but continued for a longer time. As the die was cut away less at this point than any other the yielding space was reduced to a very narrow space. What is more natural, with a greater volume of stock to contract, and the portion cut away reduced to the minimum—as per the sketch—than that it should break at this point?

There are several methods whereby a die of this character can be hardened with comparative safety. The safest method, and one I have never known to fail, consists in hardening by the method known as pack hardening. This has been explained in several articles the writer contributed to MACHINERY, but as the application would be somewhat different in the case under consideration, it will be explained in a brief manner. Pack the die in a hardening box with granulated charred leather and subject to a low red heat in a furnace for about 3½ hours after the *die* is red hot. It may then be taken from the box and dipped in a bath of raw linseed oil. There should be a pump connected with the bath whereby a volume of oil can be forced against the face of the die and through the holes. The oil used should not be cold, but about 60 degrees Fahr. Since every shop is not equipped with the necessary apparatus to pack harden work satisfactorily, we will consider a method that can be applied anywhere, provided we have a suitable fire and a supply of water. First take a block of cast iron somewhat longer and wider than the die block, then cut out the center the shape of Fig. 1. The double angular-shaped opening must be about one inch larger each way than the perforated portion of die, which would make the opening one-half inch larger each way than the space taken up by the perforations. The die must be heated *uniformly* to a low red, taken from the fire and laid flat with the face uppermost. It will be necessary to lay it on two strips of iron to block the back up somewhat, so the water that passes through the holes can run off readily. Place the cast-iron piece, Fig. 1, on the face of the die, having an equal space around the perforated portion, then by means of an overhead pipe like Fig. 2, a stream of water can be run onto the exposed portion of die; and, as the balance of the die is protected by the plate, it will not be hardened, consequently there will be no contraction to speak of that will have a tendency to draw the stock from the center.

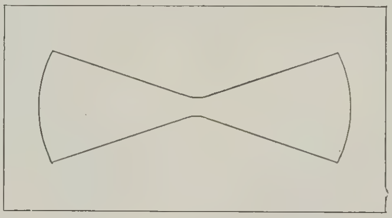


Fig. 1.

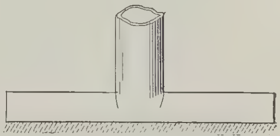


Industrial Press, N.Y.

Fig. 2.

If we have a tank of oil it is advisable to plunge the die in the oil as soon as the center is hardened and allow it to remain until cool. When cool reheat to remove strains, then draw temper. Do not use *cold* water. Water at about 70 degrees Fahr. will not be as liable to cause the die to crack.

16. S. H. S.—Are the rolls that are used for making steel plate of cast steel or iron?

Answered by J. W. Bourn, Philadelphia, Pa.

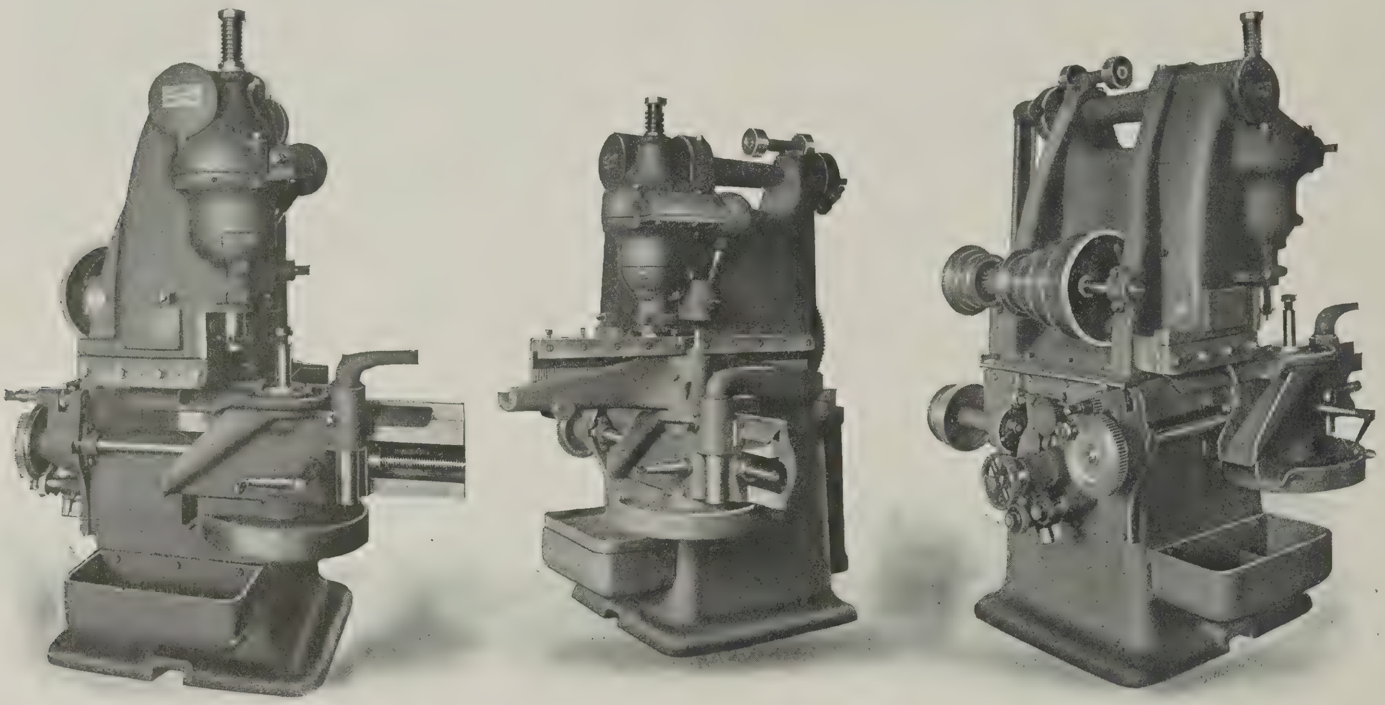
Rolls for steel, iron, brass, or tinplate are invariably made of chilled cast iron, while for rolling bars of various shapes and materials, steel rolls are quite extensively and successfully used, but they are more expensive than those of cast iron. The steel is too soft for plate rolling, and it is very difficult to obtain steel castings that will have perfectly clean surfaces when they are turned, it being a requirement of plate rolls of any description that the surface shall be practically perfect. To make a steel roll, either cast or forged, it would have to be hardened and ground after turning and in addition to being a very expensive job, it would not be very serviceable since, except for cold rolling which is comparatively rare, the hot metal would soon draw the temper and leave the roll too soft for use. Cast iron, on the other hand, can be cast without a flaw, turned easily and cheaply, and can be chilled to any depth, making a surface that cannot be softened by the heat of the plate. Steel rolls hardened and ground ready for use would probably cost from 50 to 60 cents per pound, with all the chances against their doing the work, while good chilled rolls have been known by the writer to be made as cheap as 7 or 8 cents per pound.

* * *

After many months of fighting, the Wabash R. R. some time ago secured entrance into Pittsburg. The railroad emerges from a tunnel through the hill opposite Pittsburg, crosses the Monongahela River on a double-track cantilever bridge, and enters the city hard by the old Hostetter plant, of stomach bitters fame. The bridge, which is now well along, will be the largest cantilever bridge in this country, having a clear span of 812 feet over the river. It is said that the largest eye-bars ever made will be used in its construction. No false work will be erected for the river span.

NEW DESIGN OF FELLOWS GEAR SHAPER.

A gear shaper of new design has been brought out by the Fellows Gear Shaper Company, Springfield, Vt. It is a smaller machine than the original shaper which this company have manufactured since their inception six years ago, and is built to do rapid and accurate work on small and medium-size gears of comparatively fine pitch. It will operate on blanks up to 24 inches in diameter and of 4-inch face, and is designed to cut teeth of 8-pitch and finer.



Figs 1 to 3. New Design of Fellows Gear Shaper.

The machine is quite different in appearance from the larger one, and its mechanism is different in several important particulars. The same principle of tooth formation is employed, however, which Mr. Fellows so neatly worked out for his first machine. The cutter used is a tool-steel pinion, having teeth ground with a suitable rake and clearance, and as it reciprocates, both the cutter and blank are given slow rotary motions in the inverse ratios of their pitch diameters. The teeth of the cutter thus plane out teeth in the gear blank which are conjugate to the teeth in the cutter.

In the original Fellows gear shaper provision was made for clearing the cutting edges of the cutter upon the return stroke by a slight backward-and-forward movement of the casting which supports the work arbor and carries the blank to be cut, this motion taking place at each reversal of the stroke of the cutter bar. In the new machine, however,

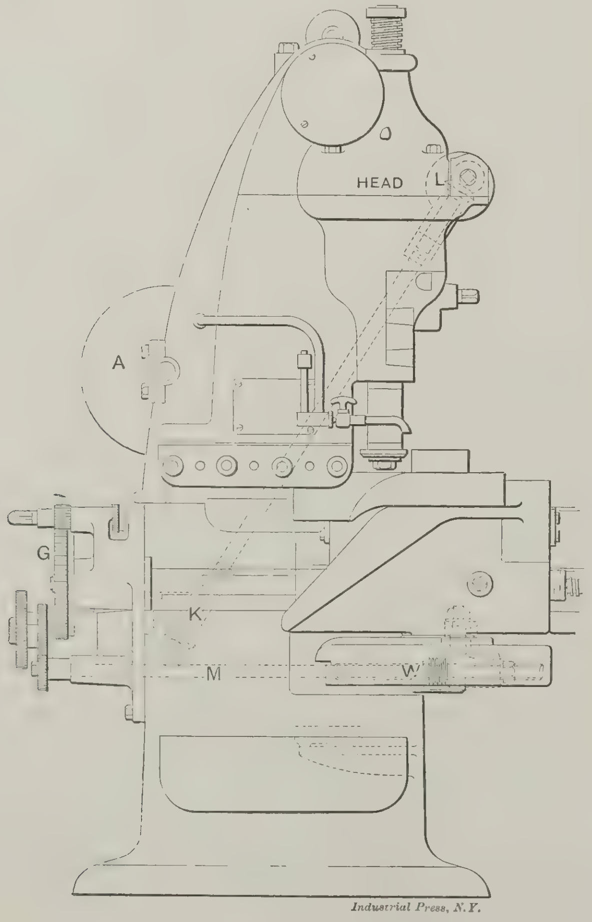


Fig. 4. Front View of Fellows Gear Shaper.

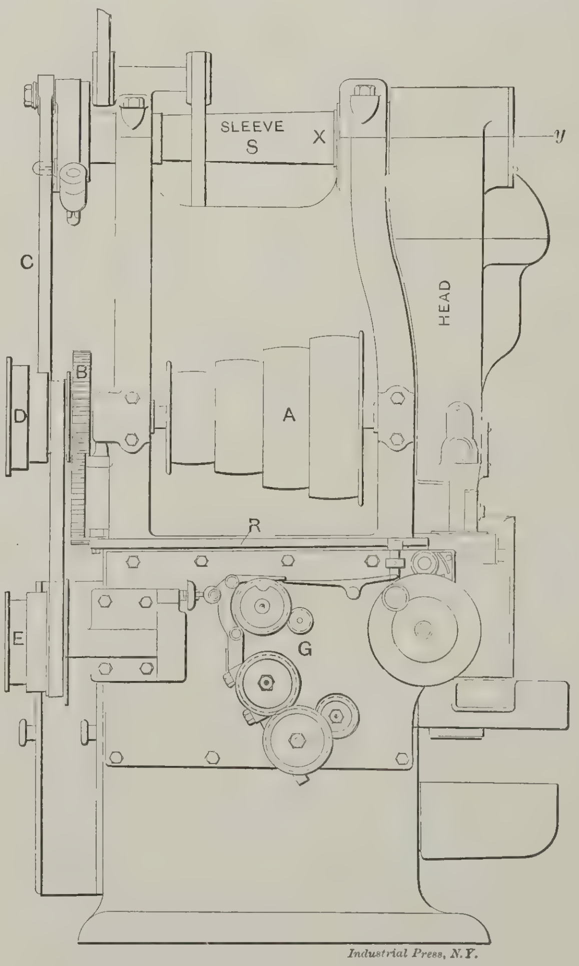

Fig. 5. End View of Fellows Gear Shaper.

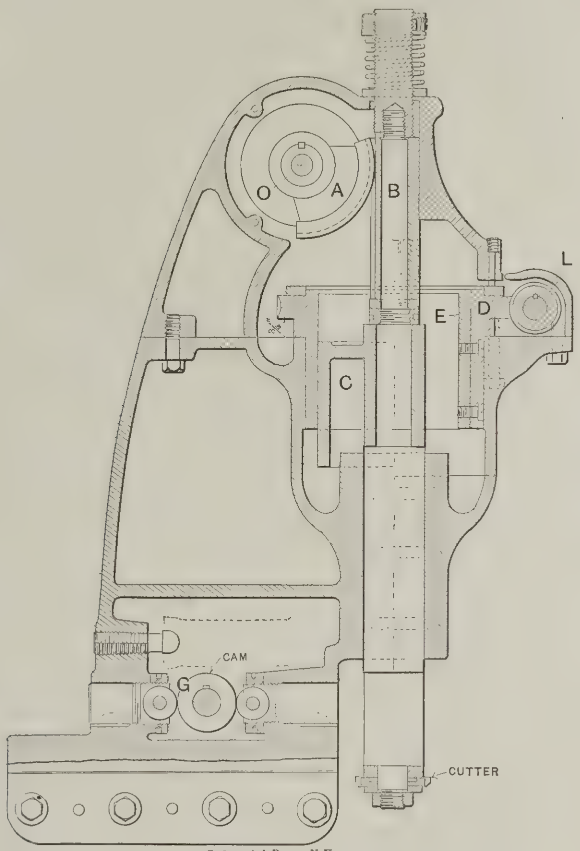
the carriage remains fixed and the tool clearance is obtained by a slight rocking motion of the head, which carries the cutter bar. By this construction the machine is adapted for the use of a rack-cutting attachment, which is attached to the carriage, and receives its feed from a pinion on the work arbor. Owing to the reciprocating motion of the carriage of the older machine, no rack-cutting attachment was made for it, as it was considered that the carriage and rack-cutting attachment combined would be too great a mass to be moved back and forth rapidly at each stroke of the cutter. The new type of machine therefore has the advantage of the rack attachment, and at the same time is convenient and rapid for gear cutting within its capacity. It is not, however, adapted for cutting internal gears.

In the half-tone illustrations, Fig. 1 is a front view of the machine. The whole visible front of the upright constitutes the head, which carries the cutter bar and connections. The head is pivoted at the top and its rocking motion is derived from a small rotary cam at its base. The alignment of the head is maintained by a heavy gib which bears against a flat, finished surface at the bottom. The carriage for supporting the work is carried by an overhanging arm, to which it is gibbed, and along which it can be moved for adjustment of the work to the cutter and for feeding the work against the cutter at the start. Channels cast in the carriage carry chips and lubricant to the pan bolted to the base of the machine.



Industrial Press, N.Y.

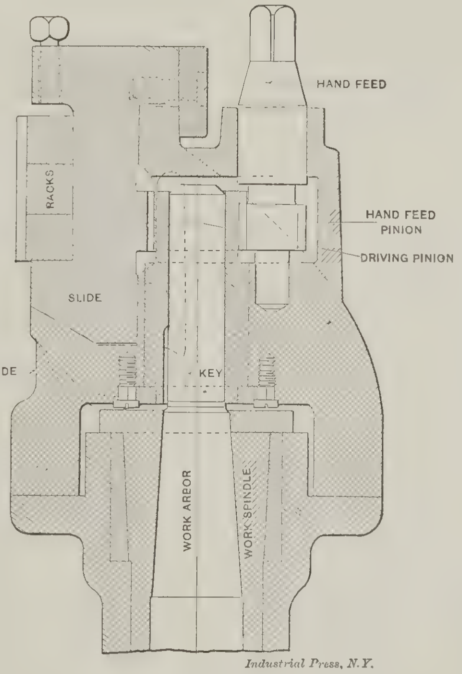
Fig. 6. Section through Head of Fellows Gear Shaper.

Fig. 3 is an end view, showing the driving cone and feed gears, which in this machine correspond to the spacing mechanism of the ordinary gear cutter. This view also shows more clearly the arrangement of the gib at the base of the cutter head.

The middle view of the group, Fig. 2, shows the rack-cutting attachment in place. This consists of a frame, which fits over the work spindle and rests on the top of the carriage, and a heavy slide in which the rack blanks are clamped. This slide advances as the cutter rotates, deriving its motion from a pinion on top of the work arbor, which meshes in the teeth of the rack visible in Fig. 2 at the back of the slide. In Fig. 7 is a sectional engraving of the attachment, in which the different parts are indicated with sufficient clearness to make further description unnecessary.

Figs. 4 and 5, respectively, present a front and end view, in which corresponding parts are similarly lettered. Power is received at the driving cone *A* and transmitted through gears *B*, to a horizontal shaft parallel with the driving shaft, but not visible in the engraving. This shaft passes through the machine and at its right-hand end, Fig. 5, carries the cam for giving the head the oscillating motion. At its left-hand end is an adjustable crank, from which the connecting rod *C* transmits motion to a shaft passing across the top of the machine, through the sleeve *S*. This latter shaft thus has an oscillating motion which it transmits to the cutter bar by means of a rack and segment. At the left-hand end of the shaft referred to as being driven by gears *B*, is also a cam which gives motion by rod *R* to the carriage feed screw, and feeds the work against the cutter to the required depth, when beginning to cut a gear.

On the left-hand end of the driving spindle, Fig. 5, is the feed cone *D*, which is belted to cone *E*, connected with the feed gears *G*. This train of gears, *G*, gives the rotary motion to the cutter bar and the work arbor, the change gears used determining the relative rates of rotation of these two members. The motion is transmitted to the head for rotating the cutter bar by means of the inclined shaft *K L*, Fig. 4, and to the work arbor by the shaft *M* and the worm and worm-wheel *W*.



Industrial Press, N.Y.

Fig. 7. Rack Cutting Attachment.

The head, Fig. 5, swings about the axis $x\ y$ and is supported upon an extension of the sleeve *S*, which passes through the frame and extends about half-way into the head, which is bored to receive it. The head is shown in vertical section in Fig. 6. The cutter bar is balanced by the spring at the top, and on its upper end is the sleeve *B*, on which rack teeth are cut to mesh with teeth on segment *A*, keyed to shaft *O*. This shaft is driven by the crank motion, as before explained and gives the reciprocating motion to the cutter and cutter bar. The cutter bar is rotated by the worm *L* and worm-wheel *D*, which latter has a long hub bored out to receive the segmental casting *C*, which is fast to the cutter bar. The vertical edges of segment piece *C* bear against the vertical edges of an annular piece *E*, which fits inside the hub of worm-wheel *D* and is fastened to it. This construction is the same that was adopted some time ago by the Fellows Gear Shaper Company and has already been described in these columns. The object of the arrangement is to allow the bar to reciprocate within the worm-wheel and to receive its rotary motion from the worm-wheel through the contact of sliding surfaces sufficiently removed from the axis of the bar to make any wear of these sliding surfaces negligible in so far as it affects the rotary motion of the cutter.

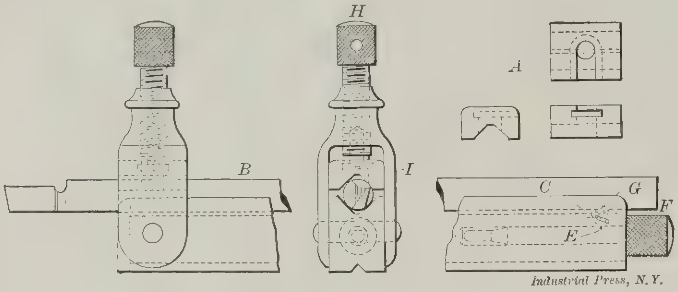
At *G* in Fig. 6 is the rotary cam which causes the head to rock about the center *O* for the relief of the cutter on the return stroke.

LETTERS UPON PRACTICAL SUBJECTS.

A HANDY BORING TOOL HOLDER.

Editor MACHINERY:

The writer would suggest a slight improvement in the boring tool holder shown in the August number of MACHINERY by Mr. E. H. R. In such a holder, where round tools are used, it is wise to place a shoe under the clamping screw and thus prevent the end of the latter from coming in contact with the tool. Such a shoe as is shown at *A* in the accompanying sketch will be found very satisfactory. This is slipped in place before the tool holder is assembled, the screw *I* being slid into the slot in the side and the screw driver being operated through the center hole. This screw should be a free fit in the shoe which it prevents from falling out and holds it always in its right place. This shoe should be cleared slightly in the center to insure its bearing properly at each end.



Boring Tool Holder.

The clamping post is arranged to swing on the pin connecting it with the body and when not in use as a tool holder, this post may be straightened out and the tool used for drill holder in connection with lathe work. With this holder the operator can feel the tension on the drill and is thus able to prevent many breakages. A hole drilled in the end of the shank carries a bar *F* which is used for tightening the binding screw. When not in use this bar is held in the shank by the pressure of the plunger *E* and spiral spring *C*, which is retained by a small screw *G*.

It often happens that one is required to bore a comparatively long and smooth hole for which no reamer is provided and, in such a case, the side tool *B* will be found to work very satisfactorily. It should be always set with the point leading slightly, as it is not the point but the side of the tool that is to do the cutting.

New Haven, Conn.

"BABBITT METAL."

Editor MACHINERY:

In the November issue of MACHINERY is the quotation from *Metal Industry* claiming for Isaac Babbitt the invention of the idea of lining boxes and bearings with an antifriction metal, known as "Babbitt" metal, the patent of which was no doubt applied for and granted in good faith. My grandfather being identified with the Norris works in Philadelphia, and afterward with the mechanical department of the old "State road" at Parkesburg, Pa., was the inventor of a lining metal which he called "composition." At that time driving boxes (which were solid brass), engine trucks, and tender brasses, and crosshead gibs and rod brasses as they became worn, were refilled to their original size, with this "composition." My father being the brass molder at the Parkesburg shops, made and used the composition as required, in the locomotive repairs. As I became strong enough to go into the brass foundry, taking the place of an older brother, I mixed and used a great deal of the "composition." The ingredients were tin, copper, antimony. I don't know what the proportions of copper and antimony were, as my father always mixed it in a crucible and poured it into molds, convenient for breaking up. This mixture was called "hardening," and had a bright crystalline appearance at the broken surface. The composition was made by melting in an iron basin, four parts of block tin, and one part of the hardening. The tin was melted first. There was no patent on it that I am aware of. The mixture was a family secret, well kept. I did know at one time what were the proportions of copper and antimony, but have forgotten it. My father had been making and using this composition when I was in infancy, and I am now very near my sixty-seventh birthday. As I grew up to boyhood, and began to notice things, I often heard the old railroad men speak of the "old man's composition." Its wearing qualities were wonderful, and it would run cool, when applied to journal bearings.

W. DE SANNO.

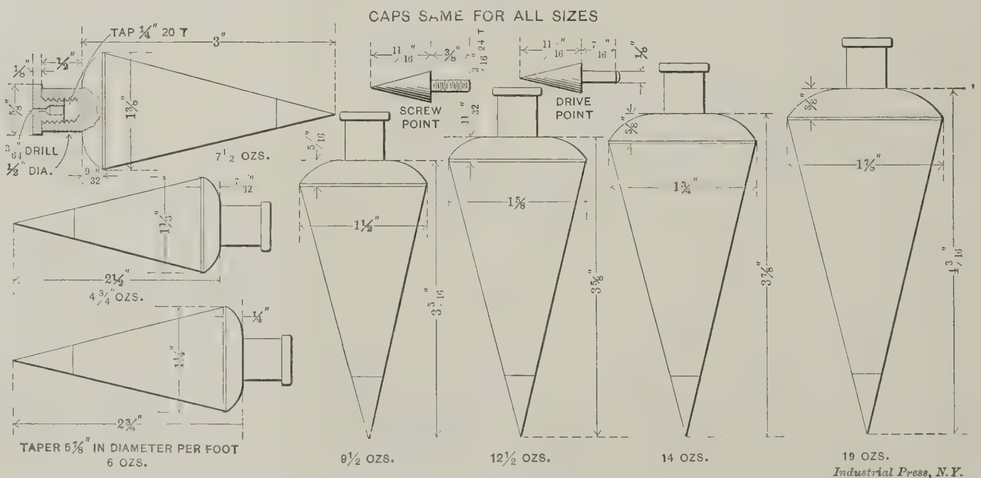
San Francisco, Cal.

DESIGN OF A MACHINIST'S PLUMB BOB.

Editor MACHINERY:

A fine plumb seems to be one of the instruments that is used in almost every trade as a kind of master instrument by which the work done by other tools is checked or proven, so that it is very natural that every mechanic should prize such an instrument. Of course there are many ways and styles in which these plumb bobs may be made, but those shown in the accompanying details will be found admirably suited for use on the better class of surveying instruments and for fine machine work in erecting and adjusting machine tools, engines and other things requiring to be accurately set.

The drawing shows seven sizes ranging in weight from 4¾ to 19 ounces. They should be made of cast brass or bronze or of bar brass, but in no case should cast-iron be employed, because at the present time the use of electricity is so common that a cast-iron plumb bob is often drawn out of its proper position by some local attraction. For this same reason the steel points are made comparatively small. The cap that screws into the head to receive the string or line should be knurled on the edges so as to be readily screwed in or out. The points, either drive or screw, should be made of machine steel and casehardened. These directions, with the detailed measurements given, should enable the machinist with very little trouble to construct a very handy plumb bob of almost any size that he is likely to wish.



Details of Plumb Bobs from 4 3-4 ounces to 19 ounces.

Burlington, Iowa.

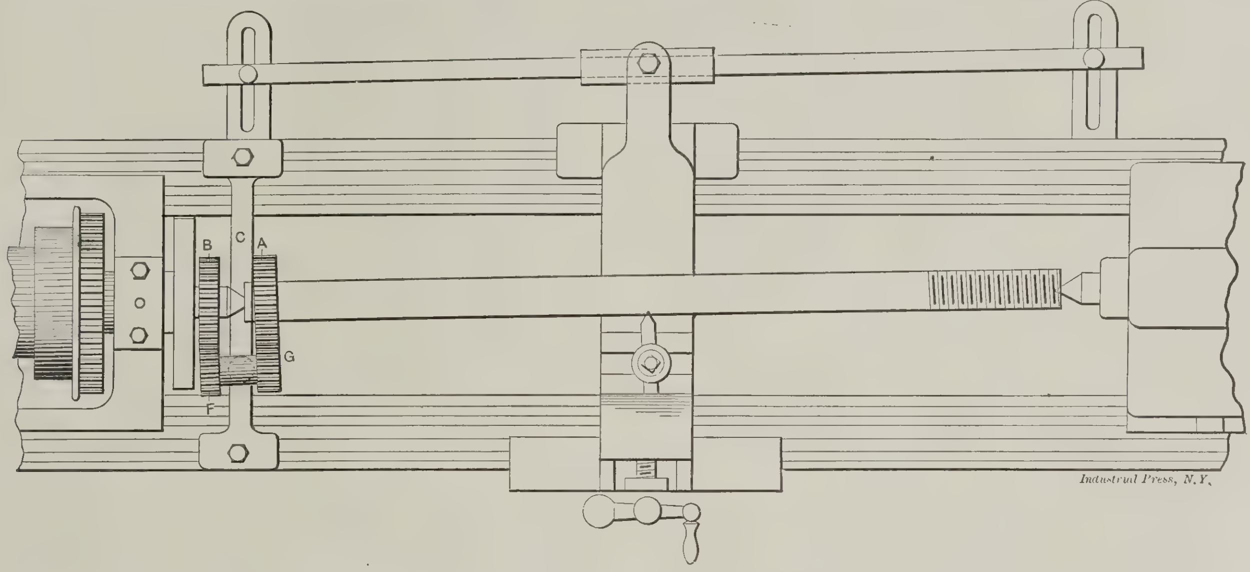
ACCURATE THREADING OF TAPS AND DIE HOBS.

Editor MACHINERY:

Experience in tap and die making has taught that it is one thing to make a perfect screw and quite another to make a tap which will perfectly correspond with it. It is well known that a tap shortens in tempering, this shrinkage varying somewhat with different grades of steel, so that a tap and a screw made with the same leadscrew will not correspond in pitch. Therefore to be accurate, allowance must be made in chasing the thread on the tap for the shrinkage that is to take place in the hardening.



Method of Cutting Taps and Hobs with Allowance for Shrinkage in Hardening.

To carry out this idea a little further: A hob and a tap may thus be made to correspond but after a die is hobbed and tempered it will not exactly match the hob or the tap which it is intended to suit. So we see that the hob should be made with an allowance of two shrinkages to counteract the shortening that takes place when it (the hob) is hardened and again when the die is hardened. While it is not the best policy to make taps and dies in the tool room it often becomes necessary to do so for sizes varying from the standard, and the problem then presents itself to cut them so as to make the proper allowance for shrinkage. The following method shows how the writer has accomplished this in a very satisfactory manner:

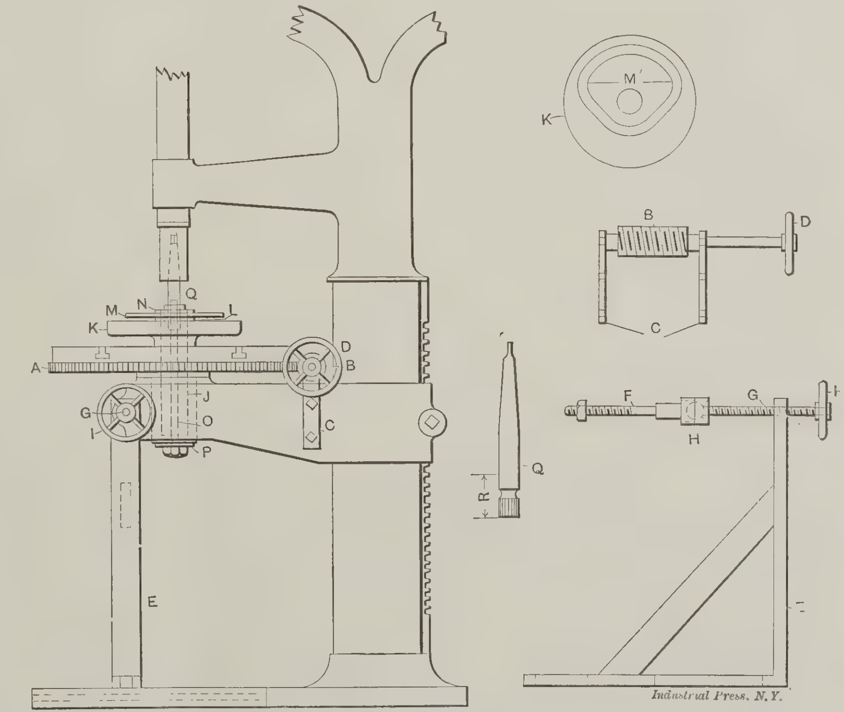
The change gears of the lathe are first arranged as usual for cutting the required number of threads per inch. The tailstock is then set over either way for a short distance and the taper attachment is set to correspond with the set-over of the tap. The thread is then cut as usual, the tool being set by the face of the tap. The thread cut in this way will be slightly coarser than would have been the case if the centers were in line with the axis of the lathe. The reason for this will be obvious from the illustration, and a little practice will enable the machinist to judge just how much the tailstock should be set over to obtain the required result. For example: If the tap is 10 inches long and is set over ½ inch, while the tool is moving the whole length of the tap, the movement of the carriage parallel to the axis of the lathe would be through a distance of but 9.987 inches, so that the thread is lengthened .013 inch; in other words, there are as many threads in 10 inches on the tap as would have been cut in 9.987 inches had the centers been in line with the shears.

If now in cutting this tap we were to use an ordinary dog, driven from the faceplate, it will be apparent that the result would be a drunken thread, since the velocity of revolution of the tap would not be constant throughout its revolution but would be variable; so some means for driving is required that will transmit a uniform motion from the spindle to the tap. To accomplish this a small gear *A* is mounted upon the end of the tap, and a similar gear *B* is attached to the live center or to the faceplate. A fixture *C* is used for supporting a short shaft on each end of which is placed a pinion, as shown at *F* and *G*. These pinions are of the same size and engage with the gears *A* and *B*. When they are properly adjusted so as to run freely with these gears, they impart a perfectly uniform movement to the tap which is being chased. QUIRK.

CAM MILLING IN THE DRILL PRESS.

Editor MACHINERY:

Some years ago while building automatic machinery in a small shop connected with a manufacturing plant, the writer had occasion to cut a number of cast iron face cams, which were all different and varied in size from 6 to 14 inches in diameter. After an amount of consideration it was decided that we could cut these cams upon the drill press cheaper than we would be able to get them cut elsewhere.



Drill Press Arranged for Cam Milling.

The press available was of the ordinary upright type and to fit it for this work the plate was taken off and bored out to 1 15-16 inch. Then the lower edge of its periphery was turned to accommodate a strip of steel rack, *A*, ½ inch wide and about 14 pitch, which was procured from the stock of a gear manufacturing company. This rack was bent and fastened to the plate by screws passed through clearance holes in the rim of the plate and tapped into the rack. When this was in place it made a very good substitute for a worm wheel, and a piece of steel, *B*, was turned up and threaded to correspond with it. As the space between the post of the drill press and the plate was only 1¼ inch it was found necessary to place the worm at a slight angle in order to give the thread as good a bearing as possible on the teeth of the rack. Two pieces of ½ x 1½ inch wrought iron, *C*, were cut and drilled to fit the reduced ends of the worm shaft, and these were then bolted on each side of the arm, supporting the plate in a position to allow the worm to mesh properly with the worm wheel. A handwheel, *D*, procured from an old valve, was fastened to the end of the worm shaft with a pin and this completed the rotary feeding mechanism.

The table and its supporting arm were free to swing around the post of the drill and were fed around by means of the mechanism shown at the right of the cut. The angle, *E*, had a long bolt, *G*, tapped into its upper end and the head of this bolt was turned to a ball shape which fitted easily in the socket, *H*. This socket was made in two parts and screwed into the hole previously occupied by the clamping bolt in the end of the supporting arm. The shank of this socket bolt was made a snug fit in the arm so that it would be rigid without interfering with the free rotation of the plate.

Upon a sheet of soft steel, 3-16 inch thick, the different cams were laid out and each carefully cut out to the exact size of the inside of the groove in the cam, as shown at *M* in the sample cam, *K*. As all of the cams were to be keyed to the same shaft, both cams and templets were bored to 1 15-16 inch, the exact position of the keyway being left to be determined by trial when the machine was assembled. A short piece of 1 15-16 inch shaft, *J*, which was a snug fit in the hole of the plate, was drilled to clearance for ¾-inch bolt, *O*, and a washer *P* was provided large enough to cover the hole at the bottom of the plate hub. The cam blanks were mounted, face upward, on the piece of shafting, then a collar, *L*, about ¼ inch thick was placed on the cam and above this the templet, *M*. A large washer, *N*, and the ¾-inch bolt then clamped the whole firmly to the plate.

For cutting the cams we made a right-hand end mill, *Q*, with a short length of the body the same size as the cutting edges, and hardened for a distance up the shank indicated by *R*. The shank of this cutter was made No. 3 Morse taper to fit the drill spindle socket.

The concentric portions of the groove were produced by simply turning the worm *B* by means of the hand wheel, and the rise and fall of the cam was produced by using both feeds simultaneously, keeping the body of the mill against the templet, the edges of which were moistened with oil. In order to make as little side thrust as possible the cams were cast with grooves, which allowed about 1-16 inch finish on each side, and they were thoroughly pickled to save the corners of the mill. The cams produced were equal to those made with more expensive and intricate mechanism, and having the templet at hand, it was a simple matter to replace any cam that became sufficiently worn to require it. F. W. A.

Philadelphia, Pa.

FIGURING A PAIR OF SPIRAL GEARS.

Editor MACHINERY:

Perhaps there has already been enough said about spiral gears without this sketch, but it contains an idea or two that appealed to the author as a little different from any seen before. It was desired to make a pair of spiral gears with a ratio of one to four and with pitch diameters about 2½ and 6 inches. Of course from the start we should not expect to obtain exactly these pitch diameters with spiral gears (although it might happen) any more than we would expect to get diameters 1½ to 6 with a 5 diametral pitch cutter and a ratio of 1 to 4 on spur gears.

The spiral gears are to be cut with a 6 diametral pitch cutter. As the diametral ratio of 2½ to 6 is the same as 1 to 2.4, this ratio must be taken into account in the total ratio of 1 to 4; therefore the angles of the teeth must be such that it will be the quotient of the ratio 1 to 4 divided by 1 to 2.4, or 4 to 2.4, which is equal to 1.666 to 1.

By constructing a triangle with 1.666 as one leg and 1 as the other then the hypothenuse will represent the angle of the teeth, where the acute angle adjacent the long leg is the angle of the larger gear, and the acute angle adjacent the short leg of the triangle is the angle of the smaller gear or pinion.

Thus we have the ratio of the angles of a triangle. The tangent $= \frac{\text{opposite side}}{\text{adjacent side}}$ or the tangent of the angle of the pinion is equal to 1.666, which is the tangent of 59 + degrees, and its complement 31— degrees for the angle of the teeth of the gear. These are only our trial angles. In the following equations let

$C.P =$ Circular pitch measured according to spur gears;
$N =$ the number of teeth in a gear;
$P\ D =$ pitch diameter;
$\pi = 3.1416$;
Sec. = secant of angle of teeth with axes of gear.

Then $\frac{C\,P \times \text{sec.} \times N}{\pi} = P\ D$ on any spiral.

The corresponding circular pitch of a 6 diametral pitch cutter is equal to $\pi \div 6 = .5236$.

Transposing the first equation $N = \frac{P\ D \times \pi}{C\ P \times \text{sec.}}$ and substituting $\frac{6 \times 3.1416}{.5236 \times 1.166} = \frac{18.84}{.6105} = 30.85$ as the number of teeth. We cannot have this number of teeth in the gear, and 31 would not be divisible by 4, as the ratio must be 1 to 4, so 32 and 8 must be taken as the required number of teeth in the gear and pinion respectively. This will increase the pitch diameter, but as eight teeth will make quite a small pinion, it was thought advisable to make it larger, rather than smaller, for although 28 and 7 could be taken just as well, this would make the total number of teeth 3½ smaller than the first result of 30.8 and 7.7, whereas 32 and 8 make the total only 1½ teeth larger.

The example up to this point can be worked in a very short time on the slide rule and save much work. Using the *C* and *D* scales take the approximate pitch diameters 6 and 2½, place 6 on the *C* scale opposite 2½ on the *D* scale, and over the left-hand index read 2.4 on the *C* scale. Place 2.4 on *C* scale over 4 on *D* scale, and over right-hand index read .6 on *C* scale. If the rule has a slot in both ends on the back, simply transfer the slide so that 6 on the *C* scale is over left-hand index of *D* and read 31 degrees nearly on the scale of tangents. If the rule has no slot in the left-hand end, invert the slide and over 6 on *D* scale read 31 degrees nearly on the scale of tangents.

In a trigonometrical table look up the secant of 31 degrees and find 1.166, and then find the corresponding circular pitch for 6 diametral pitch equal to .5236. Set left-hand index of *C* to 1.166 on *D*, and opposite .523 on *C* read .61 on *D*. Then place right-hand index of *C* opposite 6 on *D* and set runner to 3.14 on *C*; set .61 on *C* to runner, and under right-hand index of *C* read 30.9 as the number of teeth, which gives very nearly the same number as before. Using the first equation again: $\frac{C\,P \times \text{sec.} \times N}{\pi} = P\ D$ and transposing $\frac{C\,P \times N}{\pi \times P\,D} = \frac{1}{\text{sec.}}$ or $\frac{\pi \times P\,D}{C\,P \times N} = \text{sec.}$, substituting $\frac{3.1416 \times 6}{.5236 \times 32} = \frac{18.8496}{16.7552} = 1.125$, which is the secant of 27 degrees 16 minutes.

But in the above substitution the number of teeth was increased from 30.85 to 32 and the pitch diameter was not increased because we do not know how much to add, therefore we should expect that this angle would be too small. For the sum of the angles of the teeth with the axis of the gear and pinion should equal 90 degrees; therefore the angle of the teeth of the pinion will have to be found by the same formula as the gear.

$\frac{\pi \times P\,D}{C\,P \times N} = \text{sec.}$; substituting, $\frac{3.1416 \times 2\frac{1}{2}}{.5236 \times 8} = \frac{7.854}{4.1888} = 1.875$, which is the secant of 57 deg. 46 min. 27 deg. 15 min. plus 57 deg. 46 min. is equal to 85 deg. 02 min. This subtracted from 90 deg. = 4 deg. 58 min., which shows that the numerator of the fraction must be increased, therefore the pitch diameters 2½ and 6 must be increased, as the other factor is a constant.

The ratio we have found for the angles is 1 to 1.666, so we must increase the angles in this proportion. $1 + 1.666 = 2.666$.

4 deg. 58 min. = 298 min.

298 divided by 2.666 = 112 min.

$112 \times 1.666 = 186 +$ min.

112 min. = 1 deg. 52 min. This must be added to the angle of the gear, which was 27 deg. 16 min, making it now 29 deg. 8 min.

Also 186 min. = 3 deg. 6 min. and this added to 57 deg. 46 min. = 60 deg. 52 min. Taking the first equation once more and working to get the correct pitch diameters with these new angles, we have $\frac{C P \times \text{sec.} \times N}{\pi} = P\ D$; substituting $\frac{.5236 \times 1.1448 \times 32}{3.1416} = 6.105$, which is the pitch diameter of the gear of 32 teeth.

Also for the pinion $\frac{C P \times \text{sec.} \times N}{\pi} = P\ D$; substituting $\frac{.5236 \times 2.0541 \times 8}{3.1416} = 2.738$, which is the correct pitch diameter of the pinion of 8 teeth.

Therefore our example stands as follows:

6 diametral pitch cutter used.

	Pinion	Gear.
Number of teeth	8	32
Ratio of speed	4	1
Angles with axis	60 deg. 52 min.	29 deg. 8 min.
Pitch diameters	2.738 inches	6.105 inches

A relation for instance in a worm and worm gear, is that the pitch circumference of a worm gear divided by the ratio of the worm to gear, is equal to the lead of the worm. The same thing will hold true of a pair of spiral gears, for they are only modified worm gears. Therefore the pitch circumference of the large spiral gear, which is 19.1813 divided by the ratio 4, equals 4.7953. This should be the lead of the small spiral pinion. The lead of a spiral gear equals the pitch circumference divided by the tangent of the angle of the teeth. The pitch circumference of the pinion equals 8.6042; divide this by tangent of 60 deg. 52 min. = 1.79214, and we get the result 4.7955, which proves that the gears are correct.

E. M. Willson.

SOME SUGGESTIONS FOR DIE MAKING.

Editor Machinery:

In traveling around from one shop to another it is very interesting to the tool maker or die maker to note the different methods that are employed for the production of practically the same pieces of work. The writer remembers building, some time ago, the die shown in Fig. 2, which was designed by Mr. Thomas Gierding, of the New Haven Clock Company. This die performed five distinct operations before the piece shown in Fig. 1 dropped completed from the press. Recently in visiting a factory, I was somewhat amused to find three presses employing the services of three pressmen occupied in producing exactly the same piece.

In constructing this die it was not deemed practicable to make it of one solid piece since one small flaw would, in this case, spoil the entire die. A die block of machine steel was therefore used, having recesses counterbored for the insertion of tool steel bushings. These recesses were accurately spaced by the method illustrated in Fig. 3. One side and one end of the die block were machined perfectly square and a center line drawn lengthwise on the face of the block. The location of the recesses was approximately laid out with lead pencil and the recess *A* bored in the lathe, by strapping the block to the faceplate. Before loosening the straps by which the block was held, the parallels, *B* and *C*, were strapped to the faceplate bearing against the finished edges of the block. The straps holding the block were then loosened and the block moved along the strip *C* sufficiently to allow for the insertion of the spacing block, *D*, which had previously been made of the required size. The die block was then fastened and the hole *E* recessed. By repeating this operation, and adding a block each time until all of the recesses were bored, it was possible to space the die far more accurately than would have been possible by the time-honored method of laying it out with dividers. The punch holder and the stripper were then bored in the same manner, using the same spacing blocks.

The bushings *F*, *G*, *H*, *I*, *J*, *K*, were next made, and after being hardened they were lapped to size. The outside of the bushing was ground concentric with the hole by wringing the bushing on a piece of soft steel held in the chuck and turned to fit the hole in the bushing. The bushings were then forced in the die block and the die was completed. The punches were ground all over, to insure straightness, and they, in turn, were forced into the punch holder. The drawing and forming punches *L* and *M* were held with setscrews to prevent them from pulling out.

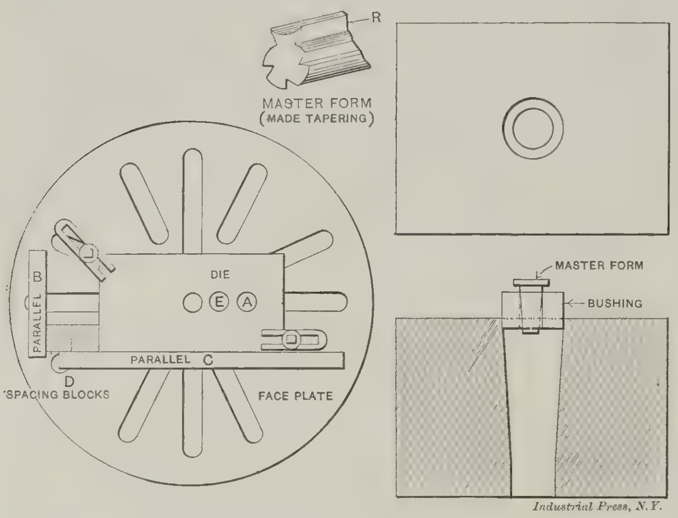
SHOWING HOW PUNCH O CUTS OUT WEB BETWEEN BLANKS AND ALLOWS STRIP TO SLIDE ALONG.

Fig. 2. Punch and Die for making Pieces shown in Fig. 1.

In using a die containing two or more punches, considerable trouble is sometimes experienced on account of the variation in width of the stock to be punched. Should the stripper be planed to fit one of the strips of stock very nicely the chances are that the next strip would not enter the stripper at all. The part, *N*, shown in the plan of the die, is a novel and practical way in which this trouble is overcome. The stripper is planed out 1-16 inch wider than the stock and recessed to allow the spring guide *N* to slide freely when the stripper is in position in the die. By glancing at the sketch the reader can readily see how the springs keep the stock pressing against the gage side of the stripper. The punch *O* does not perform any work pertaining to the finished blank but is used for cutting out the web in the stock in order to allow the strip to move along until the next web touches the stop pin. As the stop pin *P* does not come out of the stock it is therefore impossible to "jump" the stock and make a miscut, which would mean disaster to the drawing and forming punches.

After "setting up" the die in the press, the punches of course descend five times before a single finished piece appears but thereafter a finished piece drops at each stroke of the press. The first punch, beginning at the left, indents the stock and the punch is so adjusted that the face of the punch levels the stock. The second punch pierces the bottom of the indentation. The next punch draws the stock and at the same time forms the feather shown in the finished piece. The fourth is the forming punch and the last punch does the blanking.



Industrial Press, N.Y.

Figs. 3 and 5. Die-making Kinks.

Fig. 4 shows a very good method of making a die that is to contain a number of identically-shaped teeth or points, such as dies for gear blanks, etc. While not being the most accurate method known, the writer considers that for all work intrusted to a punch and die the method illustrated will be sufficiently accurate. A set of broaches are made, as shown in the sketch, the number of steps being governed entirely by the length, or depth, of the teeth. The pilot fits the hole in the die, which is the diameter at the top of the teeth, and each step on the broach is .002 inch larger than the preceding step. The broaches are made on centers and necked in at *Q* to allow clearance for the chips. With a cutter of the proper shape the teeth are then milled on the broaches, using the dividing head on the miller. After cutting the teeth on all of the broaches the teeth on the punch should be cut at the same setting. The broach is then hardened and ground on the faces as indicated. In use each successive step is driven through the die until the last is reached, and this should be driven through as many times as there are teeth in the broach, turning it one tooth each time. By doing this whatever error may have been caused by hardening is overcome.

Fig. 5 shows a method for making very small, difficult-shaped dies, which are hard to duplicate when filed out by hand. First a master form is made, of the desired shape and tapering. This is carefully hardened. A hole is then drilled and reamed tapering, through a substantial block of tool steel, the block is hardened, and the hole lapped out perfectly smooth. A bushing of well annealed tool steel is then made, .005 inch smaller in diameter than the larger end of the tapered hole, and a hole drilled and reamed through it sufficiently large for the master form to just protrude through the lower end. The bushing containing the master form is then placed in the taper hole of the block and forced down by means of a hydraulic press. The stock is thus forced into the master form and dies made in this way can be easily duplicated when they are worn out.

Great Barrington, Mass. **Frank E. Shailor.**

GLOBULES OR SHAVINGS.

Editor Machinery:

The December issue of Machinery gives an account of tests of emery wheels and carborundum wheels at Sibley College, where they micro-photographed the metal removed by the wheels and found that from the emery wheel to be in the form of globules, and that from the carborundum wheel to be in the form of shavings.

I very much doubt if the experimenters had before them all of the conditions to warrant conclusions, for the writer certainly has looked through the microscope and has seen shavings from emery wheels; he has also seen globules from emery wheels. The difference was caused by different treatment and by the difference in grades and grains of the wheel for the particular material ground.

There are many things that enter in to change the results from all globules to part globules, and part shavings to all shavings. It is not so simple as would appear from the account. If the account is correct the experimenters have something to learn. **C. H. Norton.**

THE STUD-DRIVER PATENTED.

We must confess to some irritation of mind upon seeing in *Engineering's* illustrated weekly patent record that our old shop friend, the stud-driver, was recently patented (September 23, 1903) in Great Britain by Mr. E. Ravet, of London. Mr. Ravet has our sympathy. The description reads as follows:

"The object of this invention is to provide an improved appliance affixable to a screw stud, and whereby the stud can be easily screwed into place. The apparatus comprises a screw nut of greater depth than usual, and the screwed part thereof is preferably of two diameters, one diameter of screw-threaded hole encircling the stud, and the other for reception of a screw bolt, whose end engages the end of the stud, and on being tightened somewhat, tends to draw the nut toward it, and in so doing tightly clamps the nut to the screw thread of the stud, so that when the nut is operated by a spanner the stud will be turned without fear of slip. To release the appliance, all that is necessary is to turn back the lock-bolt, when the grip of the nut will be released, and the whole appliance be free to be removed by hand. The nut may have a tapering series of stud-holes of two, three, or more diameters, so as to be applicable for various sizes of studs."

RE HISTORY JOHN STEPTOE SHAPER CO.

Editor Machinery:

In your article "Old Gear Cutter—History John Steptoe Shaper Co.," the Mr. Ed. Gang mentioned is Mr. William E. Gang, president of the William E. Gang Company. He is generally known among his friends and associates as "Ed." He is proud of the fact that he served his apprenticeship in John Steptoe's shop.

Arthur H. Gang,
Cincinnati, Ohio. Secretary William E. Gang Co.

* * *

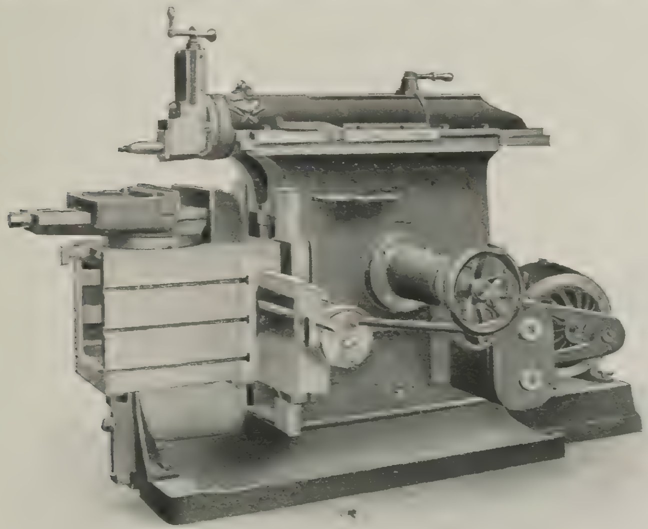
A plate mill has recently been erected at Coatesville, Pa., which is said to roll the widest plates made in this country. It will roll boiler plates 12 feet wide and up to ⅞-inch thickness. The rolls are 152 inches long.

NEW TOOLS OF THE MONTH.

A RECORD OF NEW TOOLS AND APPLIANCES FOR MACHINE SHOP USE.

TWENTY-EIGHT INCH "AMERICAN" SHAPER WITH SPEED VARIATOR.

The 28-inch shaper illustrated in the half-tone herewith has just been placed on the market by the American Tool Works Co., Cincinnati, Ohio, and while the machine in general follows the design of their regular line of shapers, it has several new features, the principal of which is the speed variator, which takes the place of the cone pulley used with the ordinary type of machine. This shaper, as shown, is motor-driven and can be used with any type of motor, of constant or variable speed, single or multiple voltage. The motor is mounted at the rear on a base cast integral with that of the machine and may be connected to the speed variator by either gearing or flexible chain. The changes of speed are obtained through the variator, while the shaper is in full operation, by a clutch mechanism operated by conveniently-located levers, and the number of speeds thus obtained is doubled by means of the back gears. The necessary adjustment for speed is determined by reference to an index on the gear box.



Twenty-eight inch "American" Shaper with Speed Variator.

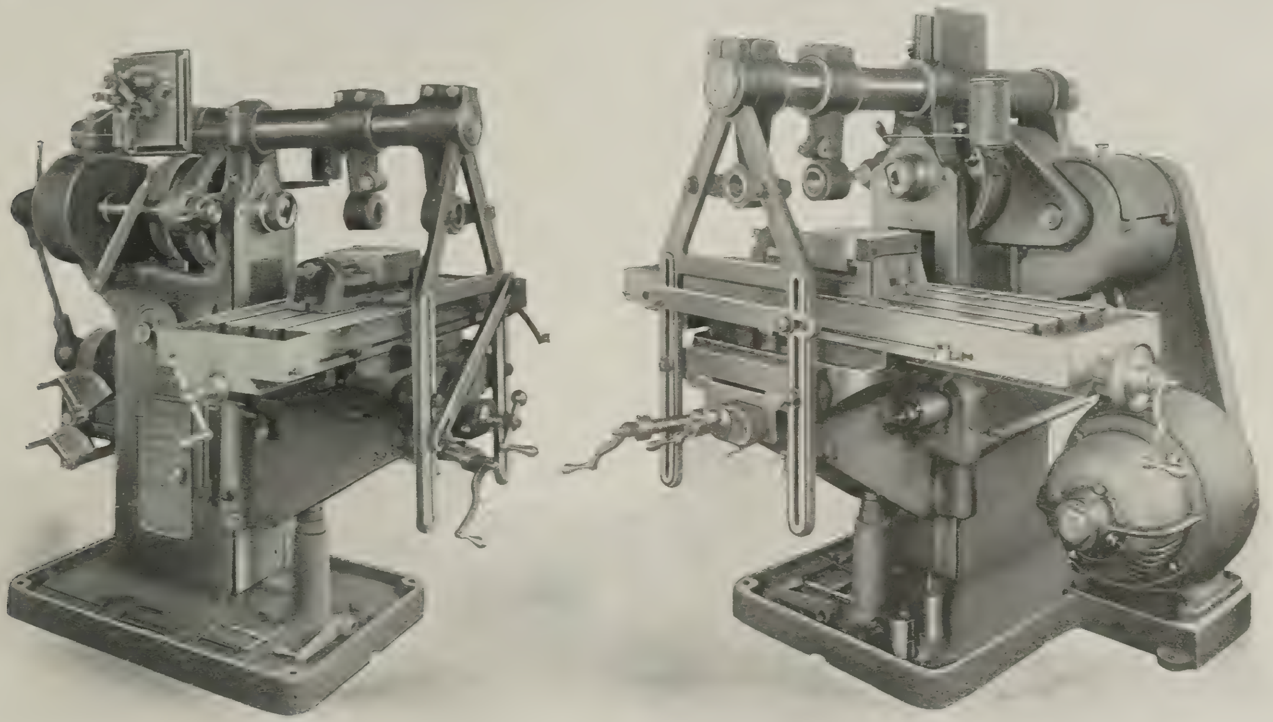


Fig 1. Cincinnati Milling Machine with Electric Motor Drive.

The stroke of the ram is positive and its length may be changed at will without stopping the machine. The rocker-arm is pivoted near the base line, giving the ram an almost uniform rate of speed throughout its entire stroke and providing a quick return. The cross feed is variable and automatic, with a wide range of feeds, and readily adjusts itself to any elevation of the rail. A reversal of the feeds is readily accomplished while the machine is in operation. This shaper is also suited to belt drive from a countershaft through a single pulley mounted on an extension of the upper shaft in the gear box, and the flexibility of this construction makes it a simple matter to equip a shaper that has been installed as a belt-driven machine, with motor drive at any time.

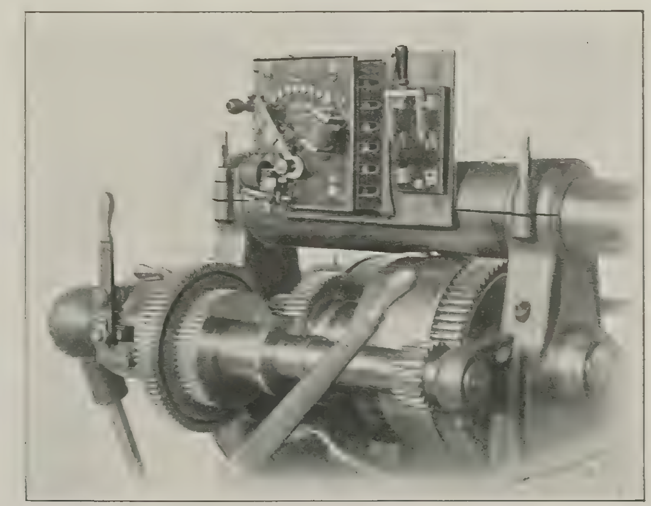

Fig. 2. Double Back Gears of Cincinnati Milling Machine.

ELECTRICALLY-DRIVEN MILLING MACHINE.

As the result of about four years' careful experiment and study of the problem of electric driving as applied to milling machines the Cincinnati Milling Machine Co., Cincinnati, Ohio, have just brought out the No. 4 plain miller with motor drive, that is illustrated in the photograph, Fig. 1. This machine is designed to be driven by a shunt-wound, direct-current motor operated by a field rheostat, the variations in speed being obtained from the motor and thus obviating the need of a nest of speed change gears. The right hand view of the machine shows how the motor is mounted on an extension cast onto the base. This brings it near the floor, thereby adding stability to the machine.

Any one of several well known makes of motors may be used provided it is shunt wound for a speed variation of 2½ to 1. This is multiplied by the double back gears so as to give a range of spindle speeds for cutters 5-16 to 6 inches in diameter of 20 feet per minute, and for cutters ⅝ to 12 inches in diameter of 40 feet per minute. Power is transmitted from the motor to a friction clutch and from thence to the spindle by Morse silent chains. This interposition of the friction clutch between the motor and the spindle is one of the novel features of the design. By its means the machine may be started and stopped quickly without stopping the motor, thereby saving considerable time that is otherwise lost in starting and waiting for the motor to stop.

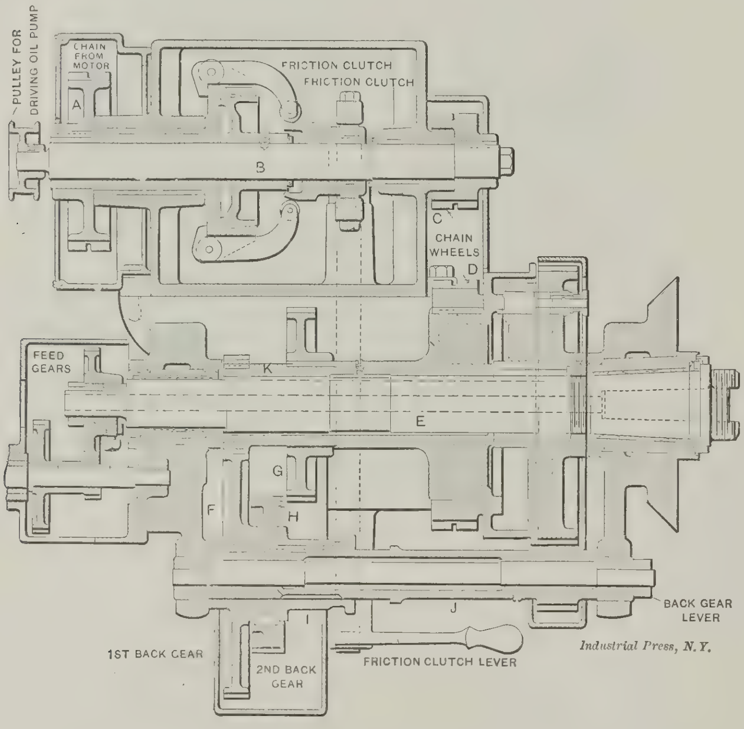

Fig. 3. Diagram of Driving Mechanism, Cincinnati Milling Machine.

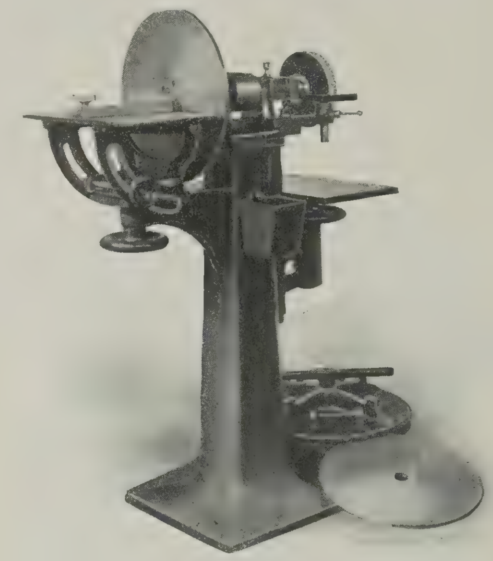
The left hand view shows the arrangement of the automatic release, starting box, field rheostat, friction clutch lever, back gear lever, and double back gears, as well as the feed changing and adjusting levers, all of which are placed at the front of the machine, within easy reach of the operator, who need never go to the rear of the machine save for oiling it. Fig. 2 shows the arrangement of the double back gears, the details of construction of which are shown in the drawing, Fig. 3. The chain from the motor drives the wheel, *A*, which transmits power through shaft *B* and chain and chain wheels, *C* and *D*, to spindle, *E*. The back gears, *F* and *H*, are both geared to a sleeve, *I*, which slides on the back gear quill, *J*, and when used in the position shown, gear *F* is driven by the small gear on the main driving quill, *K*, giving the first series or slow back gear speeds. When it is desired to use the second back gears, the gears are thrown out of mesh in the usual way, the sleeve is moved along the back gear quill to bring *H* and *G* in line and the gears thrown in again.

SANDING MACHINE AND TOOL GRINDER.

A machine designed especially for the use of patternmakers and woodworkers is the combination sanding machine and tool grinder which is illustrated herewith. On the left-hand end of the spindle is mounted a steel disk 16 inches in diameter, which is covered with sandpaper on both sides and is easily reversed. This is used for sanding surfaces at right angles, or at any angle with the plane of the disk, and is very serviceable for turning bosses, core prints, etc., either straight or tapered, which can be done in the time usually required to set up such work in a lathe. A spare disk is also provided so that no time need be lost, as one disk can be prepared while the other is in use. The sandpaper is attached to the disks, under pressure, in a press that accompanies the machine.



Combined Sanding Machine and Tool Grinder.

The work table, which is counterbalanced, is released, raised or lowered, adjusted to approximate position, and fastened by one lever and then by a hand wheel under the table, a fine adjustment or screw feed is provided. This table will lock at a right angle to the disk, or will adjust to any angle, and is furnished with a gage adjusted to any angle on the horizontal plane.

On the right-hand end of the spindle is placed an emery wheel for tool grinding and, by changing wheels, all shapes of tools, gouges and carving tools can be ground inside and outside. Under this wheel is a table for surface grinding, which is very handy for use on metal patterns and work of a similar nature. The bearings, which are babbitted and dustproof, are provided with an adjustment for wear. This machine is the product of the Rowbottom Machine Co., Inc., Waterbury, Conn.

THE "IDEAL" ENGINE LATHE WITH MOTOR DRIVE.

The photograph shown in Fig. 1 illustrates the method by which the Springfield Machine Tool Company, Springfield, Ohio,

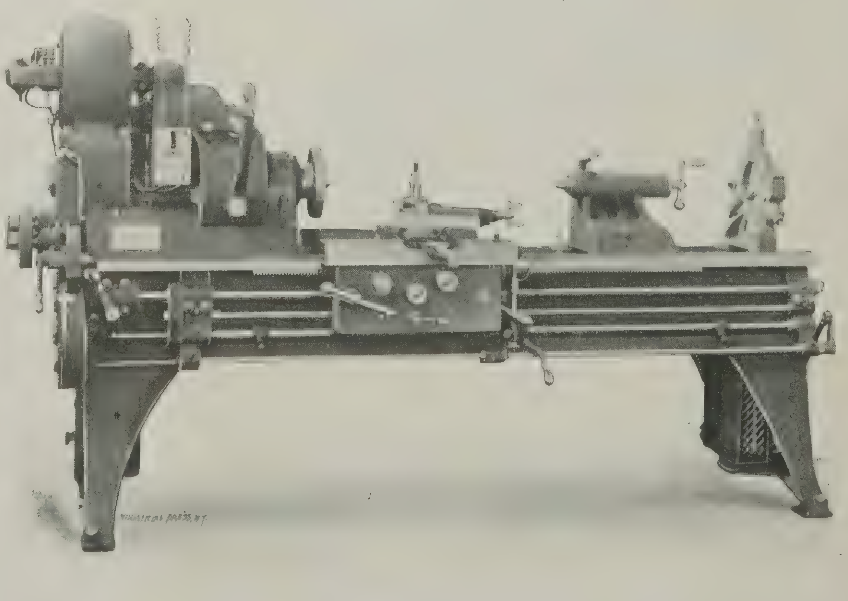


Fig. 1. "Ideal" Engine Lathe with Motor Drive.

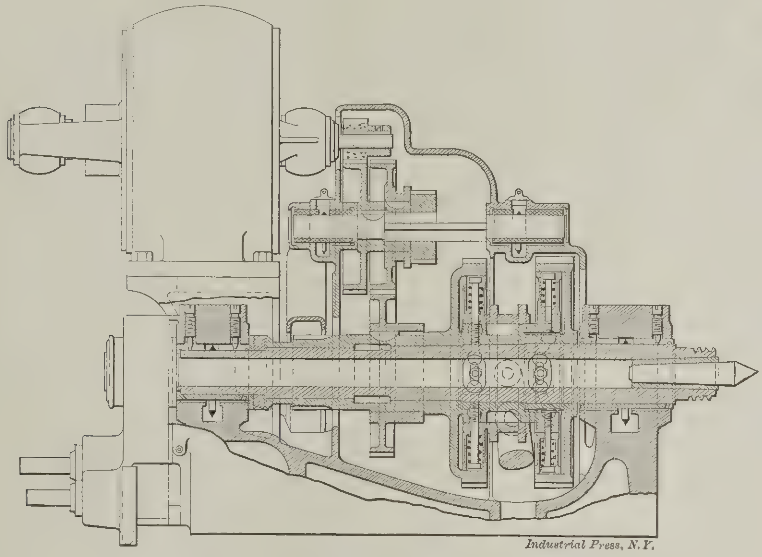
have equipped their 18-inch "Ideal" engine lathe for the use of motor drive. As will be seen in the illustration, this lathe has been completely redesigned as a motor tool so that, instead of bolting a motor-bracket to the headstock, projections for carrying the motor and also bearings for the extra shaft are cast integral with the headstock. The details of the driving mechanism are clearly shown in the line drawing, Fig. 2, which represents a section through the headstock. A pinion on the motor shaft engages a gear on the extra shaft which is mounted directly over the lathe spindle. On this shaft are placed a pair of gears which may be slipped into mesh with either of the gears which take the place of the usual cone pulley. In connection with the back gears, which are thrown in and out by means of a pair of friction clutches, four mechanical changes of speed are obtained, and these, with the 100 per cent. of speed variation of the motor, provide for a wide range of speeds.



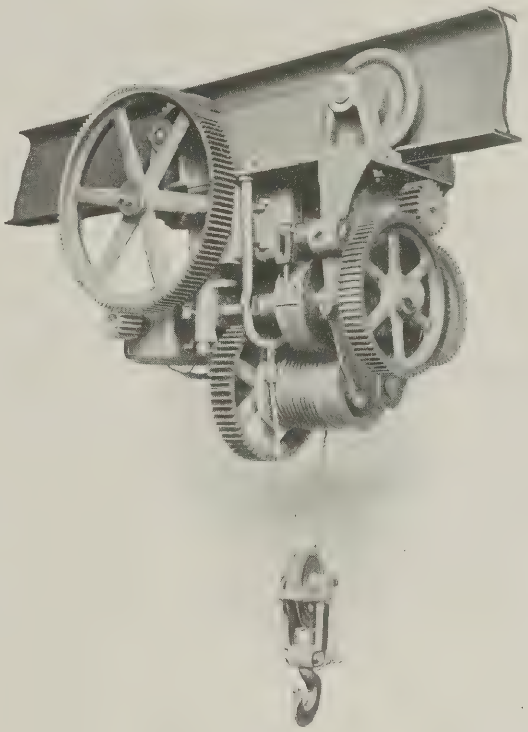
Industrial Press, N.Y.

Fig. 2. Section through Head of "Ideal" Lathe.

The motor employed is a 1½ horse power machine built by the Northern Electric Manufacturing Company, Madison, Wis., and runs at a normal speed of 600 revolutions per minute, which may be increased to 1,200 revolutions by weakening the fields. The speed of the motor is regulated by a Cutler-Hammer controller, which is bolted to the inner side of the rear leg of the lathe, where it is protected from injury yet easily accessible if repairs are necessary. The rod by which the controller is operated is supported in extensions to the leadscrew box, while a handle at the right-hand side of the carriage operates the controller rod by the means of miter gears. In other respects this lathe embodies all of the principal features of the "Ideal" lathe as built by the company.

ELECTRIC TROLLEY HOISTS.

The use of small cranes or hoists, running on overhead I-beams, has widely extended in machine shops and at present the majority of heavy tools are provided with some type of hoist for quickly and easily handling the work on and off from the machine. These hoists may be operated by hand, steam, compressed air, or electricity, the latter power having proved very satisfactory and convenient since it does away with all the piping that is involved by the use of air or steam. A new line of this type of hoist, operated by electricity has just been brought out by the Northern Engineering Works, Detroit, Mich., and one of them is illustrated herewith. This hoist is of the two-motor type and has a capacity of 3 tons. It is spur-geared throughout and has a hoisting speed of from 10 to 25 feet per minute, the hoist being operated by a 3 horse power motor. The travel movement is operated by a separate motor of 2 horse power capacity which is capable of giving a travel speed of about 200 feet per minute. Two automatic brakes are provided, one mechanical and one electrical, and a safety stop prevents the block from running into the trolley. This hoist can be made to run on any size of I-beam or on two beams if preferred, and it may be modified so that it will run around curves if desired. These hoists are made in capacities of 2, 3 and 5 tons, and the motors may be wound to run on 110, 220 or 500 volts, direct current. The motors are of the enclosed type and are adapted for use in the presence of considerable dust and dirt and when so used the gears are provided with casings.



Electric Trolley Hoist.

POSITIVE SELF FEED FOR THE DRILL PRESS.

The W. F. & John Barnes Co., Rockford, Ill., have just adopted for use on their entire line of upright drills a new positive self-feeding mechanism which is a radical departure from anything yet produced for this purpose. Fig. 1 shows one of the drills thus equipped and Fig. 2 is a detail of the feeding mechanism, showing the back gearing and the feed-changing device. The vertical feed rod is driven from a feed disk having four series of teeth, with any one of which the

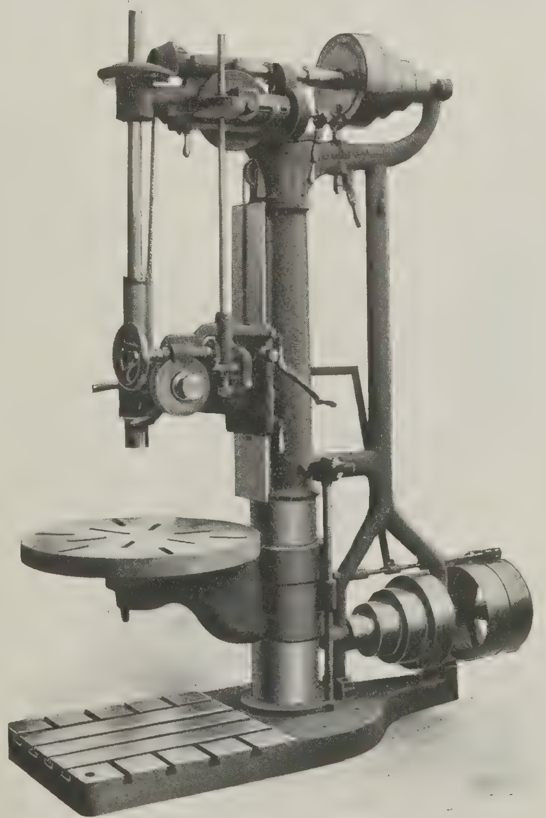


Fig. 1. Barnes Drill with Positive Feed Device.

driving pinion on the horizontal shaft may be engaged. A notched lever is employed to move this pinion and to lock it in position and when this lever is raised the pinion may be moved from the position shown in the illustration to engagement with any other set of teeth in the disk. This provides for four changes of feed and, with the back gearing used on the larger sizes of drills, eight changes of feed may be obtained, and these changes may be made while the drill is in operation, thus avoiding the delay of stopping the machine for throwing in or out of belts. These feeds are arranged to vary from one adapted to reamer work, or one for drilling in steel, to one of suitable coarseness for boring in cast iron. The wide variation of feeds also fits these drills for use with both the regular grades of steel and with the high-speed steels that are now being used very extensively.

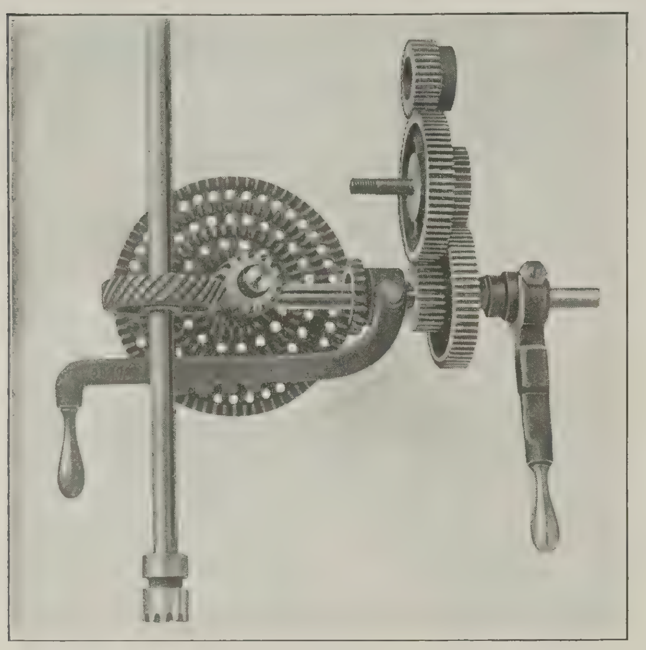

Fig. 2. Positive Feed Device used on Barnes Drills.

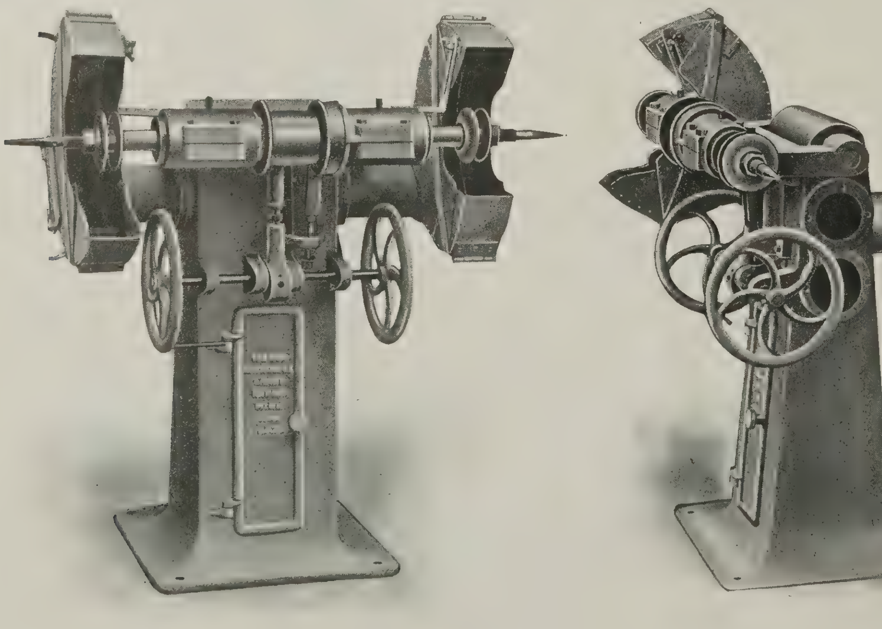
DOUBLE POLISHING STAND.



Double Polishing Stand.

The Fox Machine Co., Grand Rapids, Mich., have just brought out a new polishing stand embodying several novel and very convenient features that fit it for rapid work and clean service. The polishing spindle of this machine, instead of being carried directly by the column, is supported in a swinging yoke which is pivoted about the top of the column, as will be clearly seen in the end view of the machine. This yoke is connected, through a right- and left-hand connection, to an eccentric shaft journaled in brackets on the face of the column. On either end of this shaft is placed a large hand wheel so that the polisher may be started or stopped by either operator from his position in front of the machine. A partial turn of either of these wheels in one direction tightens the belt and causes the spindle to rotate, while if the wheel is turned in the other direction the arm is raised and the belt thereby loosened while at the same time a brake is automatically brought into action so that the machine is instantly stopped.

These polishers are designed for use with an exhaust system and for this purpose both of the wheels are covered with dust hoods or collectors, which have exhaust connection with the hollow column. The columns themselves may be connected with the exhaust system either from the back or down through the column and the floor. By this system all of the dust and dirt of polishing is immediately removed, a feature which is especially valuable where gold and silver are being polished, as in jewelry shops, where the dust is conducted to a precipitating tank and all of the valuable metal recovered. The hoods may be adjusted to accommodate different sizes of wheels from the maximum of 14 inches in diameter down, and they are bolted to the column in such a manner that they may be readily detached if desired. The arbor runs in roller bearings which are thoroughly protected from dust and dirt. No special countershaft is required, as the yoke acts as a belt tightener and the flanges of the pulley prevent the belt from running off. The machine complete weighs about 450 pounds.

ELECTRICALLY-DRIVEN TOOL ROOM DRILL.

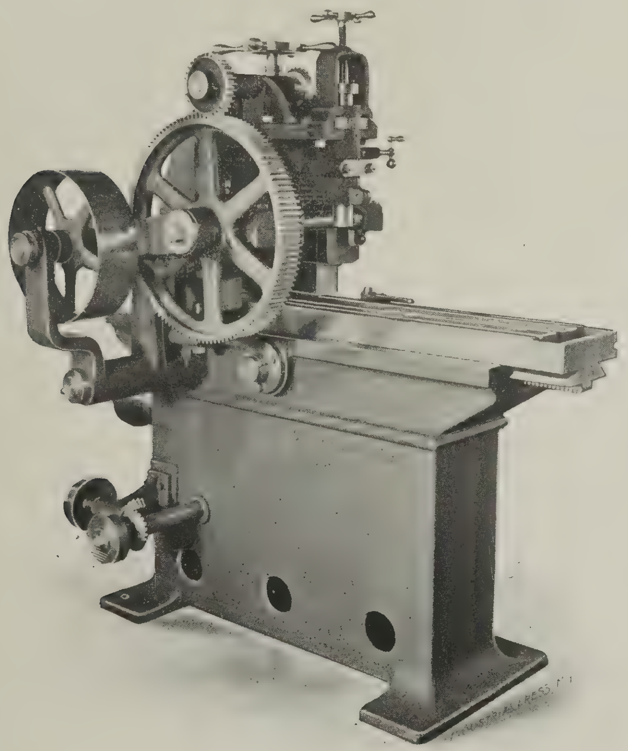
An application of electric drive to small drills has lately been brought out in the form illustrated herewith, which is a tool room drill built by the Dwight Slate Machine Co., Hartford, Conn., to the spindle of which is directly connected a one-quarter horse power motor made by the Emerson Electric Mfg. Co., St. Louis, Mo. Owing to the specially compounded and series field, the motor employed is connected directly from line to binding posts without starting box, being started and stopped from a small two-pole snap switch within convenient reach of the operator. The rush of starting current is cared for by the speed regulating coils of the motor itself, and the proportions of this field are such that if the motor should be stopped entirely by the drill sticking in the work, or by the use of too large a drill, no damage to the motor would result. This special winding also enables

Electric Tool Room Drill.

the motor to automatically adjust its speed to the size of the drill in the chuck and the material being drilled, this regulation being obtained by the motor itself entirely automatically. The motor furnished will handle work up to the full capacity of the drill press, being capable of running a ⅝-inch drill in cast iron, but it is not recommended for drills much over 5-16 inch for general use. This machine may be placed and operated anywhere that a 110 or 220-volt direct current is available.

KEYSEAT MILLING MACHINE.

The accompanying half-tone illustrates a new keyseat milling machine that has just been placed upon the market by John T. Burr & Son, Brooklyn, N. Y., which is designed for keyseating shafts up to 6 inches in diameter, and which has an extreme capacity through the housings for work up to 10⅜ by 9⅜ inches. The platen, provided with three T-slots, oil channels and pockets, has an automatic feed of 48 inches with automatic adjustable tripping device. The spindle is designed for cutters with 1½-inch standard hole, up to 5 inches in diameter, and this spindle has an adjustment allowing it to work at a distance of 1⅛ inches above the platen up to a maximum height of 11½ inches. The friction countershaft provides for two changes of spindle speed and there are twelve changes of feed for each spindle speed.

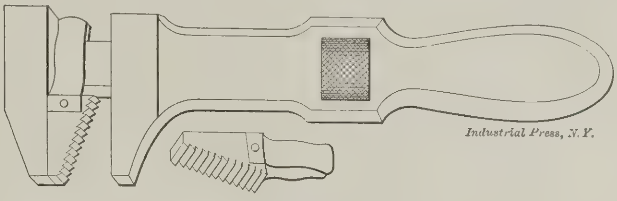


Keyseat Milling Machine.

Connected with the main driving gears is a chain of gearing by means of which an independent routing spindle is operated. This spindle has an independent vertical adjustment of 3¼ inches and a horizontal movement of 3⅛ inches, while, in connection with the saddle movement, it may be used at a height from the face of the platen up to 13⅜ inches above it. An oil pump with flexible connections is provided for the use of lubricant with the cutters. This machine complete, as shown, weighs about 3,200 pounds, and it may be furnished without the routing spindle if desired.

PIPE ATTACHMENT FOR WRENCH.

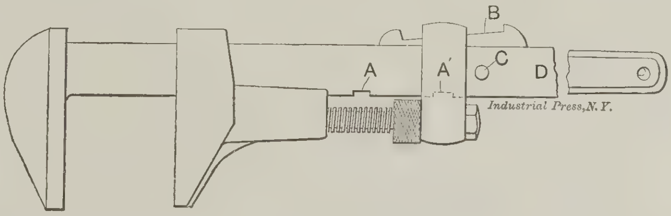
The Billings & Spencer Company, Hartford, Conn., have just placed upon the market an attachment for use with their 6- and 8-inch adjustable wrenches, by means of which the ordinary wrench is immediately converted into a pipe wrench. This attachment consists of the small removable pipe jaw which is shown in the cut both in position on the wrench and also as it appears when it is removed. This jaw is made of steel, provided with a toothed face for gripping the pipe and is held in place by two side springs which allow it to be put in place or removed without any trouble or the need of any tools. By simply reversing its position on the wrench, it is fitted for either right or left hand use. The wrenches, when supplied with this attachment, are suited for use on pipe up to and including ¾-inch.



Adjustable Wrench with Pipe Attachment.

IMPROVED MONKEY WRENCH FOR LARGE NUTS.

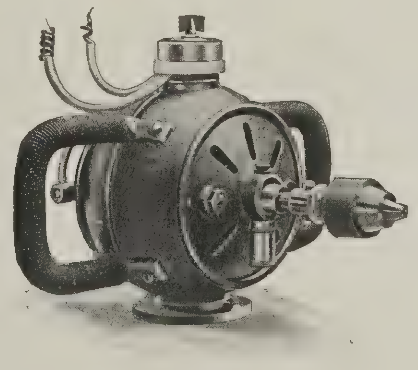
That indefatigable inventor and improver of the monkey wrench, Mr. Loring Coes, evidently has again been engaged in his favorite amusement, since the Coes Wrench Company have recently brought out an improved form of this useful tool, designed to be of greater service in heavy work. The new style, shown in the accompanying cut, is made in two sizes, viz.: 26-inch and 30-inch for nuts up to 5 and 6 inches respectively. The improvement consists of making the handle in the shape of a flat iron bar and notching it in two places, *A* and *A'*, for the reception of a projection on the inside of the strap next the bolster. Obviously the strap is placed in position *A* for the smaller nuts and at *A'* for the larger ones, this device doing away with an excessively long screw. In either position the strap is firmly held by the double-headed key *B*. A pin *C* through the handle *D* prevents the strap sliding off when the change is being made.



Monkey Wrench for Large Nuts.

SMALL PORTABLE ELECTRIC DRILL.

The Sprague Electric Company, New York City, have just placed on the market two sizes of the small portable drill that is shown in the accompanying illustration. This type of drill will be found very handy for all kinds of shop drilling which is now performed with the breast drill, and saves much time and labor in the erection of machinery where small holes, such as oil and pin holes, are drilled after the machines are assembled. A small round type of motor is employed, which is suited for use on a 115 or 230-volt direct current, and two substantial handles are attached to its sides to hold it while in use. The motor shaft is fitted with a standard adjustable chuck for any size of drill up to and including 5-16 inch. The two sizes that are now being furnished are of a capacity of 1-20 and 1-10 horse power respectively.



Portable Electric Drill.

NEW TRADE LITERATURE.

The Stow Flexible Shaft Company, Philadelphia, Pa. Circular calling attention to the portable drills of the company's manufacture. Several varieties of these are here shown.

The William E. Gang Company, Cincinnati, O. Pamphlet illustrating and describing the radial drill manufactured by this company. This was illustrated in Machinery some time ago.

The Buffalo Forge Company, Buffalo, N. Y. Two new circulars relative to the "Buffalo" disk wheels and "Buffalo" improved ventilators. These are illustrated, and the two named products are described quite at length.

The Northern Electrical Manufacturing Company, Madison, Wis. Bulletin No. 34 illustrating their motors for operating valves. These motors are built for operating large sluice and gate valves, and are here fully described.

The Carlyle Johnson Machine Company, Hartford, Conn. "Booklet C," treating of the Johnson friction clutches for machines, gas engines, countershafts. Also circulars illustrating and describing their No. 4 and No. 6 single clutch.

The Binsse Machine Company, Newark, N. J. Catalogue and Treatise No. 3, 1904. This illustrates the "Binsse" horizontal boring machine, sizes 1, 3, 5 and 9, and gives brief descriptions and fine half-tone views of its various features and of work done.

The Kempsmith Manufacturing Company, Milwaukee, Wis. Advertising card illustrating their No. 24 universal miller, among whose features are automatic feeds in all directions; feed reverse at front of knee; telescopic vertical screw and deep and broad column.

The Newton Machine Tool Works, Inc., Philadelphia, Pa. Catalogue No. 37, of rotary planers. These are built in eleven sizes, with heads from 14 inches to 84 inches in diameter over tools, and several styles are shown such as the rotary planer on round base, the portable rotary planer, duplex rotary planer, vertical rotary planer, etc.

The Armstrong Brothers Tool Company, Chicago, Ill. Catalogue No. 10, of tool holders and machine shop specialties. The new goods added to their regular line are: A drop head tool holder; left-hand offset cutting-off tool; side tools; a slotter tool; a universal ratchet drill; and a machine for cutting off self-hardening steel.

The Woodward & Powell Planer Company, Worcester, Mass. Catalogue B4, of metal planing machines. This illustrates the company's planers, 22 to 120 inches; widened planers from 36 by 30 inches to 76 by 48 inches; and special planers, for work on globe valves, frog crossings, locomotive rods, etc. Several half-tone views show the works at Worcester, and interior views of the business offices, the various departments, etc.

The Fosdick Machine Tool Company, Cincinnati, O. Handsomely illustrated folder treating of the new Fosdick horizontal, boring, drilling and milling machine. A general description of this machine appears, and excellent photographic reproductions showing the operations of boring, drilling and milling, also cuts reproducing the working drawings of the plan, side elevation and front elevation of the machine.

The Northern Engineering Works, Detroit, Mich. Catalogue No. 18, of electric and hand power traveling cranes. This supplements the company's general crane catalogue and illustrates their cranes for pumping stations, power stations for electric railways, large industrial plants and lighting stations. Besides these they also manufacture cranes for foundries, machine shops, etc. A number of views show these cranes installed in different shops.

The Curtis & Co. Mfg. Co., St. Louis, Mo. Illustrated catalogue, 1904, of pneumatic machinery. This includes air compressors, air hoists and pneumatic appliances. The "Curtis" automatic compressor, belt-diven and electrically-driven is shown by half-tones and line drawings; and air hoists of different sizes and styles for many and various purposes. Also "Curtis" single and double I-beam traveling cranes and trolleys and other hoisting apparatus. A number of views show these hoists, cranes and trolleys installed in foundries, shops, etc.

The Bradford Machine Tool Company, Cincinnati, O. Illustrated catalogue, standard size, of the "Bradford" lathes. This is an attractive piece of advertising literature, containing handsome half-tone illustrations, printed on heavy coated paper, showing the different sizes of lathes, and its notable features, such as the spindle and its mountings; spindle bearings; lathe apron; improved taper-turning attachment; lathe parts; turning tools; chucks; screw-cutting attachment; the driving and feeding arrangement for their 36 and 42-inch lathes, etc.

The Bullock Electric Manufacturing Company, Cincinnati, O., inform us that their Shop No. 2 of their plant, containing punch presses, annealing ovens and forges, was recently partially destroyed by fire. Their tools are not seriously damaged, however, and they have erected temporary sheds over them, so that there will be no delay whatever in completion of orders they have on hand or of any they may receive. Shop No. 2 will be immediately reconstructed and on a larger scale than originally planned.

The F. B. Shuster Company, New Haven, Conn. New illustrated catalogue of straightening, cutting and riveting machinery. This includes automatic wire-straighteners and cutters; slide feed, automatic wire-straighteners and cutters; roll wire-straighteners; self-feeding roll wire-straighteners; geared roll straightener and cutter; rotary straighteners; elastic rotary-blow riveting machines; double-head riveting machines, etc. Views of these machines are shown, and samples of the work done. The company will be pleased to supply this new catalogue on request.

The Brown & Sharpe Manufacturing Company, Providence, R. I. Latest edition of the company's machinists' tool catalogue. Here are illustrated and described their regular line of machinists' tools; and a colored insert calls attention to the various new tools that have been added during the past year, among which is the new clamping device for their micrometer caliper, which they inform us is entirely new in design and much superior to the old-style clamp nut. The catalogue contains 153 pages, some of which are devoted to tables and other data of convenience to the machinist.

The Hyatt Roller Bearing Company, Harrison, N. J. Bulletin Twenty, of the Hyatt flexible roller bearings. This roller is here thoroughly treated, illustrations being given showing its application to shafting, traveling cranes, transfer cars, trolleys, hoists, etc. The advantages claimed for these bearings are durability, practicability, simplicity, efficiency, low cost, oiling facilities, and the fact that they have been thoroughly tested and have proved successful. The company refer those desiring further information upon this subject to an account of a series of exhaustive tests of these bearings conducted by the Franklin Institute and published in their Journal, February, 1899.

American School of Correspondence, Armour Institute, Chicago, Ill. Folder relative to the "Cyclopedia of Engineering." This is a compilation of the most practical and instructive papers of the School, intended to furnish actual instruction to those who cannot take a correspondence course. It has been carefully prepared with a view to meeting actual shop needs and conditions. It consists of four volumes and comprises 2,500 pages, illustrated with 1,500 colored plates, diagrams, tables, formulas, etc., and treats of mechanical, electrical, stationary, marine and locomotive engineering, etc. The folder gives an outline of the contents of this work, which is edited by Prof. Louis Derr, of Massachusetts Institute of Technology.

The Charter Gas Engine Co., 9-11 Wallace St., Sterling, Ill. Catalogue P, just issued, of the "Charter" gas and gasoline engines. The special features of this engine are here described and illustrated. and the different styles of horizontal engines, for a great varity of purposes, and built in sizes of from 4 to 40 H. P. are shown. A 1½ H. P. vertical "Charter" engine appears, also cuts and description of the "Sterling" portable gasoline engine of from 8 to 25 H. P. capacity. Several circulars have likewise been received from the Charter Gas Engine Co., containing testimonial letters from a very large number of firms in every line of trade in which these engines may be used, speaking in very favorable terms of the "Charter" engines.

Hammacher, Schlemmer & Co., New York. Booklet entitled "Fifty-five Years at It," calling attention to the large line of articles the company manufacture, and to the fact that they issue yearly 3,000 pages of catalogue matter pertaining to this line. This literature is supplied gratuitously to manufacturers having worthy commercial ratings, and on fair terms, to individuals desiring same. Those having no printed letter head are requested to announce what their requirements are. Mention is made of Catalogues No. 180, presenting 908 pages concerning tools; No. 114, relative to bolts, screws, nuts and supplies; No. 145, builders' hardware; No. 151, cabinet hardware; No. 192, fancy cabinet trimmings; No. 170, tool outfits for home use, etc.

MANUFACTURERS' NOTES.

Maris Bros., makers of hand and electric power cranes, Philadelphia, Pa., are building a 30-foot addition to their works. They report business as good.

The Cochrane-Bly Machine Works, Rochester, N. Y., have recently moved into their new factory, corner of Sherman Street and St. James Park. The new shop is very substantially built and is 40 feet by 200.

The Howard Iron Works, Buffalo, N. Y., manufacturers of elevators, vises, bolt machinery and power transmission machinery, inform us that they are just completing a new and large modern foundry, with all the improved equipment necessary.

The J. W. Cregar Agency, The Bourse, Philadelphia, Pa., have been made purchasing agent for the Limon and Agricola Mines, near Jalapa, Nicaragua, Central America, and would be glad to have manufacturers send their catalogues and export trade prices on everything used in mines and sold in mining companies' stores.

The Homestead Valve Manufacturing Company, Pittsburg, Pa., announce that in conjunction with their brass foundry they have installed a complete iron foundry for the production of brass and iron. They inform us that through their method of using a conversion furnace in which heavy blast is used, they obtain a very pure metal, which enables them to make a superior semi-steel valve.

The Derry-Collard Company, 256 Broadway, New York, are publishing a series of "Monographs on Popular Technical Subjects." We have already noticed in these columns the two booklets treating of Turning Tapers and of the Drafting of Cams. Two more have since appeared: Commutators, and Threads and Thread Cutting, and others are in course of preparation. The price of each monograph is 25 cents.

The Hartford Blower Company, Hartford, Conn., have received an order for furnishing exhaust systems for the buffing and plating departments of the N. Y., N. H. & H. R. R. Co., at their new shops at Readville, Mass. The apparatus consists of two special, direct-connected, motor-driven "Hartford" adjustable exhaust fans, "Hartford" patent improved dust collectors, galvanized sheet steel piping, hoods, etc., with many new special fittings and attachments.

The Cling-Surface Manufacturing Company, Buffalo, N. Y., have sent us a duplicate of a letter they recently received from the Norcross Brownstone Company in regard to their Cling-Surface preparation. It speaks most favorably of Cling-Surface and says, among other things: "We are perfectly satisfied with what it (Cling-Surface) has done and our intention is, when we put on another rope, to give it a thorough application of your Cling-Surface before the rope is put on."

The Hartford Blower Company, 120 Suffield Street, Hartford, Conn., have gone to press with a new catalogue, No. 56, entitled "The Hartford Blowers and Exhaust Fans," which illustrates and describes the well-known Hartford patent improved adjustable blowers and exhaust fans, steel plate steam and pulley fans, disk fans, countershafts, blast gates, dust collectors, etc. The Hartford Company make a specialty of installing heating, ventilating, and mechanical draft apparatus, and announce that they will be pleased to send one of these new catalogues, free of charge, to any one interested.

The National Twist Drill and Tool Company, Detroit, Mich., announce the completion of their factory for the manufacture of reamers, cutters and all kinds of special tools. This has been equipped with modern machinery and an improved tempering process. They state that only high-class workmen are employed, and the most careful selection of steel made, with the object of placing on the market a product of superior quality. All their tools will be subjected to careful inspection and micrometer test. Mr. P. J. Hoenschied, their manager and superintendent, has had 22 years' experience in this line.

The Wilmarth & Morman Company, Grand Rapids, Mich., announce among their shipments of the "New Yankee" drill grinders in November, the following: Geometric Drill Company, New Haven, Conn.; English Iron Works Company, Kansas City, Mo.; Bridgeport Machine and Motor Company, Bridgeport, Conn.; Hydro-Carbon Light Company, Wichita, Kan.; Ideal Manufacturing Company, New Haven, Conn.; Fairfield Motor Company, Bridgeport, Conn.; Omega Steel Company, New Haven, Conn.; Homer D. Bronson Company, Beacon Falls, Conn.; North Penn Iron Company, Philadelphia, Pa.; Dodge Bros., Detroit, Mich.; Springfield Boiler and Manufacturing Company, Springfield, Ill.; New Jersey Zinc Company, Hazard, Pa.; Manning, Maxwell & Moore, New York; also seven drill grinders to England, and one to South America.

The Detroit Lubricator Company, Detroit, Mich., inform us that the Circuit Court for Wayne County, State of Michigan, issued an injunction on November 17 in their favor against the Michigan Lubricator Company, restraining them from using the words "Detroit Lubricators," "Improved Standard Lubricators," "Detroit Improved Standard Lubricators," in connection with their lubricators or advertising matter; also restraining them from using boxes or packages for their lubricators bearing the words "Detroit" or "Detroit, Mich.," unless their firm name be also given. For some time past the Michigan Lubricator Company have been making lubricators resembling those made by the Detroit Lubricator Company in outward appearance, and they have stamped on these lubricators and on the boxes containing them only the words, "Detroit, Mich.," making no mention of their firm name, the object evidently being to have such lubricators substituted for the genuine Detroit lubricators. In order to prevent their customers from being deceived and imposed upon by such tactics the Detroit Lubricator Company asked for this injunction, which was at once granted.

MACHINERY.

February, 1904.

SHOP NO. 3 OF THE BULLOCK ELECTRIC MFG. COMPANY.

THE works of the Bullock Electric Mfg. Co., although nominally in Cincinnati, Ohio, are really in the outskirts, in the pleasant suburb of South Norwood. The buildings constituting the works are of unusually attractive appearance (for a manufacturing plant), being built of buff pressed brick, with well-kept grounds. A recent addition, with which this description has to deal, is the heavy machine and erecting shop No. 3, or rather that part which was completed during the past year. A general view of the west end of shop No. 3 and of the service building, appears in Fig. 1. As intimated the new shop is not yet completed, the plan being to extend it 300 feet further east, but since the addition will be in harmony with the completed section, a description of the latter will largely apply to the whole structure.

Shop No. 3 was erected for building heavy generators and rotary converters—the former in the largest sizes up to 10,000 K. W. if demanded. The section shown in the plan view, Fig. 2. is 175 feet wide and 200 feet long. The east wall is a temporary wooden structure which will be torn down when the extension is built. The middle bay, as shown in the views, Figs 3, 4 and 5, is very high and wide. The width is 77 feet 10½ inches and the clearance beneath the hook of the 50-ton traveling crane is 50 feet. The north bay is 48 feet 9¼ inches wide and is served by a traveling crane of 30 tons capacity. The south bay is of the same width and is served by a 20-ton crane. Both cranes in the side bays have a lift of 26 feet. The roof is of the monitor type, with four skylights and windows in the sides of the monitor. Fully 50 per cent. of the side walls and of the permanent west end wall below the gable is glass. The sides of the monitor are practically all glass, and the skylights of translucent fiber that pierce both slopes of the monitor roof and each slope over the side bays, are continuous from one end of the shop to the other. The result is that a vast flood of light is admitted from all directions, leaving little to be desired in this respect. A valuable feature of the translucent fiber skylight is that it is not affected or broken by severe hailstorms or the vibration of the building, but its chief advantage is that the light admitted is softened and subdued, which is particularly agreeable in summer.

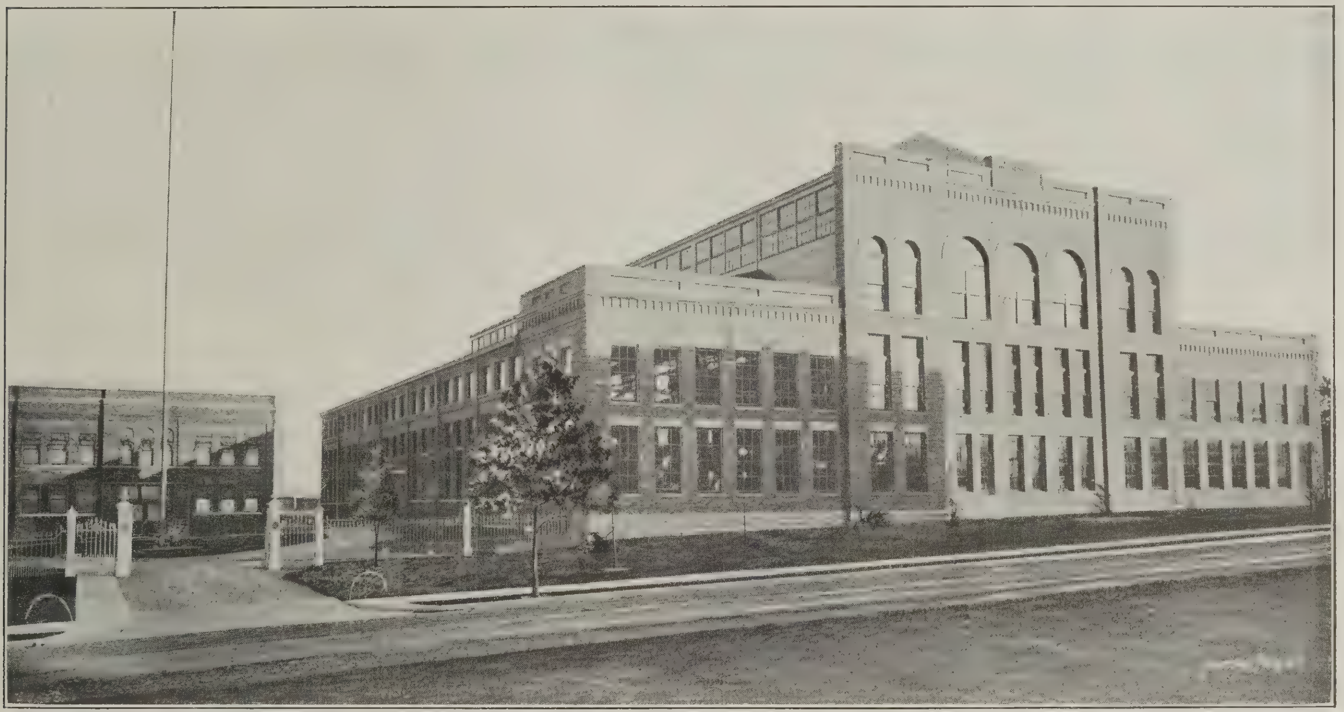


Fig. 1. View of West End Shop No. 3, Bullock Electric Mfg. Company. Service Building at Left.

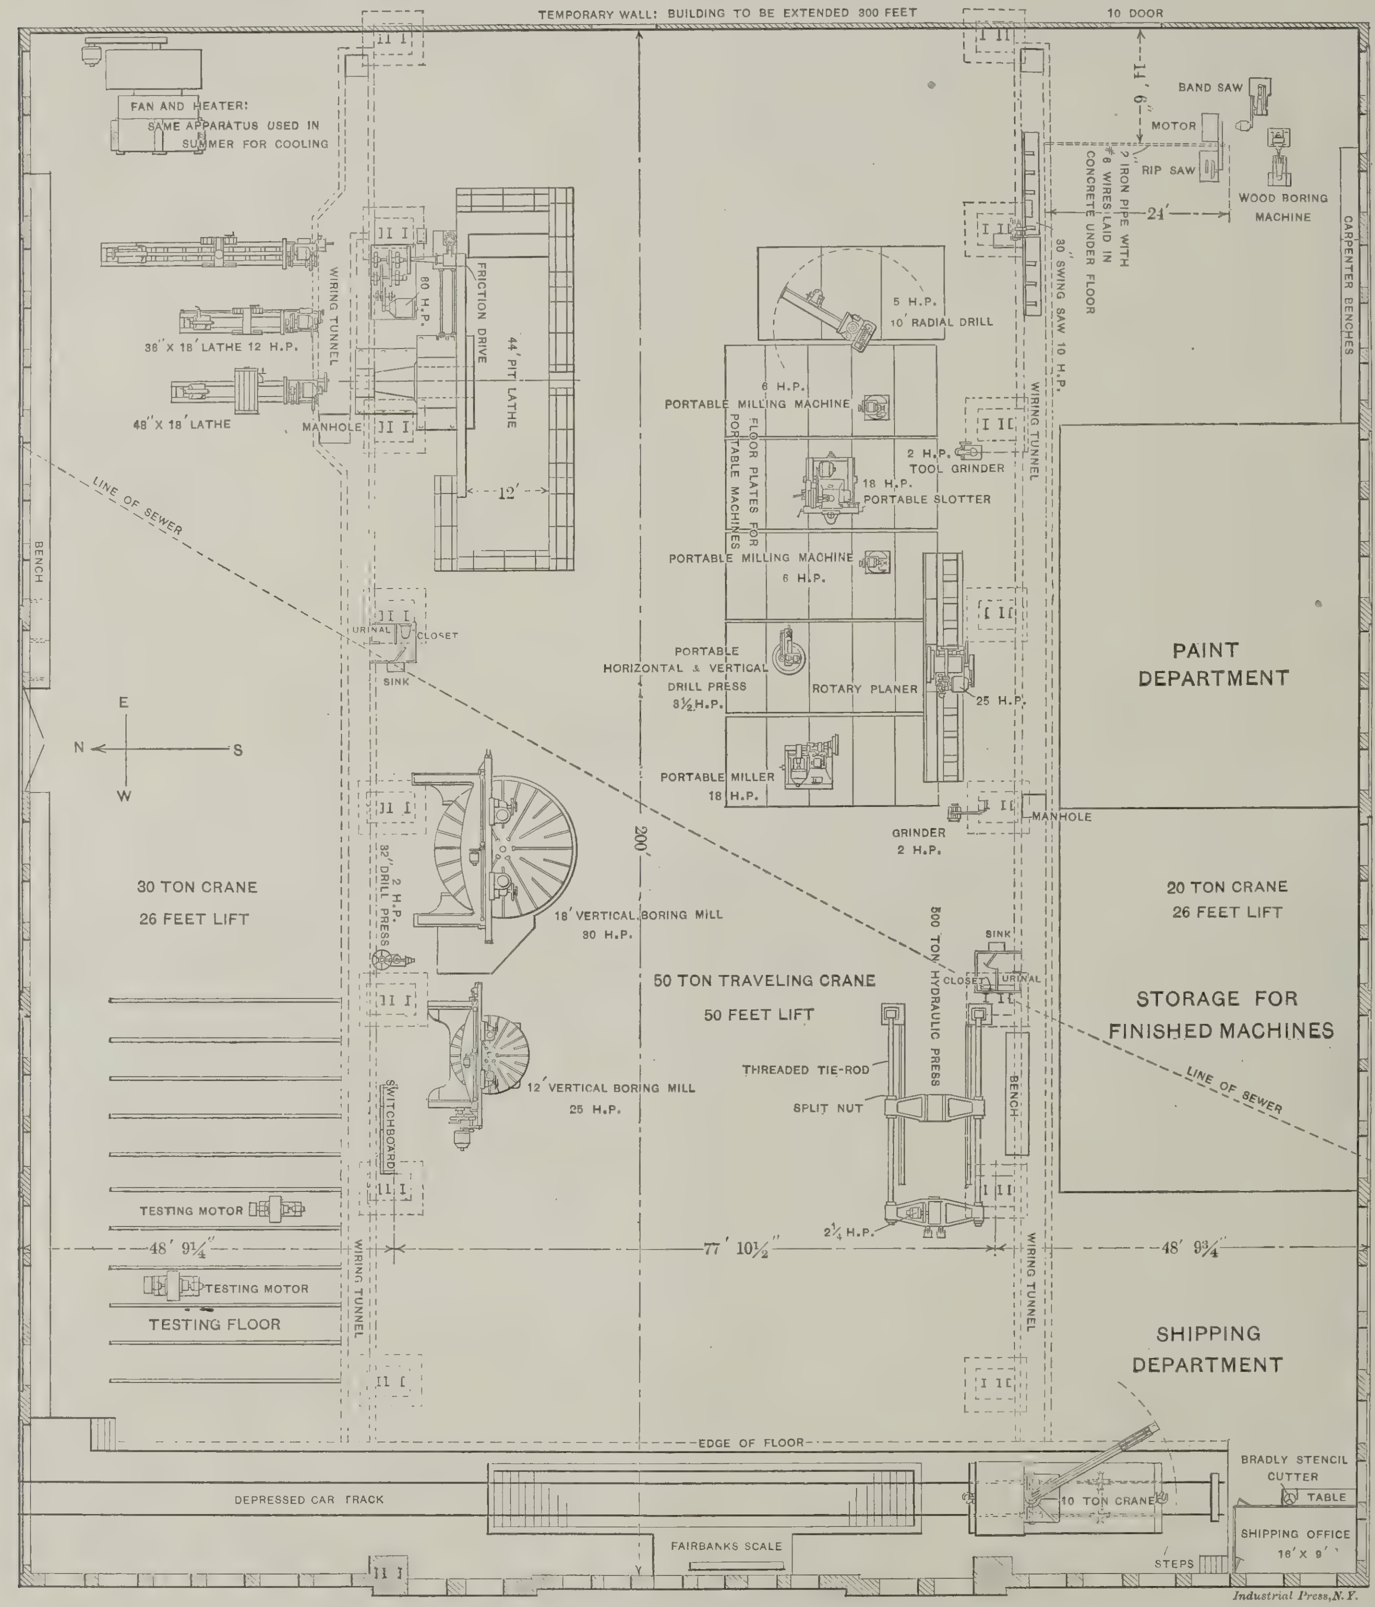
The shop is heated in winter by the Buffalo Forge hot air system. The conduits are carried through the side bays at a height of about 35 feet from the floor and the air is discharged at this height, the nozzles not being carried down near the floor. The heater and circulating fan are located in the northeast corner where they will be quite centrally located when the extension is built. The same apparatus is used in summer to cool the shop, cool air being blown through the pipes the same as warm air is in winter. The air in summer is drawn from the outside and passed through pipes around which cold water circulates. This system was found to be quite successful during the past summer and very agreeable to the workmen.

The floor has several features of interest. The foundation consists of rock concrete 2 feet deep in which the sleepers are laid and grouted. On the sleepers are laid 2-inch oak plank, This applies to the main floor. The testing floor in the northwest corner where the large machines are subjected to running tests, has a foundation of rock concrete 16 inches deep in which are buried at 5-foot centers 12-inch steel I-beams. On top of the I-beams are laid 2-inch planks and on these are laid 2-inch pine planks or flooring. The cast-iron floorplate in the middle bay, upon which the portable milling machines and slotters are used, is 60 feet long and 27 feet 8½ inches wide. It consists of 25 sections like that shown in the working drawing, Fig. 6. The T-slots in each section are continuous, but at the ends a transverse groove or slot 2½ inches (1¼ inches on each section) is provided for the convenient removal of chips and other debris. The general views, Figs. 4 and 5, show the floorplate with tools at work and Fig. 7 shows the floorplate with the rotor of a 3,200 K. W. generator in the foreground. In this view the 10-foot radial drill at the left is mounted on a separate floorplate of three sections. It, of course, may be shifted to any part of its floorplate required for advantageous working, the stump being provided with a circular base with bolt holes for this purpose.

All tools and machines are electrically driven by independent motors save, of course, the pneumatic hammers and drills used on the erecting floor. The electric power wires are laid in two wiring tunnels or subways located on each side of the middle bay. The location of the principal machines and of the testing floor and floorplate is such that the wiring tunnels serve them with comparatively short leads. Inclosed arc lamps are used and the wiring for these and the traveling cranes is, of course, carried overhead.



Industrial Press, N.Y.

Fig. 2. Floor Plan of Shop 3—Bullock Electric Mfg. Company.

A railway switch enters from the north side and crosses the west end. The tracks are depressed so that the floor of a flat car is on a level with the shop floor. A Fairbanks track scale enables all car weights to be determined independently of the railway company; also all castings received from the foundry both individually and in bulk. A 10-ton derrick car is part of the plant equipment for handling heavy parts and is indicated in the shop plan, but of course the shop traveling cranes are preferably used for loading and unloading cars unless otherwise employed.

The largest machine tool in the shop is the 44-foot pit lathe indicated in the plan and shown individually in Fig. 8, working on an armature shield and support for a 3,200 K. W. alternating current generator. The machine can be used either as a lathe or as a boring machine, being used in the latter capacity in this instance, since the work remains stationary while the boring tools revolve with the faceplate. The faceplate is 30 feet diameter and the pit will permit a casting 44 feet diameter and 12 feet long to be swung. The novel feature of the lathe is the friction drive, power being transmitted to the periphery of the faceplate by a friction wheel or roller 18 inches diameter and 15 inches long. A slotted cast-iron

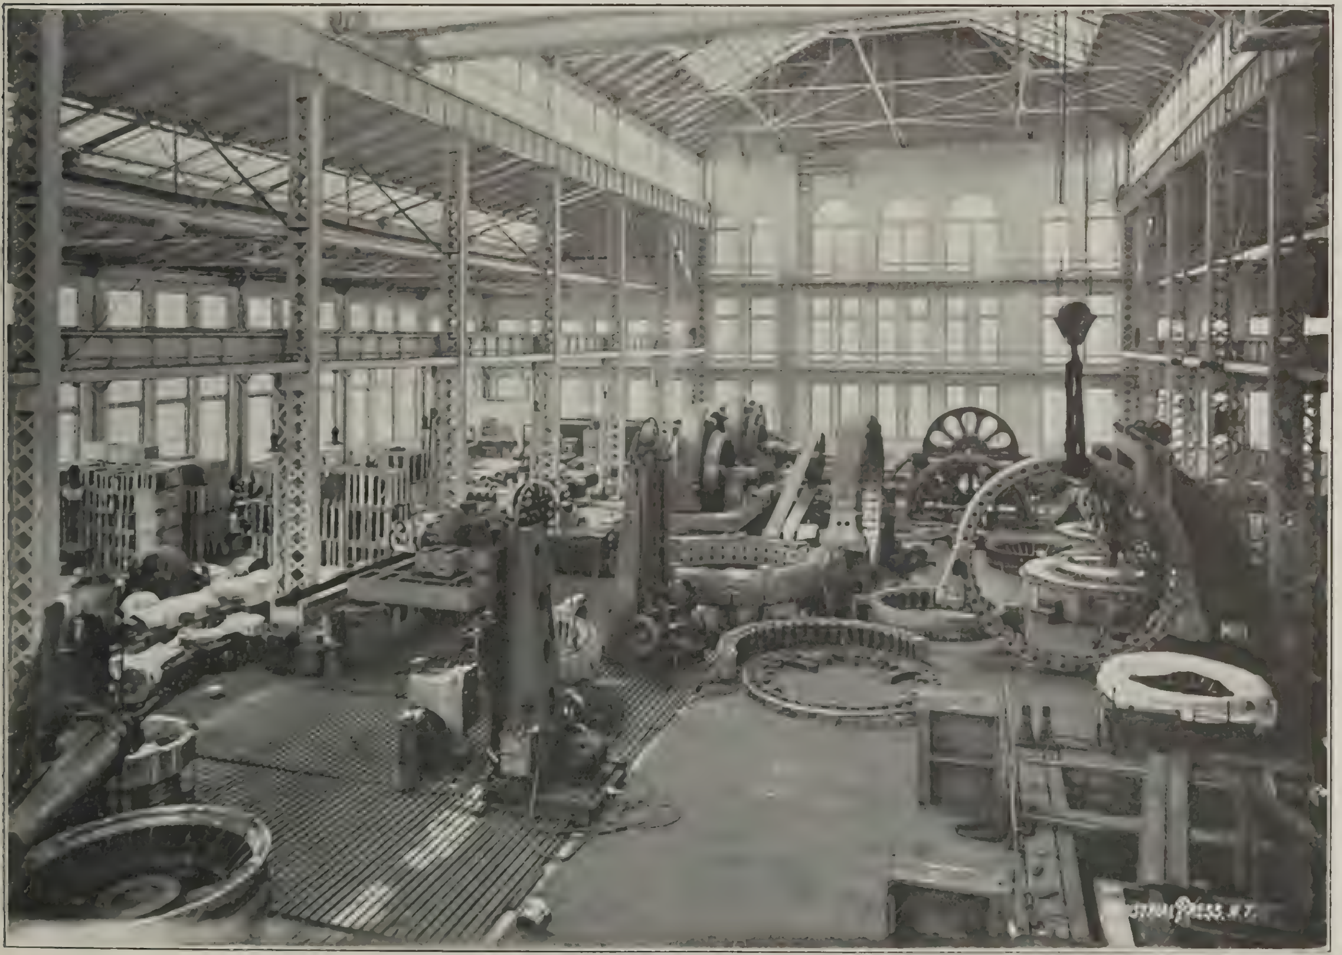

Fig. 4. General View, looking towards Southwest Corner.

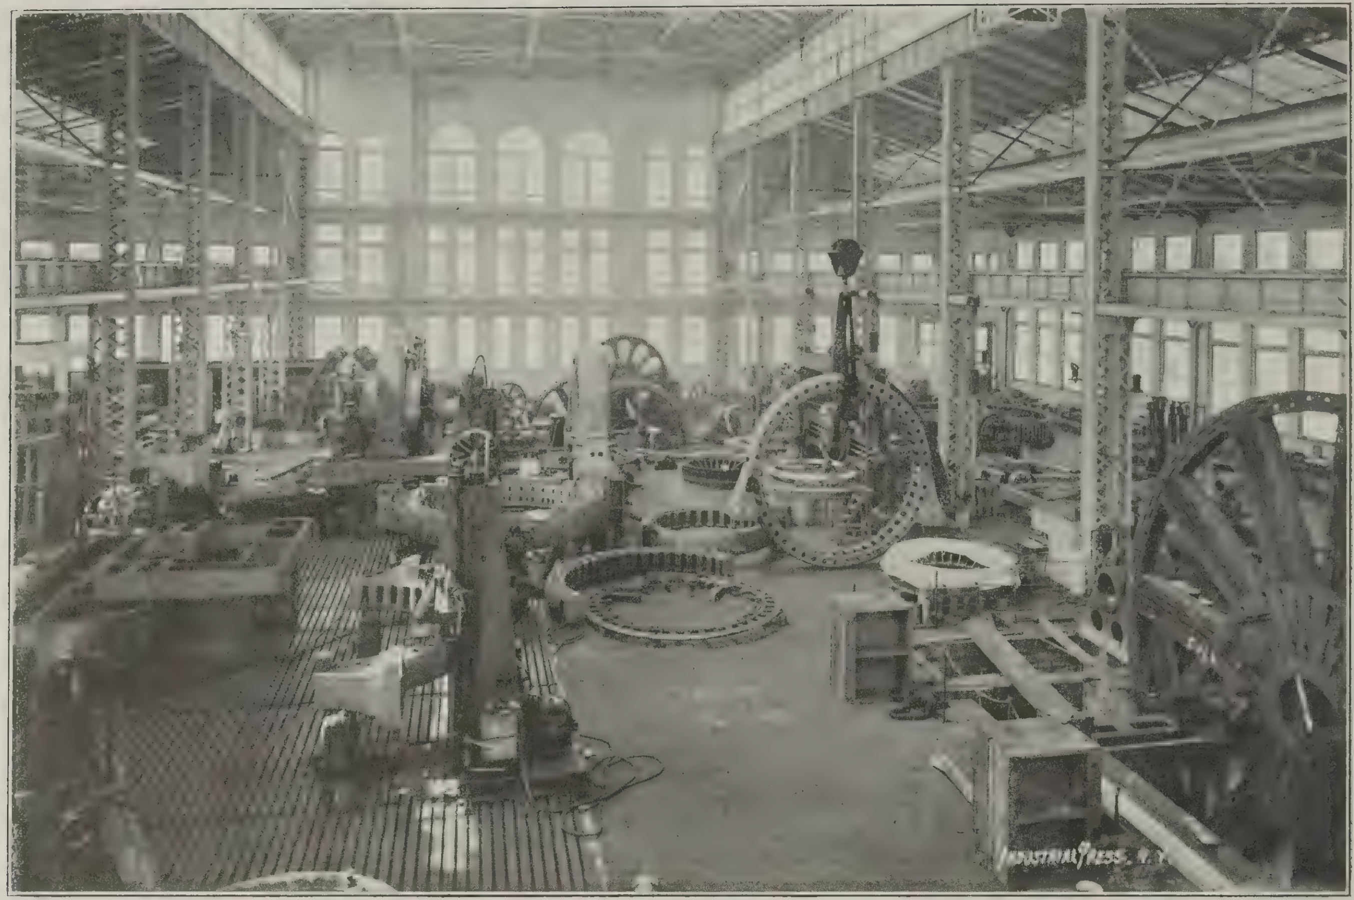

Fig. 5. General View of Shop, looking Northwest.

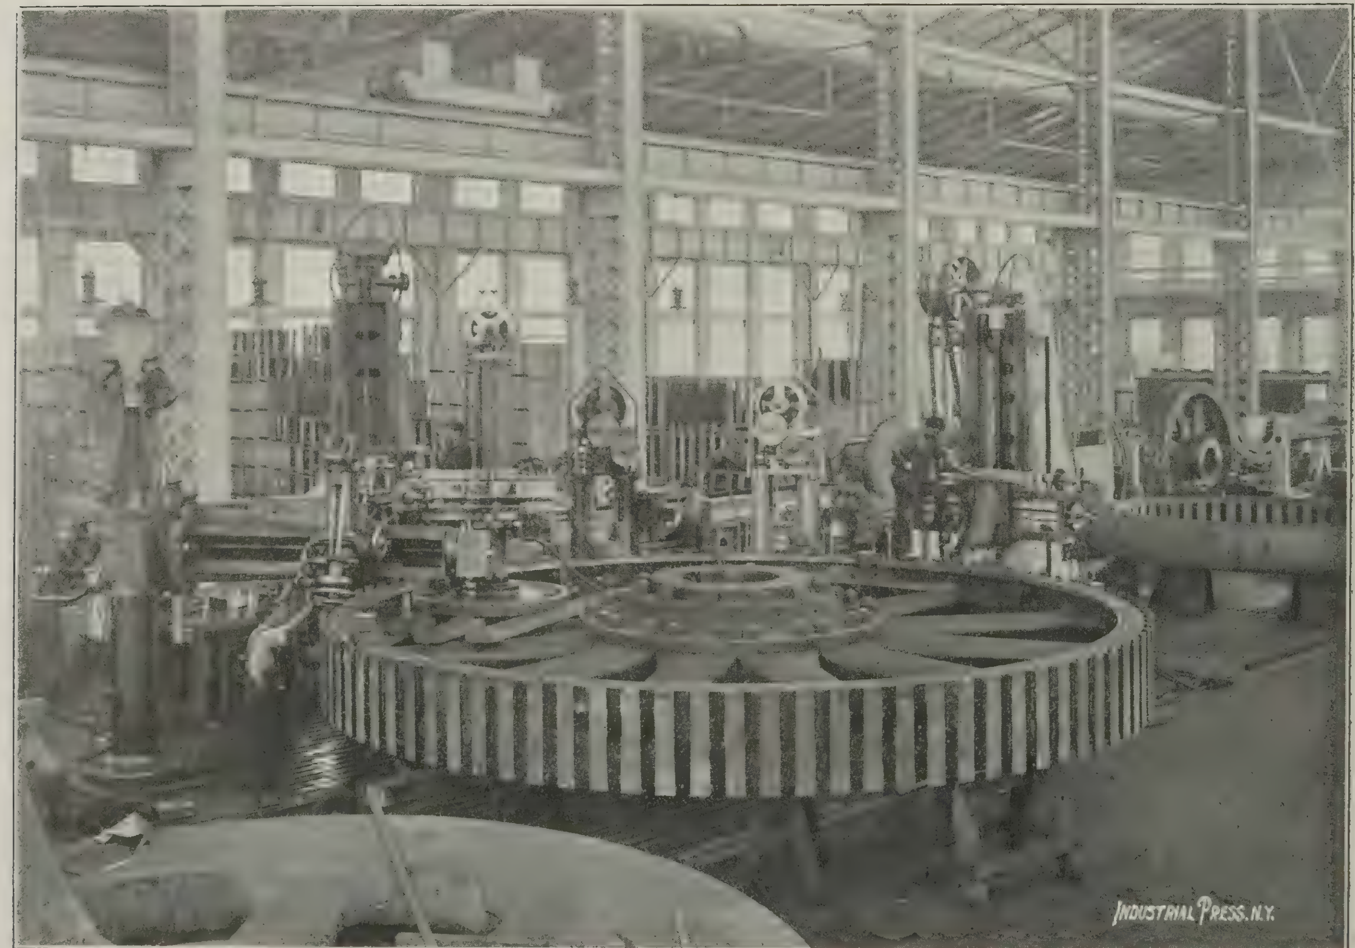

Fig. 7. Floorplate, showing Rotor of 3,200 K.W. being Machined.

floorplate is laid on three sides of the pit for the erection of work that is to be bored and for supporting the cutting tools when work is swung on the faceplate. The floorplate will be used for the latter purpose only when the full capacity of the pit is taken up. Ordinarily the turning tools are supported on massive cast-iron columns resting on the floor of the pit. The feed mechanism of the tool carriages is driven by an independent motor controlled by a feed regulator so that any rate of feed from 3-64 inch to 2¾ inches per minute may be gotten and strictly in accord with the movement of the faceplate. The floorplate is also used for an outboard bearing or support for boring bars and mandrels when turning or boring large rotors or flywheels. The total weight of the lathe is estimated at 480,000 pounds. Fuller particulars of the friction drive were contributed by Mr. John M. Barnay in the January, 1903, issue. The company are satisfied with the friction drive as applied to this particular machine, since it suited the purpose better than any other drive. It works even better than they anticipated. In general, however, they do not advise the use of the friction drive for machine tools.

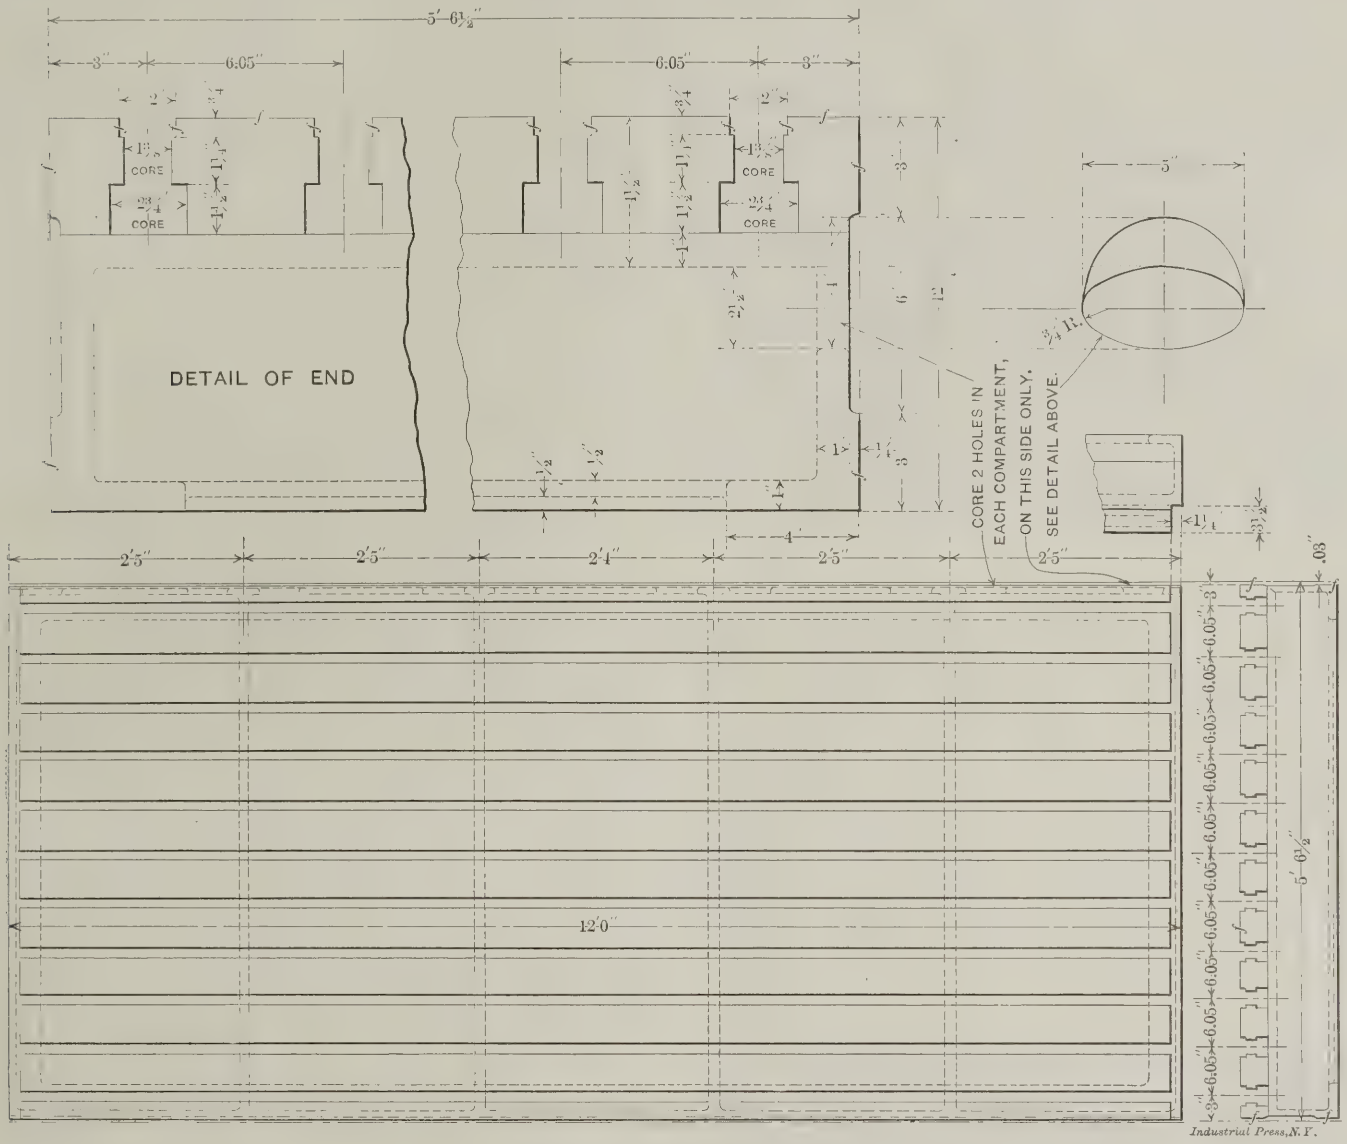

Fig. 6. Details of a Floorplate Section.

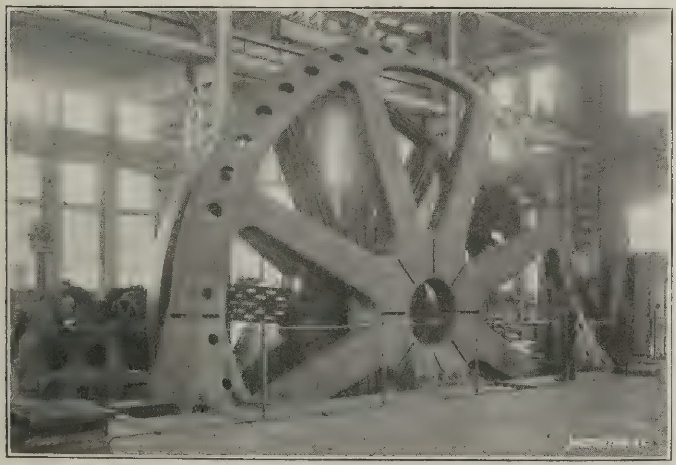

Fig. 8. Forty-four foot Pit Lathe.

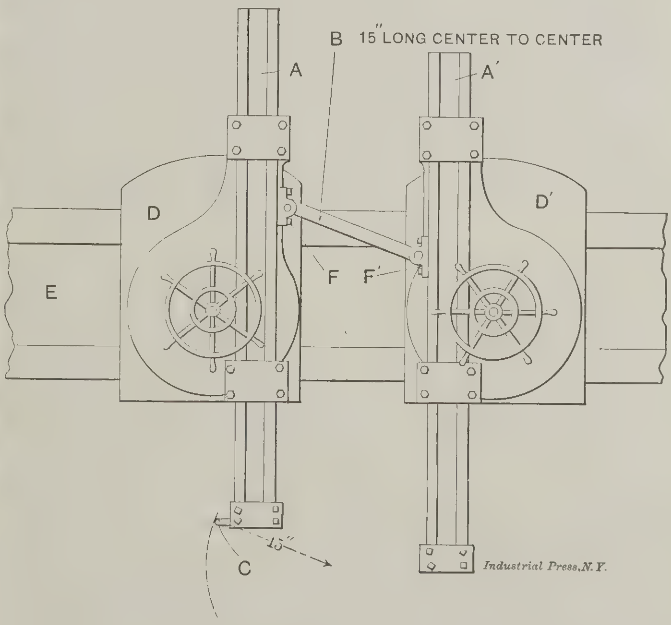

Fig. 9. Boring Mill Attachment for Boring Spherical Seats.

On the same side of the middle bay as the pit lathe are two vertical boring mills of 12 and 18 feet capacity respectively. Both these mills have been adapted to boring spherical seats for the self-aligning bearings used on all large generators. The device is shown in Fig. 9 and consists essentially of the bar or link *B*, which is made of the required radial length from the centers of the pin holes in the ends, links of different radii being provided to suit the work. The blocks *F F′* are secured to the boring bars by two screw bolts each and either bar can be used for boring a spherical seat. The bar *A* is supposed to be so employed in the sketch and in that case the slide *D* is made free to move on the cross-rail *E*, the cross-feed nut or screw being disengaged for that purpose. The slide *D′* is clamped to the cross-rail and the bar *A′* remains stationary so that the pin at *F′* forms a pivot about which the link *B* swings as the bar *A* feeds down. Therefore the whole bar, including the point of the cutting tool *C*, moves in an arc of the same radius as that of the link *B*, which, in this case, is supposed to be 15 inches. The same scheme may be employed for spherical turning or for the generation of cycloid curves if required.

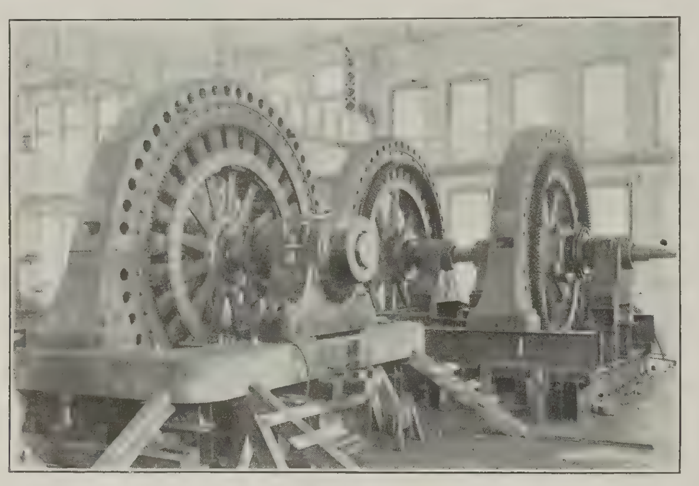

Fig. 10. Generators on Erecting Floor, in Position for Testing.

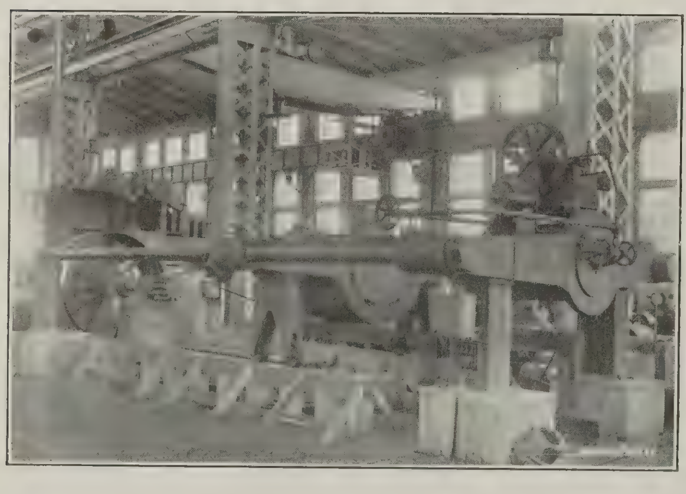

Fig. 11. Hydraulic Press, Motor-driven, for Forcing Fits.

Another feature of these boring mills which is of minor interest is that the counterbalance weights are not supported by pulleys on the frame or housing in the usual manner. When this is done it requires that pits be dug and bricked up for the reception of the weights when the cross-rail is raised to the top of the mill. In these cases the pulleys are mounted on the shop girders at a distance of about 25 feet from the floor and close to the columns. In this manner ample movement is gotten without making pits.

The construction of the testing floor has already been described. Fig. 10 shows three heavy generators in position on it for testing. The machine in the foreground is a 3,000 K. W., 50-cycle, three-phase, 2,400 volt, 231 R. P. M. water-wheel type alternator for the Kern River Co., California, and in the background are two 1,000 K. W., 25-cycle, three-phase, 375 volt, 94 R. P. M. engine type alternators for the Scioto Valley Traction Co.

The heavy Watson-Stillman Co. hydraulic press for forcing fits, shown in Fig. 11, is located on the opposite side of the shop from the testing floor and near the shipping department. It has a capacity up to 500 tons and is motor driven. The yoke is a heavy steel casting and is locked to the longitudinal tie rods by split nuts. The rods are cut with a coarse buttress thread and the halves of the split nuts are similarly threaded and operate substantially the same as the split nuts in a lathe apron. Fig. 12 shows one end of the yoke more in detail. *A* is the yoke, *B* detachable handle for operating the nuts, *C* is a rod connecting the opposite side so that the nuts on both sides work in unison, *D D′* are the halves of a nut, and *E* is a screwed tie-rod.

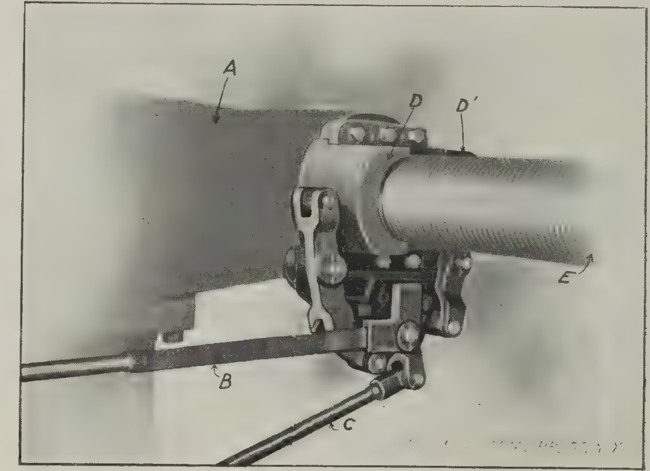

Fig. 12. Detail of Split Nut in Hydraulic Press Yoke.

Shop No. 2, which was recently badly damaged by fire, is being rebuilt and enlarged so that it will be about twice as long as the old structure. The new building will be 200 feet long and 140 feet wide and two stories high.

A dining room is provided for the employees in all the departments. The men may bring their own lunches and eat them in the dining room, or buy a well-cooked, palatable meal from the company at a nominal cost. Shower and plunge baths, lockers and the other modern conveniences are provided that so sharply differentiate the present generous policy of up-to-date concerns from that of the old regime.

* * *

The United States consul at Liege, Belgium (Mr. James C. McNally), says that the catalogue system of advertising American goods is not of much avail with the merchants of that city. The buyer wants to see the goods in bulk so that he can personally examine their details, and he wishes to listen to the arguments of the American drummer, that is, personal efforts are necessary to put American goods on that market.

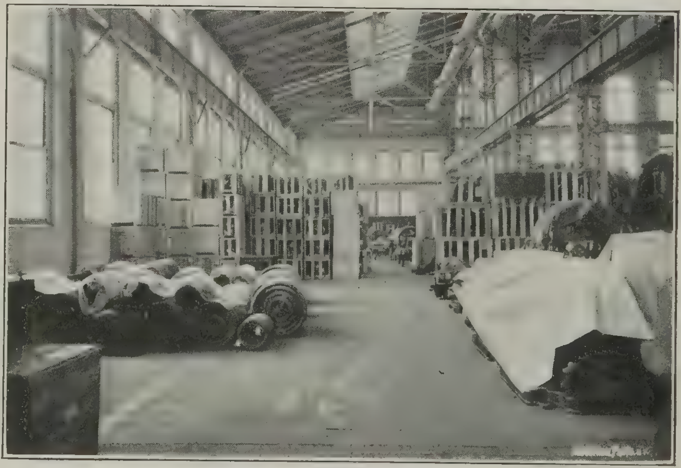

Fig. 13. Storage Department.

TOOL MAKING.—3.

REAMERS (Concluded).

E. R. MARKHAM.

Shell Reamers.—The larger sizes of chucking reamers are oftentimes made in the form of "shell reamers." As several reamers may be made to be used with the same arbor, there is a great saving in cost of stock. But in order to prevent the reamer turning on the arbor when in use a slot is cut across one end, as shown in Figs. 19 and 20, and this engages with a pin passing through the arbor, or a tongued collar on the arbor. Owing to the liability of change in size of hole in the reamer when hardened, it is necessary to leave a small amount of stock in the hole, to be ground out after hardening; or the hole may be made tapering and the arbor given a corresponding taper to fit the hole.

When making shell reamers, select stock enough larger than finish size to allow of turning off all the decarbonized portion. The piece should be placed in a chuck on the lathe and a hole drilled and reamed through it 1-16 inch smaller than finish size. It should then be placed on a mandrel and turned to a size 1-32 to 1-16 inch larger than finish, after which it should be annealed. This is to eliminate any tendency of the piece "going" to any great extent when hardened. This process should be employed when making almost any piece of work that we wish to prevent from altering in shape or size of hole when hardening; it also helps to decrease the tendency to crack from internal strains when the article is hardened.

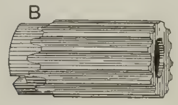

Fig. 19.

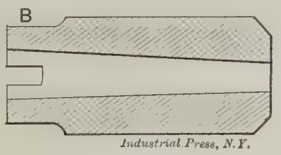

Fig. 20.

After annealing, the piece is placed in the chuck and the hole finished to grinding size, which ordinarily would be about .005 inch smaller than finish. If a taper-shaped hole is desired, it may be bored and reamed to the desired size and taper. When this form of hole is made in a reamer, it is not generally considered necessary to make any allowance for grinding, as any slight inequality of size would be taken care of by the shape of the hole in the reamer and arbor it is to be used on. When the hole is finished the blank may be placed on a mandrel, the ends faced to the desired dimensions, and the reamer part turned to a size .010 to .015 inch larger than finish size. The portion marked *B* at the end of reamer may be turned to finish size. If we are making a rose reamer, the cutting end should cut to the proper bevel.

Before cutting the flutes that form the cutting edges it is advisable to cut the tongue slot in the end. To accomplish this the reamer blank may be placed in the chuck on the index head spindle of the milling machine; and as this slot must be central, extreme care should be exercised in setting the machine and cutting it. Select a cutter somewhat narrower than the desired width of slot; set this as centrally as possible with the end of reamer, then cut across the end. Give the index pin handle 20 revolutions, thus turning the work one-half way around, and cut across again. The width of the slot that has been cut may now be measured and the saddle moved one-half the difference between the size cut and that desired. However, before taking the final cuts measure the distance from the slot to each edge of the reamer to ascertain if the piece of work is chucked true. If not, we will be obliged to cut each side of the slot to a measurement from the outside of the piece. After removing the burr thrown up in the hole by the cutting of the tongue slot, the reamer blank may be placed on a mandrel and the grooves cut. The direction given for cutting grooves of solid reamers apply to shell reamers.

If the reamer is pack-hardened the results will be more satisfactory than if any other method known to the writer is used, for the danger of cracking is eliminated and the liability of the size of the hole being affected is reduced to the minimum. However, if this method cannot be used excellent results may be obtained by heating in a muffle furnace, or in a tube in a blacksmith's forge. The reamer should be heated uniformly to a low red and plunged in a bath of water or brine—preferably the latter—from which the chill has been removed.

When the reamer is taken from the fire, and before plunging in the bath place it on a hook of the form shown in Fig. 21 in order that no part of it may be kept from the action of the water when cooling. If the reamer is larger than 1¼ inch diameter it should be removed from the bath when it ceases "singing" and be plunged into a tank of oil and allowed to remain until cool. When it is removed from the bath, whether water or oil, hold it over a fire, revolving slowly until heated sufficiently to remove the tendency to crack from the internal strains set up by hardening. Ordinarily it is not necessary to draw the temper of rose reamers. Fluted reamers may be drawn to a straw color.

The hole should be ground to size—provided it is to be ground—and the reamer placed on an arbor and ground according to instructions given for grinding reamers.

Arbors for Shell Reamers.—Fig. 22 shows an arbor for use in holding a shell reamer, having a straight hole. The smaller sizes are usually made from tool steel, while the larger ones are sometimes made from a stiff grade of machinery steel. If tool steel is used a cheap grade answers the purpose as well as a more costly article.

Make the tongues used in keeping the reamer from turning, on a separate piece from the arbor itself. Make a collar from tool steel and cut the tongues on the end as shown. These must, of course, be central with the sides of the collar. The collar may then be placed on the arbor and the pin hole drilled and reamed, after which it is removed and spring-tempered. It may now be placed on the arbor and the pin driven in place.

Roughing Reamers.—Very often when large holes are to be produced from solid stock it is found more economical to drill a hole with a drill smaller than the desired size then to enlarge it with a roughing reamer than to attempt to drill it to size. The two operations can be done more quickly than the one and then again the roughing reamer, being short and strong, will in a great measure true up the hole which may have run when drilling. This form of reamer is extensively used on screw machines and chucking machines, for enlarging cored holes.

Fig. 21

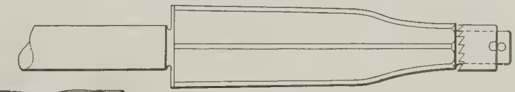

Fig. 25

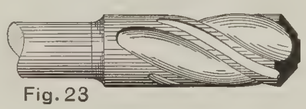

Fig. 23

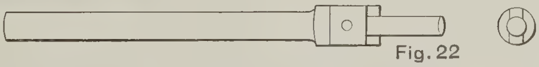

Fig. 22

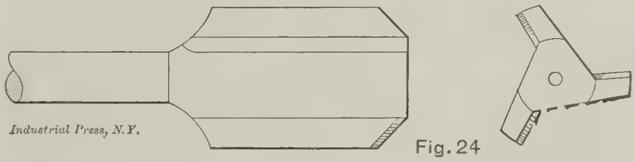

Fig. 24

The grooves are cut both straight and spiraling. Straight grooves are generally cut when the material to be machined is cast iron. When they are to be used for cutting steel, spiral grooves give best results. When the reamer is to be used for cutting steel it is best to cut oil grooves, as shown in Fig. 23, as these grooves convey lubricant to the cutting edges, and as they remove a portion of the land the frictional resistance is reduced.

When the tool is to be used for machining large holes—those above 2 inches—the form shown in Fig. 24 is preferred by many mechanics for use on either cast iron or steel, the grooves being straight as shown. The flutes are large and easily accommodate the chips and at the same time convey the oil or other lubricant to the cutting edges.

As the use of this form of reamer is generally followed by a boring tool, to true up the hole in case it may have run, it is not essential that it cut exact as to size, and consequently it need not be ground after hardening. However, if it is considered necessary to grind to size a sufficient allowance may be made when turning in the lathe, and as the centers are left in the piece, the grinding is a simple matter.

Formed Reamers.—Formed reamers are used to ream a hole of irregular contour. They are employed very extensively in shops where fire arms are manufactured, for reaming the end of the barrel that goes in the frame to receive the shell, and are then generally termed "chambering reamers." That these reamers may retain their size and shape for as long a period as possible they are made in sets. A roughing tool cuts out the principal part of the stock, then a reamer a trifle smaller than finish size is used, leaving a very small amount to be removed by the finishing reamer.

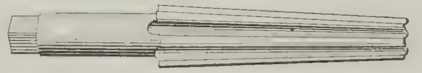

Fig. 26

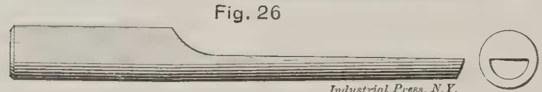

Industrial Press, N.Y.

Fig. 27

As it is necessary to machine the formed hole in exact alignment with the rifled hole in the barrel the reamer must be provided with a pilot of the exact size of the hole at the tops of the lands of the rifling. Such a reamer is shown in Fig. 25. And to prevent the lands of the rifling from becoming marred by the pilot, this part is made a trifle small, and a sleeve is placed on the outside of it. This does not revolve when the tool is cutting; the pilot proper being a running fit in the hole in the sleeve revolves in it. But the tendency of the reamer is to throw a burr at the end where it stops cutting, and should we attempt to draw the sleeve back through this burr it would get stuck and in all probability spoil the rifling. To avoid this we must remove the burr and for this purpose teeth are cut on the sleeve on the end toward the reamer, as shown. A pin is driven through a hole in the pilot, just beyond the end of the sleeve, thus leaving the sleeve free when the pressure on the reamer is ahead; and grooves are cut in the end of the sleeve toward the pin, as shown. Now when we draw back on the reamer the grooves in the sleeve engage with the pin, the sleeve turns with the reamer and the teeth on the opposite end cut away the burr. As the teeth are to be on the opposite end from what general practice would call for, attention must be given as to which way they face, so that they may cut.

Reamers of this character must be exact as to shape, and it is therefore necessary to make them to gages. First, a sheet steel gage is used, to shape the general outline to; then a receiving gage, which consists of a block having a hole of the right size and shape in it, in order that the fit may be easily observed. A portion of this block must be cut away, leaving a trifle more than one-half the hole in the block.

Owing to the peculiar shape of a reamer of this style, and to the fact that it is so slender that it would not be possible to use a forming tool to shape it, it may be roughed somewhere near to shape with the ordinary lathe tools, but the finishing to shape and size must be done by means of hand tools. Where these tools are made in quantities sufficiently large to warrant the outlay a special form of turning lathes may be made, but for ordinary purposes the method described is used.

To prevent change of size, and springing, it is advisable to harden tools of this character by the pack-hardening method. If this cannot be done, however, the piece should be heated in a muffle furnace, or in a pipe in a forge, and dipped in luke-warm brine. If shape or size is altered it may be fitted to gage by oilstoning.

Taper Reamers.—Taper reamers are used for various classes of work. We have in common use roughing taper reamers, finish taper reamers, dowel pin taper reamers, etc. These are made with straight flutes, as shown in Fig. 26, and also with spiral flutes. Then we have the half reamer with only one cutting edge, as shown in Fig. 27.

Ordinarily the roughing taper reamer is simply intended as a means of removing stock so that the finish reamer will not have much work to do, that it may maintain its size and shape as long as possible, and cut a smooth hole accurate as to size. It is made of a form that breaks the chips into short lengths, that is, in the form of what is sometimes termed a "multiple counterbore," as shown in Fig. 28. Each of the bodies, *B*, *B*, is straight and a trifle larger than the one preceding it. The stock at the end of the body is cut somewhat below the size of the next smaller body, by cutting grooves, *A*, *A*, as shown, with a parting tool whose corners are slightly rounded to prevent cracking when the reamer is hardened. It is customary to give roughing reamers of this character four flutes. The ends of the steps are given clearance so that they may be cut, which is done by filing. The commercial "roughing taper reamer" is usually made as shown in Fig. 29; this has a thread cut its entire length, as shown, to break the chip.

In cutting the thread which should be left-hand, use a square-thread tool having its corners slightly rounded. The tool should be about 1-16 inch thick; the thread cut about 1-32 inch deep. After the grooves are cut the reamer may be hardened, the temper drawn to straw color and the reamer ground to size and to the proper taper. Then it may be given clearance for cutting, which is done by grinding, as explained under grinding fluted reamers, excepting that the grinding may extend to the cutting edge of the tooth. The proper clearance for cutting extends back about 1-32 to 1-16 inch from the cutting edge—according to size—the remainder of the tooth being given greater clearance.

Taper reamers intended for reaming holes to receive taper dowel pins are made of the same form as a finish taper reamer, or as a "half" reamer like that shown in Fig. 27. The latter form is in general use in many shops, while the commercial article is usually made of the first form.

When exactness of shape is desired the reamer must be made of the form shown in Fig. 30, leaving the portion at small end full size until the reamer is ground, in order to preserve the center. After being ground to size and shape the extra portion may be ground away, leaving it of the shape shown in Fig. 27. When milling articles of this sort it is necessary to support them from the milling machine table with the adjustable support furnished with the machine, or by some means to prevent springing from the pressure of the cutter.

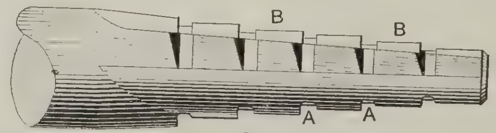

Fig. 28

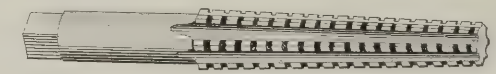

Fig. 29

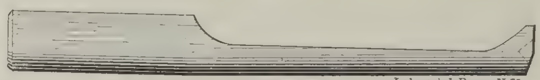

Fig. 30

Industrial Press, N.Y.

When hardening, heat very carefully in a tube in the fire, then dip in the bath with the reamer inclined, as shown in Fig. 31, the heavy portion being down to cause it to cool quickest. This keeps it straighter than if it were dipped in a vertical position; the angle of inclination cannot be given, it must be determined by experiment.

If the reamer is ground in a dry grinder care must be exercised that a coarse, free cutting wheel be used; for the reamer will spring if heated, as all of the heat would be applied to one side. After grinding the round portion may be honed, being careful to come only to the cutting edge. The honing is to relieve the bearing surface, or rather to reduce it.

Finish Taper Reamers.—Taper reamers used for finishing holes are usually made to appear like Fig. 26, although the grooves are sometimes cut with a right-hand spiral, which tends to make them cut a smoother hole, especially if the stock is porous, or the walls of the hole imperfect. A spiral of this kind would not do on a straight fluted reamer; the tendency would be to draw into the hole being reamed faster than the reamer could cut, and consequently when the flutes of straight reamers are cut spiraling they are given a left-hand spiral. But on account of the inclination of the sides of a taper reamer the amount of spiral usually given would not cause it to draw in, although it might cause it to cut somewhat easier than if the flutes were straight.

Square Reamers.—This form of reamer is used mostly by makers of gun barrels and similar work. It differs from the other forms of reamers in that the cutting is done on the end nearest the shank. The reamer is pulled through the hole rather than pushed through, as is generally the case. This form of reamer is sometimes termed a "chip reamer" on account of the method used in enlarging the size of the hole cut with it. A chip of wood is placed on one side, as shown in Fig. 39. When the size of the hole should be increased a small amount a piece of paper—or tissue paper—is placed between the chip and reamer.

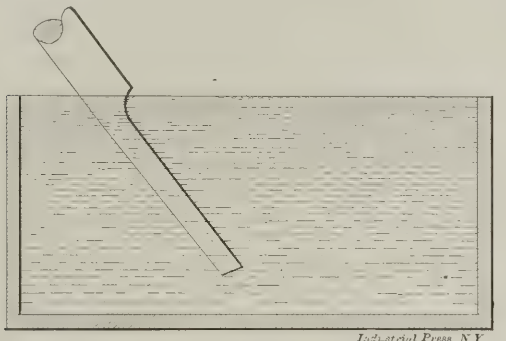

Fig. 31. Proper Position of "Half" Reamer in Hardening Bath.

This form of reamer is turned a size somewhat larger than the size across corners, then milled square. When large reamers are made a convex cutter is used to mill the sides concave; but small reamers are milled square on their sides and the concave surface is obtained by the emery wheel when grinding. The shank is made short and after the reamer is ground to size it is brazed or welded to a long shank.

After the reamer is hardened it is placed in the grinder, the corners ground to size, and the sides also ground. The concave shape is given by the face of the emery wheel—and should not be carried quite to the corners. The end toward the shank is made slightly tapering for a short distance for the cutting portion. Now by using a flat oilstone we can hone the reamer slightly flat at the corners, and this prevents its digging into the work. This form of reamer is used to remove a very small portion of stock at each cut and will cut a very smooth hole.

Single Lip Reamer.—This form of reamer is used very extensively in some shops, while in other shops it is never seen. For certain purposes it is more satisfactory than any other form of reamer. As it has but one cutting edge its action is similar to that of a boring tool used for lathe work. And as more than one-half the stock is left on the reamer when it is milled for the cutting edge it is supported in the hole, and if properly started, will not run when cutting, but is bound to produce a straight hole.

The form of single lip reamer shown in Fig. 32 is the one commonly used. Select stock somewhat larger than finish size. When turning in the lathe leave portions *A* and *B* somewhat larger than finish, to allow of grinding. *C* is turned to dimensions given, because it is not essential that it run true. The size, and any distinguishing marks desired, may be stamped here.

When milling for the cutting edge do not mill away quite one-half the stock, as more than one-half the circumference of the reamer is required to support it in the hole when cutting. If the countersunk hole (center) in the cutting end is made small we need not mill away sufficient stock to disturb it. If, however, the center should be large and the reamer a small one, we can mill it as shown in Fig. 33, leaving it this shape until after it is ground to size. Then the end containing the deep center may be removed by grinding, leaving the reamer as shown in Fig. 32. It is necessary to bevel the end of the cutting portion as shown, while one-half of the end is beveled off so as to be out of the way, or it would strike on the opposite side of the hole from the cutting edge and prevent the reamer penetrating the stock. When hardening reamers of this character it is important that they be hard the entire length of body (*A*, Fig. 32) or they will be apt to rough up in the hole being reamed. Unless they are small the temper need not be drawn.

Single lip reamers are made at times with a pilot, as shown in Fig. 34. This pilot, which is considerably smaller than the hole it is to pass through and which is to be reamed, fits a bushing at the further end of the hole. The bushing receiving the pilot guides the reamer and causes it to cut the hole at the desired location. This form is made the same as the reamer without pilot; enough stock is left on pilot to finish to size by grinding after hardening. It is necessary to neck down at the end of the pilot nearest the cutting portion so that the reamer may be given clearance by filing, and also to allow the emery wheel to pass over the pilot when grinding.

Reamers with Inserted Blades.—Generally speaking it is not good practice to make small reamers with inserted blades. Large reamers are, however, made this way (see Fig. 35) as a matter of economy. Not that the first cost is any less; but it is possible, when the blades are worn so that the reamer cuts small, to insert new blades at a cost much less than that of making a new solid reamer. Then again the reamer may be so made that the blades may be made to cut larger by moving them. It is then called an expanding reamer.

The body of an inserted-blade reamer may be made of a cheap grade of tool steel, or of a high-carbon machine steel. It would not be good practice to make the body of ordinary low-carbon machine steel, as it would not resist the pressure of the blades on the sides of the slots when the reamer was in use; and if they became loose in the slots the reamer would be of no use, as the blades would bite into the walls of the hole and prevent the reamer cutting and in all probability spoil the piece being reamed.

After turning to the desired size the slots may be milled in the body. These slots should be milled somewhat shallower at the end toward the shank than at the cutting end, and they should also be wider at the bottom than at the top in order to hold the blades from being drawn from their seating. The side of the slot corresponding to the cutting edge of blade should be radial—on a line with the center—or slightly ahead of the center, according to the custom in the individual shop. For milling the slot wider at the bottom we may use a cutter slightly narrower than the desired width of the slot at the top. Set this cutter to bring the face of blade in proper location and the desired depth, mill all the slots, then turn the index spindle the necessary amount to give the proper angle on side of slot corresponding to the back of tooth, as shown in Fig. 36. As stated, the slots should be less deep at the end toward shank than at the front end. This may be easily accomplished by lowering the index head spindle sufficiently to produce the desired result.

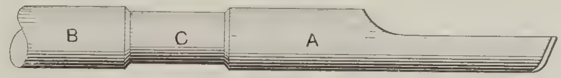

Fig. 32

Fig. 33

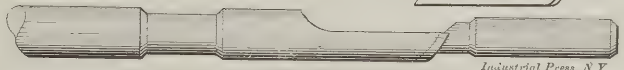

Fig. 34

The blades are machined to shape and hardened; they are then driven to place and ground to size. The clearance is given the same as a solid reamer of the same class. A reamer need not be made of as high carbon steel as tools whose cutting edges are heavier, as the water has free access to the surfaces and the portions not being very heavy, harden very readily. On the other hand, while it is advisable to use a steel of a percentage of carbon especially adapted to the class of tool being made, in shops where detail is closely followed and where the hardener is sufficiently versed in the proper method of treatment for each grade of steel, yet in the average shop this would lead to endless confusion. For this reason it is best as a rule to select some certain make and grade of steel and use it for as great a proportion of the tools as is possible. Probably the most satisfactory percentage of carbon, when almost any of the leading makes of steel is used, is that containing 1¼ per cent. of carbon.

Adjustable Reamers.—When it is desired to ream holes to varying sizes, regardless of interchangeability, reamers are used which can be adjusted to the desired size. In most shops they are a source of endless annoyance, because they are never adjusted to the proper size when found, and in nine cases out of ten a man will ream a hole too large before he succeeds in setting it right. However, they have their uses and in many shops are indispensable.

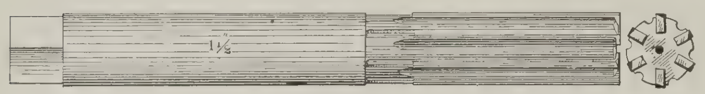

Fig. 35

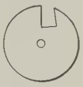

Fig. 36

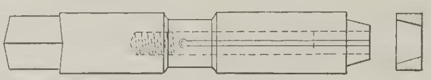

Industrial Press, N.Y.

Fig. 37

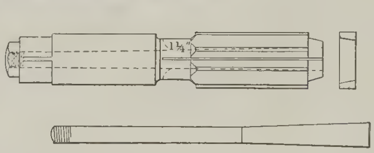

Fig. 38

There are many forms of the commercial reamer, but as most of these require special machinery and tools for their manufacture we will simply consider the most common form—shown in Figs. 37 and 38—which differ from each other simply in the form of the expander.

For making this form of reamer select stock from 1-16 to ⅛ inch larger than finish size. After the ends have been squared to length, the piece of steel should be turned straight and true to a size at least 1-32 inch larger than finish. When drilling the end as in Fig. 37, to receive the expanding screw, the outer end should be run in the back rest while the opposite end should be so strapped against the live center of the lathe that there will be no strain sideways to draw one side of the countersunk hole away from the center. In other words, it should be drawn back squarely against the live center, which should run true. The outer end may now be drilled and reamed to the proper taper. Care should be exercised when doing work of this character that the drill is started true and that it does not run. When it is exceedingly important that the drilled hole be concentric with the outside of the piece, drill a hole ¼ inch or so deep, with a drill 1-32 inch smaller than the size we desire, then with an inside turning tool bore the hole to a size to permit the drill we intend using to enter this hole. It should be a nice fit in the bored hole. There will be very little danger of the drill running, unless it is too thick at the point, in which case it should be "wheeled out" to bring the point to the proper thickness, so that it can cut properly. A drill which is too thick at the point never does good work unless a small drill is run in ahead of it. After drilling, tapping and reaming with a taper reamer the end of the hole should be chamfered to the same angle as the lathe center (60 degrees) to provide a bearing on the center when turning and grinding to size. If this chamfering is done with a tool held fast in the toolpost it will be true with the outside surface which is running in the back rest.

After removing from the back rest the reamer may be turned to a size .010 to .015 inch larger than finish, the wrench end milled square, the teeth cut and the reamer split to allow it to expand. When splitting, use a metal-slitting saw the thickness of which will depend on the size of the reamer. A small reamer requires a thin saw; a large reamer, a thicker one. The splitting should not extend quite far enough toward the end to part the stock and a thin partition should be left until after hardening, to prevent the reamer springing out of shape. This partition may be removed after the reamer is ground, by means of a small, thin emery wheel, or a beveled wheel. A serious mistake when making articles that are split after the fashion of the reamer under consideration, is to carry the saw cut to the end and entirely sever at this point. This leaves the different portions free to go where they please when hardened, thereby occasioning much annoyance, and sometimes rendering the article unfit for use. When hardening, the reamer should be dipped in the bath with the cutting end uppermost, to do away with any tendency for the piece to crack where the narrow partition is holding it.

If the reamer is made as shown in Fig. 38 the above instructions hold good except that it must be reversed in the lathe and the hole for the expanding rod drilled in to meet that from the opposite end. In this case we do not tap the hole. The nut draws the expanding rod into the tapered hole.

The collar which goes on the end supports the cutting edges by drawing them onto the expanding rod, and preventing their opening when in use.

This form of reamer is open to the objection that the cutting end is slightly larger than the balance of the tool; but when the reamer is only expanded a limited amount this objection is not serious in the case of such work as this class of reamer is used on. When it is necessary to have a reamer that will expand uniformly its entire length, it is made with inserted blades which are adjusted by means of a nut at each end, the blade being held in slots which are cut deepest at the cutting end of the reamer.

* * *

EXPORTS OF MACHINERY.

Machinery forms by far the most important feature in our exports of iron and steel manufactures. Statistics upon these products are divided into groups, such as locomotive engines, stationary engines, fire engines, electrical machinery, sewing machines, typewriters, shoe machinery, cash registers, laundry machinery, printing presses, and pumping machinery, are shown in that manner. Aside from these, however, is a great group of machinery which is not stated in separate items, owing to its variety and the large number of different classes of machinery included. This single group of "machinery not separately classified" grew from 10 million dollars in 1892 to over 20 millions in 1902. The next largest item under general classification of machinery is electrical machinery, which was only separately classified in 1898, amounting in that year to 2 million dollars, and in 1902 to nearly 5½ millions. Sewing machines, which amounted to 2¼ millions in 1889, were over 4 millions in 1902. Typewriters, which were only separately stated in 1897, amounted in that year to less than 1½ million dollars, and in 1902 to nearly 3½ millions. Locomotive engines increased from 1¾ millions in 1892 to over 5½ millions in 1900, but owing to the very great demand of the home market upon the manufacturers of the United States, fell to 3¼ millions in 1902. Metal-working machinery, which was not separately stated prior to 1898, grew from 4½ millions in that year to over 7 million dollars in 1900; pumps and pumping machinery is next in order in the class (machinery), a little over 2 million dollars; cash registers grew from $813,000 in 1900, the first year in which they were separately stated, to $1,144,062 in 1902, the other classes of machinery ranging downward in their relative order of magnitude, shoe machinery, printing presses, stationary engines, laundry machinery, and fire engines. Thus machinery alone formed in 1900 55 million dollars' worth of the exports of iron and steel manufactures out of a grand total of $121,913,548 of iron and steel manufactures exported in that year, or nearly one-half of the total. This statement of "machinery" does not include agricultural implements, bicycles, telegraph and telephone instruments, or other articles not exclusively or chiefly of iron and steel. Adding only those items of machinery included under iron and steel manufactures, it may be said that the exportations from the United States of machinery as a group amounts to about $75,000,000 annually. Next in order after machinery is the group: locks, hinges, and other builders' hardware, amounting to 6 million dollars; wire, over 5 millions; pipes and fittings, 5 millions; steel rails, nearly 5 millions; tools, 3½ millions; structural iron and steel, 3 millions; boilers and parts of engines, nearly 2 millions; castings, 1½ millions; and other articles ranging downward in their relative value.

MACHINE SHOP EQUIPMENT.—6.

EQUIPMENT OF THE FORGE SHOP.

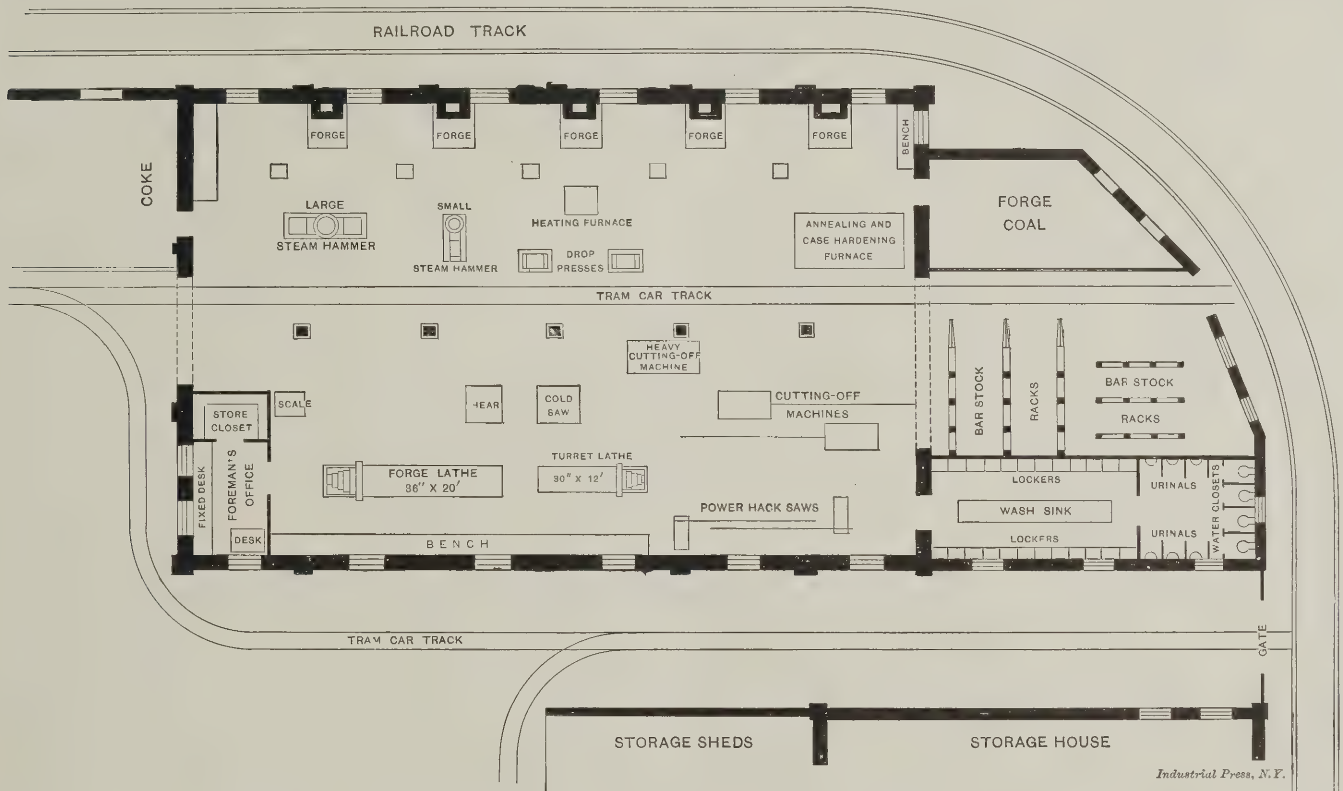
OSCAR E. PERRIGO.

It is undoubtedly true that since the very general introduction of turret lathes, forming lathes, and the large variety of similar machines now in use in almost every machine shop making any pretense to modern equipment and up-to-date methods of doing work, the forge shop has lost considerable of its importance as one of the indispensable departments upon which the machinist of former times very largely depended for much of his material for the better classes of work. The introduction of steel castings, malleable iron castings and other similar materials, superseding in many cases the old-time forgings, has also been an important factor in the same direction, and has decreased the cost of materials of complicated form, and at the same time provided the machinist with materials which have admirably answered the purpose as to strength, and lessened the amount of machining necessary for their practical use.

And yet, while the forge shop may have decreased in the matter of importance in the making of forgings, there will always remain the demand of the machine shop for a certain amount of strictly machine forgings of iron and steel which cannot be met by any other material. Many great and important advances have been made in forging by use of improved hammers, by dies in connection with them, and by the process of drop forging, yet there is a large demand for forgings requiring the services of the skilled machine forger with his expertness in hand forging, as well as his technical knowledge of handling steel of various qualities, his expert knowledge of how to produce forgings of complicated and intricate forms, and the thousand and one conditions and requirements demanded in successfully bringing out such work, correct in form and structure, and within a reasonable cost.

In the matter of casehardening and tempering the forge shop department has increased materially, as there has never been a time in the past when hardened and ground steel work has been as much used in the better qualities of machine construction as at present; and casehardening has reached such an extent that it is rare to find nuts, cap screws and the like on any well-constructed machine that are not protected from injury by this valuable process. While the actual forging work of the forge shop has decreased its scope, it has in a general way much increased in volume, since it is now customary to add to its equipment several machine tools, such as cutting-off machines, forge lathes, heavy turret lathes, cold saws, power hack saws, and other similar machines for roughing out work, which in many instances can be much more economically done by these methods than by confining the operations to forging under the hammer. In this case the appropriate machines for these purposes are included in the equipment of the forge shop and located as will be presently described, and as shown on the plan in Fig. 1.

The foundry floor, the engine foundation, and many of the foundations for machines in the machine shop, should be kept as free from jar and from shocks sufficiently strong to disturb the ground by vibrations, as possible. For this reason the forge shop is placed as far from these buildings as may be convenient; therefore, in the rear corner of the plant, and opposite the rear end of the machine shop. The spur track from the railroad, which supplies shipping facilities and brings to the plant the raw materials necessary for its use, runs across the rear end of the group of buildings, in the rear of the machine shop and storehouse. It continues in a curve around the rear corner and up the side to the foundry gate, rising as it goes, to a height sufficient for conveniently dumping coal, coke, molding sand, etc., into the storage sheds located along that side, the first of which is shown at the left of the forge shop in Fig. 1. The curve of the railroad track cuts off somewhat of this rear corner of the building space and therefore the forge shop is located far enough from the rear line to accommodate it, and the space so left is utilized for a one-story building containing a space for the forge coal, another for bar stock storage, and the wash room and water closets.



Industrial Press, N.Y.

Fig. 1. Plan View of Forge Shop, showing Proper Arrangement of the Machine Tools, etc.

The forge shop is, like the other buildings of the plant, built of brick, with steel roof construction, the roof trusses being supported in the center by steel columns. It is lighted, not only from the side windows, but from those in the monitor roof, the sashes of which are hung on pivots and controlled by cords reaching nearly to the floor, by which they may be operated when necessary for ventilation. The general plan of the forge shop is clearly shown in Fig. 1, which also shows the contiguous buildings and their positions in reference to the forge shop, as well as the location of the railroad track and the tram car tracks connecting this department with the railroad tracks in the rear and the other departments toward the front of the plant. For convenience in bringing in stock and taking out finished work the tram car tracks run nearly

FIG.7 SECTION THROUGH HEATING CHAMBER

Figs. 2 to 7. Elevation and Cross-sectional Views of Annealing and Casehardening Furnace.

midway through the forge shop, as shown, and are connected by their branches with the foundry, the machine shop, storage sheds, and practically all departments of the plant, as well as at three points with the railroad track, two of these being shown on the plan.

The foreman's office is located in the front corner of the shop, and has connected with it the usual foreman's store closet for such minor supplies as are more conveniently kept there than in the general store room near the offices. A fixed desk furnishes a convenient place for spreading out drawings, and a private desk is provided for the foreman's personal use. Outside of the office is a forge shop scale for weighing stock and forgings. This scale should be mounted on wheels so that it can be readily moved to any part of the shop where it may be needed.

Along the outer wall of the shop are located five regular forge fires having chimney flues built into the wall for their accommodation. These latter will not be necessary if the system of down-draft forges is used. This form of forge has several good qualities, not the least of which is that it offers less obstruction in handling large pieces of work, as it may be conveniently placed at a distance from the wall if desired, and will furnish quite as good ventilating facilities in clearing the shop of coal gas as those connected with separate chimneys. The draft may be increased or decreased at the will of the operator, particularly in the case of forges manufactured by the Buffalo Forge Company, in which a hinged and adjustable hood may be closed down over a fresh fire and raised for the handling of the work to be heated, as may be desired. If these down-draft forges are used it will be necessary to provide an exhaust fan with the proper connecting pipes for carrying off the smoke and gases, which may be delivered to one chimney, thus avoiding the expense of building the other four. Such an arrangement is very clean and wholesome for the workmen, when compared with the method shown, but considerably more expensive in its first cost, as well as requiring extra power to operate it.

The forges shown on the plan should be of such construction that the tuyeres may be readily attached and detached when necessary, for cleaning or for repairs. They should have such a form of bottom valve or gate as to readily discharge the clinkers or slag that may find its way down to it. These forges are usually constructed of cast iron and supported upon four legs, so as to give convenient access beneath them for cleaning, attaching the blast pipe, repairing, etc. Each should have, cast with it, or attached to it, two narrow troughs, running the length of its front, or shortest side, for holding coal and water. Many excellent ones are in the market and can be purchased more economically than they can be built on the premises. The blast pipe should be arranged to slide on and off easily, in case it is necessary to disconnect it for cleaning or repairs, and it should be provided with a regulating valve or gate, fitting as nearly air-tight as may be, and operated by a lever conveniently located within the reach of the operator. These forges are usually made of rectangular form, but large fires are often made upon a circular forge, whose sides extend to the floor. They need not necessarily be provided with the water and coal troughs as mentioned above, as they are usually used for heating work for the steam hammers, drop presses and similar large work, rather than for tempering, tool forging or small work of this class.

The blast for these forges, for the heating furnace for the drop presses, and for the casehardening and annealing furnace, is furnished by a fan blower designed for a pressure necessary for forge work, and having an outlet of six inches in diameter, equivalent to a No. 3 Sturtevant steel pressure blower, which is admirably adapted for this purpose. It should be located over the bench near the forges, at the front end of the shop, so that there may be no unnecessary turns or bends in the pipe leading to the forges. These pipes should be placed along the walls near the floor, but never beneath it. In one shop the writer saw blast pipes, composed of vitrified drain tiles, the joints made with Portland cement, and laid less than a foot beneath the surface of a dirt floor of the forge shop, and at one point passing directly under a bolt header. As might have been expected, the jar of the shop floor broke up the pipes and destroyed their usefulness. The blast pipes should be constructed of heavy galvanized iron, well fitted and fastened, and as nearly air-tight as may be. They should be easy of access, for the possible connection of additional pipes and for convenience of making repairs, which will have to be made sooner or later. They might be placed six or seven feet high, and along the walls, but this position will necessitate about thirty feet of additional pipe, increasing the friction of the air and consequently the power required, with no especially compensating gains other than getting the pipes up, out of the way somewhat.

Some of the more important rules for setting up and connecting forge blowers may be here given. Place the blower as near as possible to the forges. Make the pipe connections as direct as possible. If bends or elbows are absolutely necessary, make the curves of large radius, and with no abrupt angles; the inside radius of an elbow should not be less than twice the diameter of the pipe. Have the aggregate areas of all the outlet pipes at least equal to the delivery pipe at the blower. If the pipes must carry the air over one hundred feet, speed up the blower proportionately above the figures given in the manufacturers' catalogue. In any event, the blower should be run at such a speed as will give four to five ounces pressure at the tuyeres, not less than four ounces at the forge furthest from the blower.

The blower is driven from a line shaft running the length of the shop near its center. In front of the first fire is located a large steam hammer of the arched pattern, and capable of handling work up to ten inches in diameter. At the next fire is a smaller, single-column steam hammer of about half the capacity. The necessity of providing the larger hammer will be a matter to be decided by the size of the largest forgings to be made. For instance, if only a few forgings which come up to its capacity are to be made, it will be more economical to purchase them of some large forge shop than to provide a large hammer that may be idle much of the time. The smaller hammer should be provided for even moderate-sized work, for any plant of modern pretensions.

Next to the small hammer two drop presses are located, with a special heating furnace for use in connection with them. These drops should carry hammers weighing from one hundred and fifty to six hundred pounds, according to the work which they are to do.

The heating furnace need not be over thirty inches square outside, built with a cast-iron shell lined with fire bricks, supported on four cast-iron legs, and provided with a vertical sliding, balanced door in front. The heating chamber will be about twenty inches square and from ten to twelve inches high. A blast pipe leads up to it, and a smoke pipe from its rear side leads to the nearest chimney. Such a furnace will heat work for drop forging much more economically and satisfactorily than the usual open forge fire. They may be purchased at a very moderate cost.

The forge fires not occupied with steam hammer work will be used for ordinary hand forging, tool forging, tool dressing, tempering, and similar work. Where much tempering of special work is necessary, that is, when a large number of pieces of the regular product of the plant is to be so treated, special arrangements as to heating furnaces, dipping baths, etc., must be provided, and in many cases special automatic heating and hardening furnaces are employed. Obviously, the great variety of this class of work precludes a detailed description in this article.

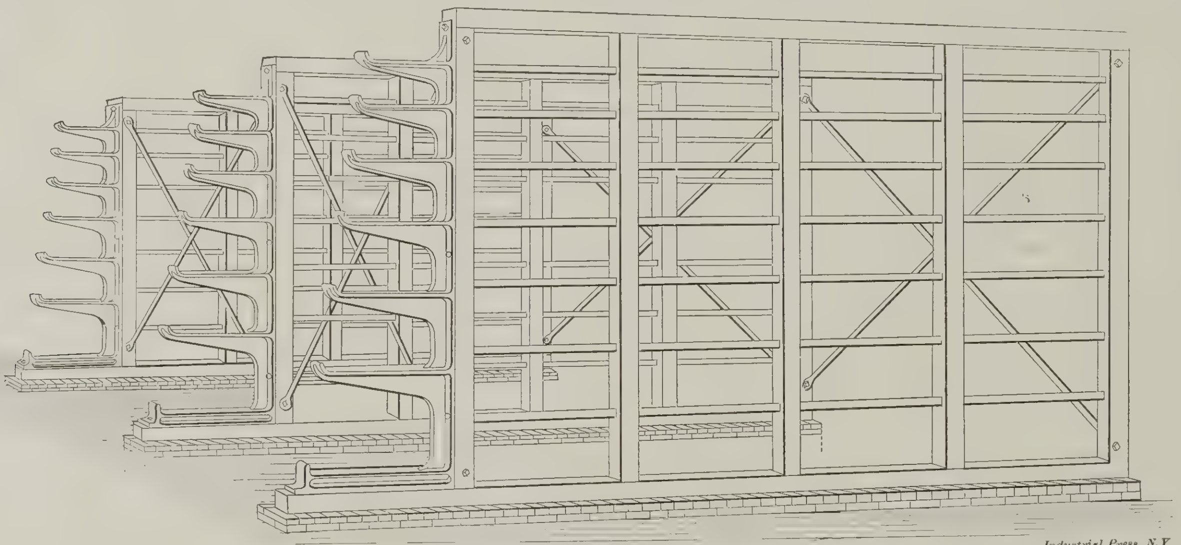
Near the end wall, at the rear, is located an annealing and casehardening furnace of ample capacity. As this will be built on the premises, and as information in reference to its requirements and its construction may not be readily available, drawings have been made showing the details of its construction and giving all necessary dimensions. While this is for a furnace of quite large capacity for a machine shop plant, a smaller one may be readily constructed on proportionate dimensions, with good and practical results. If it is to be of, say, one-half these dimensions, or one-fourth the capacity, the lower heating ducts will be single instead of double, and it will be preferable to build it with a cast-iron casing inclosing all four sides, forming the door frames, and the separate pieces being bolted together at the corners, instead of having the brickwork held together by binders and rods as shown in the drawings.

The construction is clearly shown in Figs. 2, 3 and 4, being respectively a front, side and a rear elevation. Fig. 5 is a cross-section through the firebox *A*, showing the bridge wall *B*, the form of the covering arch *F*, and the position of the blast pipe *G*. Fig. 6 is a longitudinal section showing the firebox *A*, heating chamber *C*, heating ducts *D*, *D*, and sections of the front and rear doors. Fig 7 is a cross-section through the heating chamber *C*, the heating ducts *D*, *D*, dividing wall *M*, and the main door *N*. The foundation should be laid deep enough to support the weight of the furnace and its charge, and will be quite similar to that provided for boiler settings. The shaded portions indicate fire bricks, the balance being ordinary, hard, red bricks. The grate bars are of any convenient pattern, but must have ample air spaces so as not to impede the air blast delivered through the blast pipe *G*. The top arch is of fire brick and is carried all the way through both front and back walls, for convenience in making repairs upon it. The floor of the heating chamber is composed of fire brick tiles five inches thick, nine inches wide and twenty-four inches long, their outer ends supported by the inwardly projecting side walls, and their inner ends by the dividing wall *M*. They are laid about an inch apart so as to permit the gases and smoke to pass down between them to the heating ducts *D*, *D*, and out through the smoke pipe attached to the rear door *L*. The frame and door of the firebox are from the same pattern as the rear door *K*, while the frame of the ash pit door *J*, and the smoke door *L*, are from the same pattern. The doors are different, of course, as the door *L* must be provided with a circular sleeve to which the smoke pipe is attached, its other end connecting with the nearest chimney. The main door N, through which the annealing boxes are introduced, and removed, is of special construction and fitted with a fire brick lining, perforated by a circular opening or "peek hole," and held in place by four bolts (as shown in Fig. 3), which pass through iron straps on the inside of the fire brick lining. The stopper P is of tubular form and has an inwardly-projecting flange at its inner end for the purpose of holding the lining, which is composed of fire clay packed in as solidly as possible while it is slightly wet. This stopper may be removed at any time to obtain a view of the interior of the heating chamber and its contents during a heat, as all the doors are tightly closed and the cracks fluted with fire clay as soon as the fire is well under way, one charge of coal being usually sufficient for the heat after the furnace has been heated up.

The blast pipe furnishing the blast for the forges will also supply this furnace, the pressure required being the same, and will be connected to the fixture G located in the wall of the ash pit for that purpose.

Such a furnace as has just been described will, if properly built, and with occasional repairs to the fire brick lining, last many years. The writer knows of one which was built twenty years ago that is in serviceable condition at the present time.

On the opposite side of the central columns is located the group of machines for roughing out stock, the first being a heavy cutting-off machine capable of taking in stock up to six inches in diameter and cutting it off to any required length. In this machine there should be two tools fed automatically, and the machine should be provided with a convenient speed changing device whereby the surface cutting speed may be maintained constant at all diameters, as this latter feature will materially increase the output of the machine.



Industrial Press, N.Y.

Fig. 8. Rack for Bar Stock, for Storing Long Bars of Iron and Steel.

Next to this machine are two cutting-off machines of a capacity for four-inch stock and arranged similarly to the larger machine. They are so placed as to be conveniently operated by one man.

Next to these machines are two power hack saws, provided for cutting off square and flat stock. These should carry from twelve to fifteen-inch saws, and while apparently slow-working machines, are capable of cutting off a large quantity of stock in proportion to the labor cost of attendance.

Located near the large cutting-off machine is the cold saw, which will serve for stock or forgings beyond the capacity of the cutting-off machine or the power hack saws, and will often save much valuable time in finishing up a forging. The saws in these machines are from twelve to forty inches in diameter, the former size cutting off stock up to three and a half inches in diameter, and the latter handling thirteen-inch stock. For this case the saw should be twenty inches in diameter, and capable of cutting off seven and a half inch stock. There are many of these saws in the market and apparently not very much choice between them, all conditions being considered.

The shear, located next to the cold saw is not generally as much used as before the power hack saw came into notice, yet in certain classes of rough work it is very useful and operates quickly. It should be able to cut off round stock up to one inch, square stock to the same size, and flat stock to a half inch by two.

In the heavy turret lathe much work may be roughed out from the bar and sent to the machine shop in a more satisfactory condition than if it had been forged, and at the same time it will do the work more economically. It should take in stock up to three inches in diameter and be provided with a heavy, open, hexagonal turret, bored so as to allow the stock to pass entirely through it if necessary. It should also be provided with heavy roughing tools somewhat similar to box tools, as well as a heavy cutting-off slide adjustably supported on the bed.

The forge lathe, located next to the turret lathe, will be useful in rough-turning spindles and similar heavy work, and doing it much cheaper than forging the work down to close dimensions. It should be built for cuts of six or eight to the inch, and a cutting speed from one hundred feet per minute and slower.

A short work bench and vise is provided at each end of the line of forges for the convenience of the blacksmiths, and a much longer one on the opposite side for the men running the machine tools, which should have three vises upon it.

A supply of steam will be needed for the steam hammers, and may be brought from the power house in a conduit, the pipes being properly protected by a non-conducting covering to prevent, as far as possible, the loss of heat. But these hammers may be operated by compressed air, which will not be subjected to such loss. And as power will be required to run the line shafting driving the various machines it may be more economical to bring in a current of electricity with which to drive one or more motors, by which the line shafting may be driven and from which a small air compressor may be operated, thus bringing the power within the building and under the control of the foreman in charge of it. This plan would seem more advisable than the other. If an air compressor is used it may be located between the shear and the scale, and the reservoir connected with it placed directly overhead.

If an electric motor is used to drive the line shaft it will be convenient to place it overhead and near the center of the shaft, on a platform erected for the purpose, rather than to place it on the floor level, where it will be subjected to dirt and accidental injury.

A jib crane may be erected to serve the large steam hammer and an overhead trolley for the smaller one, the latter being the more economical of the two, and will be found nearly as convenient for comparatively light weights. The I-beams carrying the trolley and hoist should run from a point nearly over the center of the forge to a point close to the left side of the hammer, as seen on the plan.

Pneumatic hoists may be conveniently used not only on this trolley but in a similar way at the forge lathe and over some of the other machines for handling heavy bars. They work quickly, are easily handled, and when necessary may be readily moved from place to place.

The space for bar stock is located conveniently to the railroad track and the tram car track, and contains two racks for bar stock, the larger one for full length bars of iron and machine steel, and the smaller one for ordinary cast steel and tool steel bars. The larger of these racks is shown in perspective in Fig. 8. This is constructed of oak timbers formed into a rectangular frame, strongly bolted together and resting on good foundations capable of supporting the heavy weights of stock likely to be placed in the racks. Three of these frames are erected, six or seven feet apart and braced by cross-braces as shown. The timbers should be six inches square and provided with iron supports for the bar stock. These should be spaced further apart at the bottom than at the top, the bottom space being, say, fifteen inches, and the top space eight inches, center to center of cross bars. These supports should be flat, say, five-eighths by one and a half inch for the upper three; for the next two, three-quarters by one and three-quarters; and the two lower ones, one inch by two. It may be preferred to make the three or four lower supports of one and three-eighths-inch round steel, upon which are placed pieces of one and a half-inch gas pipe, turning freely, and so facilitating the running in and out of heavy bars. As seen in the engraving, the right-hand end of the frames may be securely bolted to the brick walls, and the cross-braces on this end be omitted. At the opposite, or front end of the frames, the sill timber projects from the front of the frame about three feet, and upon this are erected heavy cast-iron supports, of the form shown, which will be found very convenient for holding heavy bars, as they are open at the front, and bars may be readily lifted from the tram cars to them. Experience has shown this to be a very convenient, useful and substantial form of bar stock rack. In place of wooden timbers cast-iron supports may be used, but the cost will be much greater and the results not enough better to compensate for the added expense.

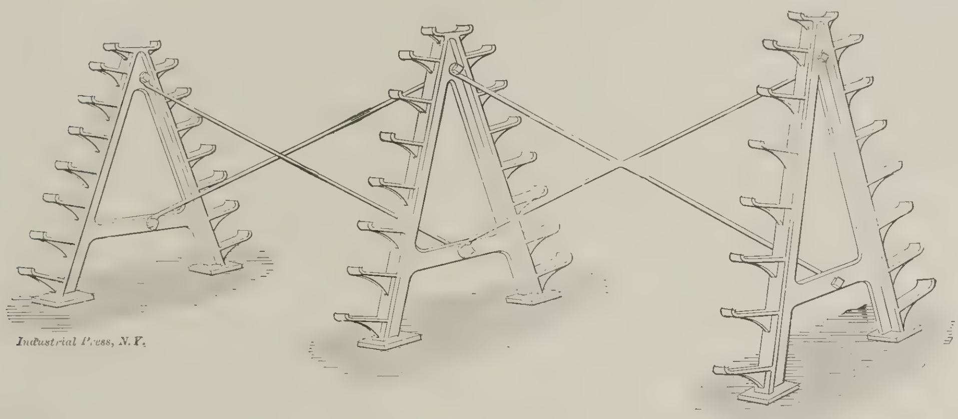


Fig. 9. Small Rack for Ordinary Cast-steel and Tool-steel Bars.

The smaller rack is built on the same plan, and may be constructed with or without the cast-iron racks in front of it. It should have substantial cross-braces between its frames, and also be securely braced from the brick wall.

For a shop rack the form shown in Fig. 9 will be found very convenient. The A-shaped supports are of cast iron, securely braced by cross-braces bolted on as shown. The base of the supports might be made relatively narrower than shown in the drawing without endangering their stability. Such a rack may be made of any number of supports and placed at any desired intervals apart that the work may require. Once we have the pattern, we may make as many castings as we choose and arrange them to suit any existing conditions. Usually they should not be over five feet high, unless rather small and light stock is to be placed on the upper supports. The lower projecting supports may be about ten inches long and the top ones about seven inches.

The wash room is located in one of the rear corners, and in connection with the water closets, which open out of it. A single wash sink of similar construction to the one illustrated and described in the article on foundry equipment is provided, and the individual lockers for the use of the men, and built of expanded metal, are arranged on both sides of the room in the usual manner. In the water closets six urinals and four closet seats are provided, the latter protected by double-hinged swinging doors, and the former separated by dividing partitions two feet wide. Both should be provided with an ample supply of water for automatically flushing them. The windows lighting the wash room and water closets are placed high enough in the wall so as not to interfere with the lockers or the urinals.

By the plans herein given all of the requirements of the operatives are placed conveniently within the building, so that whether for stock, fuel, or any reasonable cause, there is no necessity of leaving the building, as it is a well-known fact that men working near artificial heat, as do those at forges, are very sensitive to both heat and cold out of doors.

DURANGO'S IRON MOUNTAIN.

This solid mass of iron ore, close to the International Railroad depot at Durango, has figured in story and fable ever since the Spaniards and the Mexicans from the south first reclaimed this region from savages akin to the Apaches, over three hundred years ago. Geologically, examination shows it to be a very remarkable "dike," emerging from a rocky plain at the elevation of 6,300 feet, rising from 400 to 650 feet in height itself and forming a tremendous lump of iron ore 1 mile long and one-third of a mile wide. It has been calculated to contain 500,000,000 to 660,000,000 gross tons above the surface, with no notion of what may be below. The ore is a hard specular hematite, carrying on an average 60 per cent. of metallic iron, much of it going higher and some even to 67 per cent. It is suitable for practically all processes of iron and steel making.

One might think that such a property as this, where "mining" consists simply in knocking down the sides of a mountain to obtain a rich iron ore, in a country whose industrial expansion is demanding larger and larger importations of iron and steel, would be better than the best proverbial bonanza of gold. The fact is, however, that the Mexican National Iron and Steel Company, an American concern, whose mining claims cover about one-half the mountain, has never until lately been a paying concern. This seems to have been due, first, to the fact that it was formerly operated with a view solely or primarily to sale of stocks, and, in the second place, to the difficulties in securing at a reasonable price fuel with which to operate it on a paying basis. Charcoal can be obtained near here, made from the timber on the Sierras to the westward, but its production has always been limited and relatively expensive. Coke was formerly brought from the United States and at such prices that the marketing of the company's iron products in Mexico, except at near-by points, was, when the high freight rates were added, very commonly at a loss, or no gain, in competition with American iron products. As stated, Mexican coke is now obtained and at considerably lower prices. Moreover, the concern is being managed primarily as a business enterprise. Facilities are being added for an increased output, and everything augurs great prosperity for this institution, which now turns out in its foundry and machine shops steam engines, hoisting machinery for mines, stoves, and simpler products, such as nails, as well as bar iron. The steel plant, which the company's name implies, may soon be added.—*Consular Report, No. 1812.*

* * *

The total value of American machinery and tools imported into Switzerland during the first six months of 1903 was $107,000.

MACHINERY

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

66-70 WEST BROADWAY, NEW YORK CITY.

CHICAGO—1462 Monadnock Block. BOSTON—620 Atlantic Ave.

LESTER G. FRENCH, Editor.
FRED E. ROGERS, Associate Editor.

The receipt of a subscription is acknowledged by sending the current issue. Remittances should be made to THE INDUSTRIAL PRESS, and not to the Editors. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

FEBRUARY, 1904.

NET CIRCULATION FOR JANUARY, 1904,—26,694 COPIES.

MACHINERY is published in three editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages. The Engineering Edition—$2.00 a year—contains all the matter in the Shop Edition and about 250 pages a year of additional matter, which includes a complete review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering, but is printed on thin paper for transmission abroad.

SUGGESTIONS THAT HELP.

As a matter of course the editors of a technical journal receive a great many inquiries from subscribers, asking for information upon various subjects. In our own field we endeavor to give the information desired, either through the "How and Why" department, or if the subject is not of general interest, by referring the inquirer to some text-book or article which will tell him what he wants to know. We do not consider it within the province of a technical journal to devote space to matter that can easily be found in the ordinary books of reference, and thus take room that should be devoted to more timely matter of current interest.

Probably the readers of MACHINERY do not fully appreciate that such letters of inquiry are frequently of great service to the editors, in that they suggest topics for articles upon which published information is apparently lacking. A case in point is a contribution this month by Mr. Herbert E. Field, upon compositions and bronzes. A subscriber wrote us that he had tried to produce a very strong alloy by following Prof. Thurston's well-known formula of 55 per cent. copper, 42.5 per cent. zinc and 5 per cent. tin. According to Prof. Thurston a bronze of this mixture had shown under test a tensile strength of 68,000 pounds per square inch, yet our correspondent had not been able to produce a casting of over half this strength. Investigation showed that while handbooks contained statements of proportions for mixtures for alloys, nothing was said in any of them about the methods of mixing, melting and pouring to produce the best results; and it was at once evident to us that an article on this subject, telling what a man who had to make very strong bronze castings would want to know, would be of assistance to many readers, although this had not occurred to us previous to receiving the inquiry.

Another instance is a contribution in a recent number upon the coloring of metals. This was written as the direct result of an inquiry by a subscriber who could not obtain information about the best methods for producing blue, black, brown and other colors on steel, brass and copper. We found that very little had been written upon this, and that what had appeared was not fully treated, and so arranged for the article in question.

We should like to have these two instances of how subscribers have assisted us in securing interesting or valuable articles, serve as a hint to others, and accordingly ask any to write us, who are seeking information upon subjects which they believe would prove of interest to others as well as to themselves, if presented in the columns of MACHINERY. We believe we can render additional service to our readers in this way, as we have on file the names of specialists who are qualified to write authoritatively upon many branches of shopwork, machine design, and kindred topics.

Do not hesitate to send us suggestions.

* * *

IS THIS GENERAL ENGLISH PRACTICE?

The American machine tool builder who goes to Europe to introduce his product should be prepared for some surprises, agreeable and otherwise. In locomotive shops, for instance, he will very likely be impressed with the fact that in Europe locomotives are better built than in America—in a certain sense. They are highly finished, closely fitted, and generally designed for long service—how long, depends on the traditions and sentiments that eventually attach to many locomotives. But in the machine shop practice he will undoubtedly find some features not so pleasing. A gentleman, who recently visited Europe in the interest of the machine tool business, says that drilled and reamed centers in lathe work are practically unknown in many English shops. The standard taper of American lathe centers is 60 degrees; that of English lathe centers is 90 degrees (or thereabouts). As will be inferred from the foregoing, the reason for using such blunt centers is the very good one, or rather the very bad one, that all small and medium-sized work is centered with the prick-punch. The centers are *worn* into the work by heavy pressure applied on the tailstock. In fact the common practice is to put the work between the centers and screw up *hard* on the tailstock spindle for a few moments with the work revolving; then reverse the work and treat the opposite end in the same manner. Of course no 60-degree center will stand such treatment. And the 90-degree centers are found there worn into all kinds of fantastic shapes, approximating the Schiele curve, so-called.

The foregoing, relative to lathe centers, has a serious commercial aspect to the American machine tool builder when it is found to interfere with the production of accurate work. From one English shop in which a universal grinding machine had been installed, a complaint was sent that the machine did not grind work with the accuracy guaranteed by the makers. Investigation showed that the prick-punch method of centering was also being used on the grinding machine work! The suggestion was gently made that the centers should be nicely drilled and reamed to an angle of 60 degrees to fit the centers on the machine. Objection was raised that the shop had no facilities for doing this, but after some argument some Slocomb combination center drills were produced, though the proprietor insisted that they had never been able to make the "American gimcrack" work satisfactorily—that they invariably broke before the center was reamed to the proper depth. Further investigation along the line revealed that the spindle of the machine used for the purpose ran at only about 80 revolutions per minute. It was pointed out that it should run fully twenty times as fast, and when this change was made the troubles of center reaming and grinding were cured.

* * *

One of the surprising experiences of the writer has been that of visiting the plant of an old, well-known manufacturing concern and finding in what an out-of-the-way place it is located. Not as regards the town, but the site of the works—down in a narrow gorge, exposed to damage by floods and remote from the railway so that all supplies and product have to be hauled, at heavy expense, by teams. The reason for such a location, of course, is not far to seek; it was the water power, and in early years cheap power meant a great commercial advantage, perhaps more than now for many industries. Thanks to electrical transmission of power all these water powers can be made useful without placing the actual location of the plant where it is difficult to get at; it may now, in most cases, at once enjoy the commercial advantages of water power and convenient location to lines of travel. This condition is recognized to the extent that old water powers which had fallen into disuse, are being resurrected and made to turn the wheels of industry miles away. In a paper "The Influence of Electricity on the Development of Water Powers," read before the last semi-annual meeting of the New England Cotton Manufacturers' Association by Mr. F. A. C. Perrine, attention is called to this changed condition of affairs as regards water power for cotton mills. Mr. Perrine, however, expresses the belief that as a general proposition it does not pay to develop a water power where the first cost exceeds $300 per horse power for continuous power, and $200 for variable power, which makes the installation of a steam plant necessary for slack water periods.

* * *

THE DANGEROUS AUTOMOBILE.

That automobiles, or rather those racing machines which are the outgrowth of speed madness, can be built to run at great speed—equal to that of the locomotive even, has been quite amply demonstrated during the past year or two—quite too well in fact for the peace of mind and physical well-being of other road users. The latest exploit is that of whom the New York *Times* is pleased to call "a young speed maniac," who succeeded in covering one mile in 39.4 seconds on the ice of Lake St. Clair near Detroit, Mich. The ice was cleared of snow for a distance of five miles in a straightaway course. Hot cinders and sand were then spread on the course to a depth of one-half inch. This was cleared off as much as possible before the test was made. Notwithstanding the almost ideal conditions for fast speed the run was attended with great excitement and hazard for the chauffeur. What the mortality would have been if the course had been a country road lined with spectators it would not be pleasant to contemplate. The *Times* concludes an editorial comment with the following scathing arraignment of high speed machines in general:

> "Machines capable of a fraction of the speed attained at Detroit should be subject to indictment as public nuisances even when standing in the shed. They are to be classed with infernal machines, spring guns, mantraps, and other things in which reside the potentialities of manslaughter and homicide. Their manufacture promotes the end of the industry, by making necessary the enactment of even more stringent legislation than has yet been seriously proposed as the alternative of a recourse on the part of the public to summary measures of self-defense. It would be entirely proper, in the light of experience, to make the possession of a machine capable of materially exceeding the legal speed limit an offense of the kind committed in the carrying of concealed deadly weapons. To own a kit of burglar's tools is a crime, even though the owner cannot be shown to have used them burglariously. To carry hidden weapons is a misdemeanor, even though the possessor is to all appearance peaceably inclined. An automobile which can be run at dangerous speed sooner or later will be so run. If its owner has too much self-respect or respect for others to abuse it, some servant will do this the moment his back is turned. There is something in human nature which cannot resist the temptation to go fast when the means are at hand; and, curiously, those want to go fastest whose time is worth least."

* * *

THE DATA SHEET FOR FEBRUARY.

The data sheet for this month is planned to be of assistance to the designer in computing the weights of parts and for general estimating purposes. The first table presents a diagram of the weight of sheet metal for different thicknesses, both in metric and English measurements. In this country and in Europe thousands of tons of metal are sold annually by the weight per square foot, as this is considered more convenient and reliable than any other form of measurement, since owing to the operation of the rolls it is difficult to caliper the metal accurately by the edges, as the center is often thicker. In shipbuilding particularly the metal is specified in weight in pounds per square inch. In Europe material is commonly specified by thickness in millimeters and by the weight in kilograms per square meter. This table is arranged with a view of convenience in changing from one method of measurement to any other.

On the left hand side of the diagram the weight of sheets of various metals for a given thickness is given in kilograms per square meter, while on the opposite, or right-hand side, is given the weight of the same sheets in pounds per square foot. At the top of the diagram is given a scale of the thickness of a sheet in millimeters, while at the bottom is, first, a scale of 1¼ inch in hundredths and a corresponding scale in 64ths of an inch; next a scale of the thickness in United States Standard gage, while below is the same in Birmingham wire gage. Thus the diagram not only shows at a glance the weight in pounds per square foot, or in kilograms per square meter, but it also answers as a conversion table for the weight of sheets designated in any one system of units to any other units desired.

Table 2 gives the approximate weight of cast iron gears from 12 to 144 inches in diameter and having cast teeth from 1 inch to 6 inches circular pitch. These weights are the average of over four thousand standard gears that were weighed by the compiler during a period of four years. For estimations where the exact weight is not required the results derived from this table will be found to be quite accurate enough for all ordinary purposes. The figures given are for one inch of face and, for obtaining the weight of any gear, it is only necessary to multiply the number under the required diameter and pitch by the number of inches of face.

Table 3 gives the areas, circumferences and weights of the commercial sizes of cold-rolled shafting. For the weights here given we are indebted to the Jones & Laughlins Company, Pittsburg, Pa.

Page 4 comprises four tables, the first of which gives the weight of cast iron per superficial foot for various thicknesses. The second table gives the weight of nuts and bolt heads, and will be found useful when figuring the weight of long bolts. In this case the length of bolt under the head would be figured as a bar of given diameter and length and to this result would be added the weight given in the table for the nut and head. The last table gives the weight per cubic inch and per cubic foot of nearly all of the common metals and alloys and their specific gravities.

* * *

LARGE UNIVERSAL CHUCK.

What is undoubtedly the heaviest universal chuck ever built, in this country at least, was constructed last summer at the works of the R. D. Nuttall Company, Pittsburg. The diameter of the faceplate is 132 inches and its weight is 34,600 pounds. It carries eight jaws which are operated simultaneously by a ring bevel gear containing 266 teeth 2 diametral pitch and 2½ inches face. These teeth engage the pinions on the screws, which have 14 teeth each. The gear ring also has 266 spur teeth 2 diametral pitch cut in its periphery for the spur pinion gear through which the ring and jaws are operated. The pinion gear is not mounted in the faceplate but is attached to the frame of the machine, provision being made for throwing it into gear when the jaws are opened or closed. The screws moving the jaws are 2½ inches diameter. The chuck is driven by a pinion working in an internal gear cut from the solid on the back of the faceplate. The teeth were cut by a Newton gear planer or slotter having a capacity up to 30 feet diameter. The internal gear contains 120 teeth 1 diametral pitch and 9 inches face.

* * *

HUMOR OF A STRIKE.

Two strikers were picketing the entrance of an alley during the strike at the factory of the Kellogg Switchboard and Supply Company in Chicago last May. A non-union man came out of the factory and started across the street. One of the strikers picked up a brick. As he looked at it an expression of disgust came over his face and he threw it down.

"Why didn't you throw it at that scab?" asked the other striker.

"Because it is a non-union brick."—*The World's Work.*

* * *

A simple method of finding the height of high interiors, is to use a toy balloon attached to a thread. When the balloon touches the roof or ceiling, the floor line is indicated on the thread by a knot and the length measured along a convenient horizontal plane. This method was successfully used in the measurement of the height of cavern roofs in the Mammoth Cave, Kentucky.

HIGH-SPEED TOOL STEEL TESTS.

We have received from the Lodge & Shipley Machine Tool Company, Cincinnati, O., a summary of the results of tests upon high-speed steels which have been conducted at their works. This company was one of the first to adopt the Taylor-White process for treating steels for high-speed tools and have since tried nearly every high-speed steel that has been placed upon the market. While testing one of their high-speed lathes, which was designed to meet the new conditions brought about by these new steels, the experiments referred to were made with a view to finding the relative value of the several steels offered by different dealers, what speed limit it was possible to maintain with each, what the breaking-down points were, etc. The lathe used was a Lodge and Shipley 20-inch equipped with high-speed head, tailstock and double tool rest. The spindle is exclusively gear driven with two changes of speed, the ratios from pulley to spindle being 3.1 and 9.1, secured by sliding gears operated by a handwheel in front of the headstock. The tailstock is massive, and held to the shears by four bolts running through to the top. The carriage is equipped with two plain rests, both operated by telescoping screws and the same handwheel, which has a clutch in each end of the hub to engage with either front or back rest screw, as may be desired. The front tool rest has a transverse adjustment to permit easy setting of the tools and the dividing up of the cut when necessary. The power was derived through a 6-inch belt from a No. 3 Chard variator mounted on the ceiling and belted from lineshaft. This variator gives eight changes of speed, secured instantly without stopping the lathe. With the constant shaft running at 235 revolutions per minute, 637, 506, 376, 272, 200, 146, 108 and 85 revolutions per minute were secured at the variable shaft of the variator.

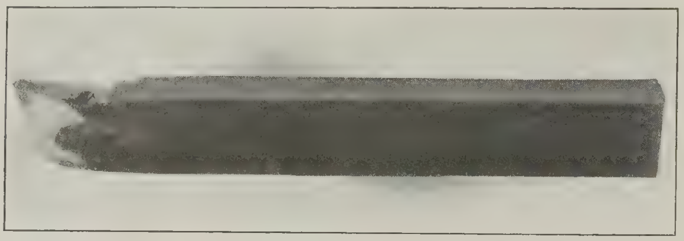

Fig. 1. Condition of Lathe Tool after Tests were Made.

Seven brands of steel were selected for tools and labeled from A to G, respectively. Several tools of each were made, all alike, and the different tools of each brand were indicated by numbers.

Limit tests were made with a 5⅛ diameter bar of machine steel containing about 0.18 per cent. carbon. Preliminary tests were made while removing scale to determine in about what order the tools might stand so as to give the better ones the higher speeds. Cuts of ⅛ depth by 1-20 feed were then made, and here tool A-2 with a cutting speed of 201 feet per minute cut a total distance of 14¼ inches without breaking down. Its nearest competitor was a tool which ran 6 inches at a speed of 180 feet per minute, the others ranging from 1½ to 5 inches at a cutting speed of about 190 feet. The bar was then turned round and a light cut taken over it at a depth of 1-32 inch by 1-40 inch feed. Tool A-2 again led, running 25 inches at a cutting speed of 361 feet per minute. The next best was a tool which ran 18 inches at a speed of 305 feet. The balance ranged from ½ inch to 6 inches.

Tests on cast-iron were then made, using a casting 8 inches in diameter and 12 inches long, clean of sand, and of about medium grade iron. After removing the scale light cut tests were run with 1-20 feed and 1-16 depth of cut, at 184 feet surface speed. Here some of the tools broke down instantly and most of the others did but little better, tool A-2 being the only one which ran across the casting, and one other ran 2⅛ inches. With a medium cut of 1-10 feed and ⅛ depth and about 1-19 surface speed most of the tools made a little better showing, although several broke down at once. Here again A-2 made a record of 15 inches. One of the B brand tools made the best showing of the balance, with two of the tools of the A brand falling in the rear but still leading the others.

The result of these tests shows that brand A, of air-hardening steel, tempered at a high heat in oil, is far superior to the others. All of the tests were run dry.

These trials were supplemented by several other endurance tests, using the two brands of steel showing the best records in the limit tests. Twenty-five back-gear sleeve forgings were selected, of about 0.18 carbon machine steel, and with from ¼ to ⅜ inch in diameter to be removed. This series was run with the tools wet, there being two tools, one in each rest, and the back tool removing only sufficient to keep under the skin of the forging most of the time. The body of the forging was 2⅞ inches diameter, with a large collar at one end and a total length of about two feet. Both tools required regrinding after finishing eight forgings, at a total of 152 feet longitudinal feed of tool at a surface speed of 169 feet. After regrinding the tools, seven pieces were finished when the back tool broke down, the front tool, however, being still in a very fair condition. They then tried a single tool, A-2, and finished nine pieces, or one more than the full run of the double tools, and found the tool still good for further use. The condition of the tool being somewhat interesting, it is shown in Fig. 1. The friction of the chip curling from the tool has worn a concave spot on top of the point, while there is no evidence of wear on the cutting edge. The outlasting of the single tool over the double, is attributed to hard spots in the forging, as in later tests on bar stock they have demonstrated a saving in the use of two tools.

Among other tests made was one upon a lot of back-gear forgings, similar to but larger than those mentioned above, in which the total time for handling and turning, by a lathe hand, unassisted, was 24 minutes, for eight forgings, or at the rate of 200 in 10 hours, although this rate could not have been maintained all day by the same man. The tool used was A brand steel, oil hardened, and was in good condition at the close of the experiment. Fig. 2 shows the forgings as rough-turned during the experiments. The larger pile contains 30 pieces rough-turned on the long end only and represents 1½ hours work had the same rate of speed been maintained for the lot as was recorded for the eight mentioned.

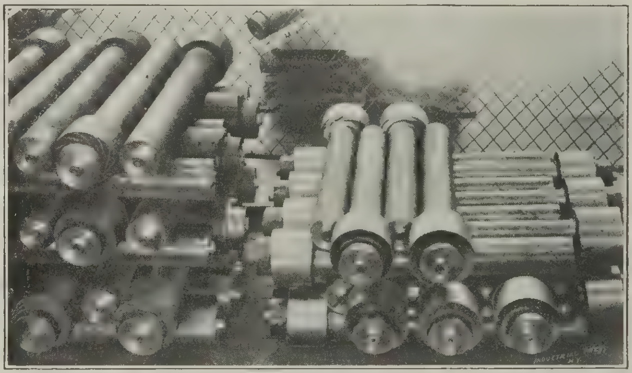

Fig. 2. Pile of Lathe Spindle Forgings Rough-turned during Experiments.

Another series of experiments were conducted to show the horse power consumed by the lathe and variator, while taking a cut at different speeds. It was quite clearly demonstrated during these tests that the higher speeds required much more power to remove a given amount of metal than the lower speeds and also that the angle of cutting edge of tool affected the power. With a depth of cut of 1-16 inch and feed of 2-15 inch about 18 horse power were required at a surface speed of 175 feet. With the same depth of cut and 1-10 inch feed about eight horse power were required, at 121 feet per minute. With depths of cut of ½ inch, feed 1-20, and speed 160 feet per minute, over 30 horse power were required, while at 128 feet only 19 horse power were necessary.

* * *

Articles of iron can be protected against iron rust by sinking them near the negative pole of an electric bath composed of ten liters of water, fifty grams of chloride of manganese and 200 grams of ammonium nitrate. Under the influence of the current the bath deposits on the articles a protecting film of metallic manganese.—*Mining World.*

THE RIEDLER-STUMPF STEAM TURBINE.*

AN IMPORTANT GERMAN WHEEL IN SUCCESSFUL USE.

"Extended study and experiment, in an entirely untried direction, having for their goal the overcoming of the many existing defects," writes Dr. Riedler, "have led Prof. Stumpf and myself to the creation of a new system of turbine construction."

The fundamental considerations were as follows:

From a purely dynamic standpoint the peripheral velocity of the wheel need be only half the velocity of the steam in order to gain the full force of the steam. This is the idea underlying De Laval's construction, which led to unserviceable rotary velocities and made the use of reducing gearing necessary. Therefore, in order to make any progress possible, while using the single or one step pressure effect and without essentially changing either the velocity of the steam or the peripheral velocity of the wheel, the following details must be technically accomplished:

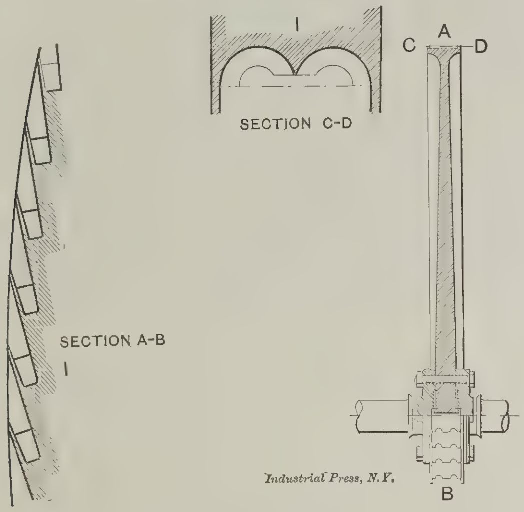

Fig. 1. Sections of Buckets.

1. When operating under the one step effect.—The diameter of the wheel should be so increased that with a practical speed of from 1500 to 3000 revolutions per minute, or just about 1-10 that of the velocity of the Laval turbine, the relative flow of the steam may be used to proper advantage.
2. By stepping down the velocity (compounding) the number of revolutions can be further reduced to 500 to 700 turns per minute for the many cases where such a velocity is deemed expedient.
3. The stepping down of both velocity and pressure is possible at one and the same time and by the application of a small number of pressure steps.
4. In all these cases, all the practical demands for proper construction and driving qualities are to be fully met.

The first essential is the increase in the diameter of the wheel and its relative shape in order to control the peripheral velocity without the use of gearing. Laval did not work in this direction and apparently thought it impracticable; he was therefore compelled to confine himself to the use of gearing and limit his power to small machines not exceeding 300 horse power. Large, rapidly revolving wheels having diameters from 2 to 3 meters, turning 1500 to 3000 times per minute, and giving a peripheral velocity of 1300 to 1700 feet per second, can be constructed with safety. They demand, however, proper use and application of the material and excellent workmanship as well as great care in the control of the dynamic forces. Such wheels have till now not been built.

To give the wheel its proper shape demands an exact calculation in advance, especially of the effects of centrifugal force, which, however, like all other calculations of material forces can be done with absolute certainty. It is further essential that for a predetermined velocity none other than the calculated material forces and their effects be permitted and that these effects should be uncommonly favorable.

The wheels are constructed as solid steel disks. The buckets are not set in but cut in the rim of the disk. The disk is smooth on its outer surface and rim, to lessen the frictional resistance of the steam. Such disks may be exactly balanced without difficulty, by simple means.

The centrifugal forces tax the disk most severely at the center of the wheel. For this reason the wheel disk is not bored out for the shaft but is bolted to a flange at one end of the shaft. Where this is not practical the disk is made with a wide boss at the center, which tapers off to the rim, maintaining a cross section, which answers all demands and makes fullest use of the material (see Fig. 1). Large wheels afford a more advantageous use of the material, and with equal velocity the safety of the disk, at least up to a fixed limit, increases with the diameter. This is easily proven by calculation. Wheels of 6½ feet diameter for 3,000 revolutions per minute may be built of nickel steel with a five-fold margin of safety. But a five-fold margin is not required, two-fold, or at most two-and-a-half-fold is quite sufficient.

Unlike all other mechanical forces the centrifugal force is in effect completely without jar and is continuous, being repeated at each point millions of times. And yet we are satisfied with small margins of safety, especially in locomotives and marine engines.

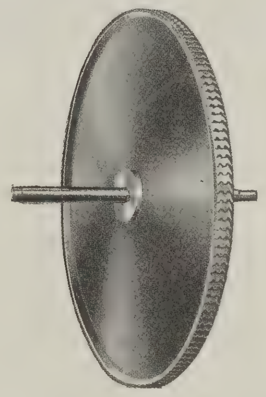

Fig. 2. Turbine Wheel Disk.

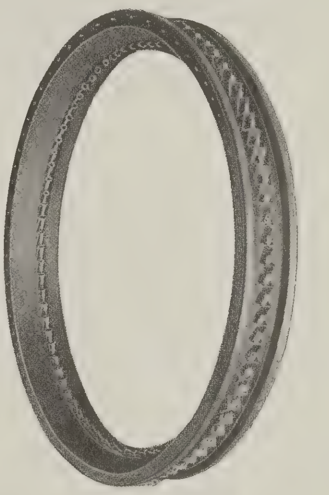

Fig. 3. Nozzle Ring.

The determinative point is the elastic limit or tensile strength of the material from which the wheel is made, at which permanent changes of form take place and should, of course, never be reached.

The first wheel built was made of nickel steel of 107,000 pounds tensile strength. This afforded a margin of safety four times greater than was theoretically required. Without danger then this might be reduced one-half.

When the extreme hardness of this material is considered the thought might well occur that there would be internal strains in the castings, more particularly in the heavier rim. To discover if such were possibly the case the first wheels were sawed across the rim, making many small slits in the periphery, and developments awaited. Should secondary tensions exist the telltale slits, by closing or widening, would disclose the conditions. Since, however, nothing of the sort followed there remained but to conclude that the castings were perfect inside and out. These slotted wheels were also driven at a velocity of 1000 feet per second without unfavorable results, which also proved that the original calculation, in spite of the weakening of the rim, provided for a sufficient margin of safety against the pull of the centrifugal force.

Different, too, from the mounting of the Laval wheels is the construction employed in setting up the Riedler-Stumpf turbines.

De Laval's pliable shaft would not answer for large, heavy, rapidly-moving wheels. To obtain any appreciable bend in the thicker shaft necessary to carry the heavier wheel, the bearings would require to be very far apart. Quite the con-

---

[*] Abstract of paper read by Dr. A. Riedler, Berlin. Published by the Schiffbautechnische Gesellschaft, Berlin, and translated for MACHINERY by Chas. A. Brassler. The Riedler-Stumpf turbine is of the De Laval type, having expanding nozzles from which the steam issues in jets and impinges against the wheel blades. The buckets are similar in construction to those of the Pelton water wheel and the turbine is constructed either in one stage, like the De Laval, or in two or more stages, like the Curtis turbine.—EDITOR.

trary is the case here. The bearings are placed as close as possible to the wheel, so that any give in the shaft is next to zero.

However, the wheels are perfectly balanced upon the shaft, and the inexactitude of the center of gravity corrected to within 0.004 inch. By indefatigable exertion this state—the one in which they are delivered from the works—may be still further corrected to within 0.0004 inch.

The center of gravity of a wheel so carefully adjusted is so true that it will be impossible to exceed the critical velocity, and in fact will not be appreciated by anyone but the most experienced expert.

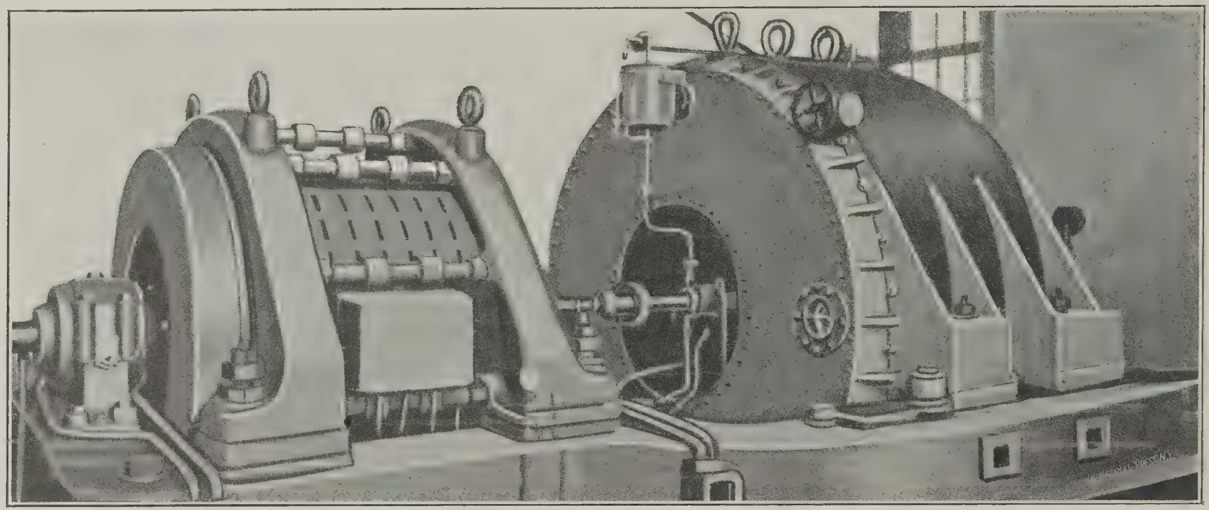

Fig. 4. Two-thousand H. P. Riedler-Stumpf Steam Turbine Direct-connected to Electric Generator.

Having exceeded the critical velocity the condition of dynamic equilibrium could only be found by a slight movement of the axis. For this purpose De Laval made his axis pliable, but in the balanced Stumpf turbine the slight motion of the shaft in its bearings is sufficient. The running of the shaft, even when turning 3,000 to 4,000 times a minute, is faultlessly quiet. The motion of the machine is neither sensible to the touch nor to the eye. Having reached such perfection in the wheel, it was an easy matter to simplify other accessories. As above stated the buckets are not set in, but cut in the solid rim, and these may be cut one, two, or more at a time on the milling machine. The resistance to ventilation is greatly improved or lessened by the overlapping, shingle-like construction of these buckets. If the power is not applied all around the inoperative parts may be uncovered by partitions, which lessen the resistance.

Having the buckets on the exterior of the rim affords a more advantageous adaptation of the nozzle angle; though the effective leverage of the wheel when in motion is slightly decreased thereby. Again, having the buckets on the top of the rim instead of on the side of the rim, as in the De Laval, permits the delivery of the full force of the cross section of the flowing power. In the De Laval nozzle the stream of steam strikes the wheel in an ellipse, whereas with square nozzles of the Riedler-Stumpf type, it strikes it in a solid square. In the former system the impact is uneven, being greater in the center of the ellipse than at its outer edges, whereas with the square stream impinging point blank upon the buckets cut in the outer rim of the wheel all parts of the buckets are attacked with equal force. The Riedler-Stumpf nozzles have a square cross section and lie close together and the steam flowing from them forms a completely closed ring of power. This arrangement makes it possible to surround the whole wheel with nozzles by which many losses may be avoided. The buckets, too, are like little pockets, and constructed either as single pockets in which the steam enters at one side, passes to the opposite side, and exits at an angle of 180 degrees; or they are double pockets with entrance at the middle and exit at the side. The Riedler-Stumpf buckets remind one of the Pelton wheels, though instead of following one behind the other, as in the Pelton, they are one above the other, in layers; nor are they set in, but instead are cut in the rim. Again the Pelton buckets are open on all sides. These are provided with walls which prevent the escape of the steam in any other than the desired direction. The water of the Pelton is not led away, but escapes as best it may, while in the case before us the steam is directed as well at its exit as at its entrance. No packing is needed on the interior of the wheel, as in the De Laval, and there is some considerable play between the rim of the wheel and the mouths of the nozzles. An increase of this distance to 0.2 inch has not shown any lessening on the pressure upon the buckets nor in the work accomplished. In the 2,000-horsepower wheel at Moabit, near Berlin, the radial distance between the nozzle and the bucket is 0.12 inch; in a tangential direction, 0.39 inch. Here we have no axial thrust as a consequence of the sidewise impact, which must be taken up in the De Laval by miter wheels, and in the Parsons by the compensating pistons. The wheels are made of steel and an admixture of 10 per cent. of nickel has been found the best to preserve them against the corrosive influence of rust. The principles of the peculiar shape of the nozzle were acquired by numerous experiments, which showed that form had a marked effect upon the degree of efficiency. In the nozzle the first important step is taken in the advantageous employment of the energy of the steam. It is here that the transition from expansion into flowing energy takes place. The desideratum is to obtain the generation of the maximum velocity as well as the proper leading of the stream.

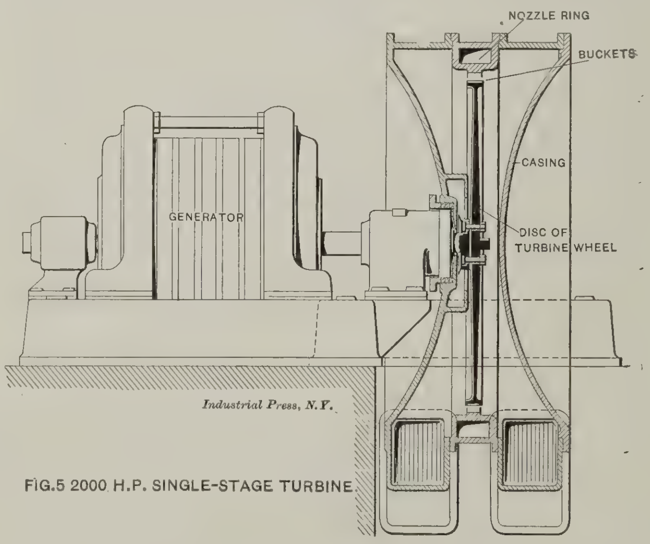

Fig. 5. Two-thousand H. P. Single-stage Turbine.

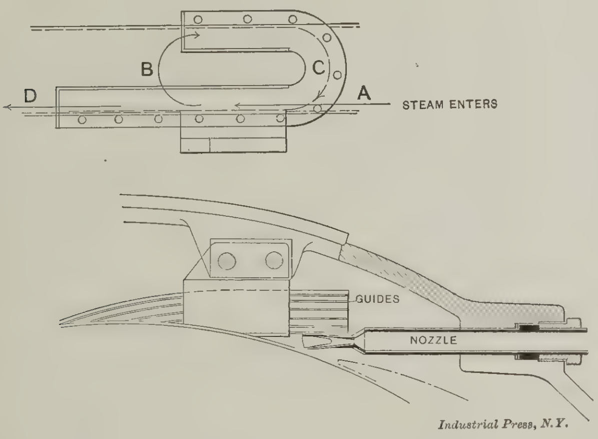
These demands are met by the construction of the nozzles, as shown, which are of easy construction, while the De Laval nozzles, with their elliptical openings do not offer the possibility of grouping them properly together and assuring a reliable leading of the streams of steam one under the other. In Fig. 3 we show a complete ring of nozzles as furnished in the 2,000-horsepower turbine in the electric plant at Moabit, near Berlin. In wheels of less power the nozzles are placed in a single group; in either case the regulation is such that the nozzles may be shut off one after the other from a central point.

The first 500-horsepower experimental turbine constructed is in the machinery department of the Technical High School. It consists of two wheels of 1.5 meters (5 feet) diameter. Where the steam is exhausted in the open air only one wheel is used; with a condenser and an intermediate chamber for changing the direction of the steam, both wheels come into requisition. The nozzle apparatus consists of two rings faced together, in one of which the nozzles are cut so that the single streams form a closed ring. Its first test was made with a hydraulic brake in the Technical High School. In the meantime the Allgemeine Elektrizitäts Gesellschaft constructed an alternating dynamo and they are now coupled together at work in the electric plant. Speeding at 3,000 turns per minute neither the turbine nor the dynamo showed the least vibration.

Using the nozzle apparatus which was arranged for condensation, but only one wheel, the consumption of steam was but 28.6 pounds per effective horse power.

The next wheel built was just four times as powerful and is shown in Fig. 4. It is a 2 000-horsepower turbine for the same electric plant. In building this machine, for the sake of simplicity, though to the disadvantage of the effective force, several losses were permitted. About 5 per cent. of the velocity at the nozzles and 15 per cent. in the shape of the buckets, and an effective loss of 15 per cent. in the intentionally exaggerated exit velocity with which the steam poured into the condenser. In spite of these defects, it was found to run with a consumption of 19.6 pounds of steam, later reduced to 17.6 pounds per kilowatt hour, which compares favorably with the best published statement (19.4) of the 1,500-horsepower Parsons turbine at Elberfeld. The working steam pressure was 195 pounds with a temperature of 294 degrees, though the vacuum was only 85 per cent., simply because the condenser at hand was not capable of producing better results. Now it is well known that the vacuum has a marked effect upon the consumption of steam, therefore with a 95 per cent. vacuum and the avoidance of the above-named losses the consumption can be brought down to 16.5 pounds per kilowatt hour. Again the exhaust losses can be diminished by increasing the diameter of the wheel from 2 meters to 3 meters (10 feet), which would bring the consumption further down to 14.3 pounds per kilowatt hour.

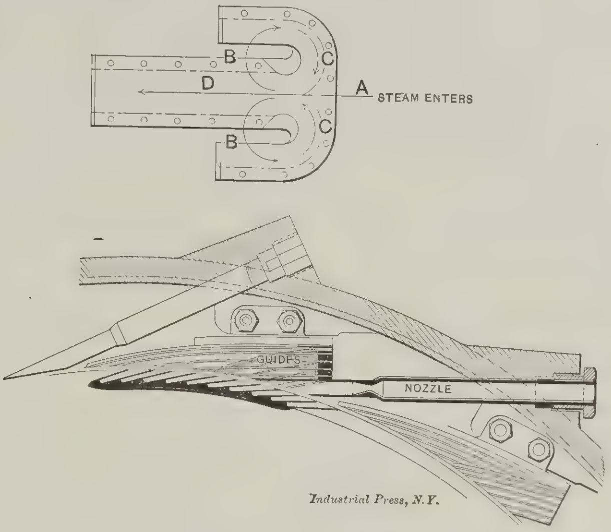


Industrial Press, N.Y.

Fig. 6. Method of Applying Steam twice to the same Set of Buckets.

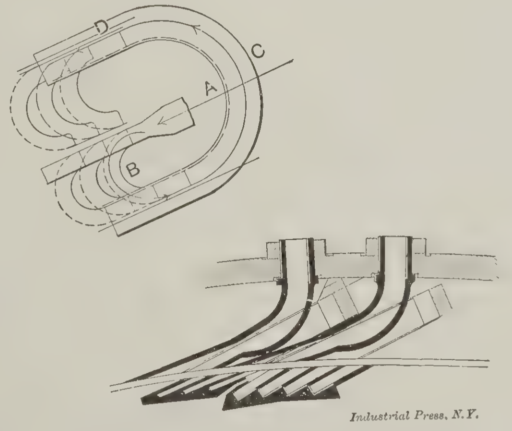
The packing of the shaft at its exit from the casing is done by an oil bearing. At the outer extremity of the oil box is forced a stream of oil which is sucked in by the partial vacuum within, and by means of a system of points the oil is all caught up and carried out again with such economy that during the running no loss in oil was apparent. The small weight of the wheel, 850 kilograms, (about 1,800 pounds), makes the question of keeping the bearings in perfect condition a very simple one. The construction of the one step Riedler-Stumpf turbine is the simplest of all turbines, and it meets at the same time all requirements for accessibility and economical consumption of steam.

The high-speed (3,000 revolutions per minute) is in many cases admissible, especially for alternating current dynamos, blowers, compressors, pumps, etc.; but it is by no means essential to the perfect working of the turbine. The same simplicity prevails when the diameter of the wheel is increased, reducing the number of revolutions to 1,500 per minute, but maintaining the same peripheral velocity. Since it is easily within practical mechanics to construct and run one step turbines of 5 meters (16½ feet) diameter, such wheels are applicable to the driving of direct current dynamos. Fig. 5 is a sketch of a 2,000-horsepower Riedler-Stumpf turbine with a wheel having a speed of 3,000 revolutions. A wheel one meter larger in diameter would need to turn only half as fast to maintain the same peripheral velocity and deliver 5,000 kilowatts at the bus bars. In these huge dynamos the armature is so heavy that the shaft is strong enough to carry the wheel on the free end of the shaft close to the outboard bearing. The casing is therefore built around the pillow block, which thus serves a double purpose. All special bearings for the turbine are in this way eliminated, simplifying the construction still further. These wheels are built in one step, two, three, and four step forms. The stepping down of the velocity is the most effective way of reducing the number of revolutions, and this is done in two ways, one we have already shown by increasing the size of the wheel, the other by stepping down the pressure.



Industrial Press, N.Y.

Fig. 7. Method of Applying Steam twice to the same Buckets when Buckets are of the Pelton Type.



Industrial Press, N.Y.

Fig. 8. Method of taking Steam from one Set of Buckets and Conveying it to a second Set in a Two-stage Machine.

This latter is accomplished by altering the form of the buckets so that with wheels of less diameter the current is made to turn completely around and re-enter the same row of buckets, or by throwing it out of line cause it to enter a neighboring row of buckets.

The formation of the guide passages to produce these results is shown in Figs. 6, 7 and 8. In Fig. 6 steam enters at *A*, at one side of the buckets, passes around the curved buckets of the wheel, as indicated by the arrows at *D*, and when it is discharged from the wheel buckets it enters the guide passages, is deflected at *C*, and finally enters the wheel buckets again at the point *D*.

Figs. 6 and 7 show the method of conducting steam from the buckets of the first wheel to a second row of buckets of another wheel parallel and on the same axis with the first one. In Fig. 7 buckets similar to those of the Pelton water wheel are used, steam impinging at their center and passing both to the right and left. It enters at *A*, is deflected by the buckets at *BB*, whence it enters the guide passages and is deflected again at *CC*, and finally it impinges against the same row of buckets again in the direction of the arrow *D*.

In Fig. 8 steam enters in the direction *A* at one side of buckets *BB*, where it is deflected and then passes around guide *C*, and finally impinges against another row of buckets in the direction *D*. In Fig. 9 is a sectional drawing of a two-stage turbine, similar in its arrangement to the Curtis turbine made in this country. The upper wheel may be classed as a high-pressure wheel and the lower a low-pressure wheel. Steam enters as indicated, and is conducted by suitable passages from the first to the second wheel. It then enters the annular passage *EE*, where it comes in contact with condensing water which enters through openings in the periphery of this passage. The mingled steam and water then flow to the center where they enter between the two rotating disks at *R*. The condensed steam and condensing water are here thrown upward by centrifugal force and are discharged through openings at *MM*. This novel arrangement of the condenser insures thorough intermingling of the water and steam and produces a high vacuum. The shaft of this turbine and generator instead of being carried on a step bearing at the bottom is supported by a bearing, *B*, situated between the turbine and the generator.

ALTERNATING CURRENT MOTORS FOR RAILWAY WORK—AMERICAN DEVELOPMENTS.

WM. BAXTER, JR.

The alternating current motor for traction work is receiving a great deal of attention at the present time and those actively engaged in its development are very sanguine as to its future. The motor which appears to be the best suited to this class of work is what is known as the commutator type. Several experimenters in Europe have been working to develop this form of machine, and it has received considerable attention in this country, the most noteworthy results having been achieved by Mr. B. G. Lamme, of the Westinghouse Company.

The commutator type of alternating current motor is a machine that is practically the same as the ordinary continuous current motor; in fact the only difference, structurally, is in the field core which is made laminated. The proportions of the various parts are somewhat modified, but the action is the same, and one of these motors will run fully as well with continuous as with alternating current; and in fact will give a trifle more power with continuous current of the same voltage and same number of amperes.

Commutator motors of the alternating current type have been made for years, but, up to recently, their performance has not been satisfactory—the efficiency and output being low, and the sparking at the commutator excessive. The motors that have been developed within the last few years are far superior to those previously made, in part because they have been designed to be operated by currents of much lower frequency, but principally because greater skill has been exercised in designing them.

Alternating current commutator motors for a given capacity are larger than continuous current motors, and are of a somewhat lower efficiency. The difference in efficiency is not very great, but in weight the difference is between fifteen and twenty per cent. This latter difference is due in part to the fact that the field coils must be much better insulated to withstand the inductive action of the current, and in part to the fact that the power developed is not equal to the product of the volts and the amperes, but is equal to a percentage of this product, equal to the power factor of the current.

Although the alternating current motor is heavier and of a slightly lower efficiency than the continuous current machine, the difference is not great, and in many cases can be more than offset by the reduced cost of installation. For long distance traction work, with continuous currents, the present practice is to use alternating currents to distribute the energy from the central station, and to provide a number of substations where, through rotary transformers, continuous currents are obtained to feed the trolley lines. As the rotary transformers are moving machines attendants must be provided at the substations. With alternating current motors, the rotary machines at the sub-stations can be replaced by static transformers that require no attendance. These transformers cost much less than the rotary machines, so that the cost of installation and the operating expense are both reduced; hence for long roads the alternating current motors appear to have a promising future. Its advocates claim that it can be shown to be more economical than the continuous current motor, even for city work, owing to the fact that the speed of the motor can be reduced without introducing resistance in the circuit, hence without wasting energy, as is the case with the continuous current motor. While it is true that this waste of energy could be obviated, it is by no means certain that the saving thereby effected would be enough to offset the increased weight of the motors.

The advocates of the alternating motor, to show as great an advantage for it as possible, claim that it could be used with much higher voltage than is now employed on the trolley lines, some of them running as high as 4,000 volts, which they propose to carry right to the car, where it would be passed through a transformer to obtain a low voltage secondary current to operate the motors. While by such means the cost of line wires could be greatly reduced, the danger of seriously injuring the passengers if the insulation failed would be so great that it is doubtful if many conservative engineers could be found who would be willing to indorse the plan. From present indications, however, the alternating current motor can make a place for itself in the railway field without resorting to such wild engineering as the transmission of 3,000 or 4,000 volt currents through the trolley wire, even much less their transmission directly to the car.

Besides the work of Mr. Lamme, of the Westinghouse Company, the most noteworthy attempt to use the single-phase alternating current is to be found in the Arnold system, in which both compressed air and electricity are employed. The motor is operated at constant speed under constant load, the means for increasing or diminishing the power required to operate the car being supplied by the compressed air. The electric motors thus have to be only large enough to propel the car and its machinery under average conditions, and when a given number of cars is in use the power house will operate under a uniform and constant load—quite an unusual condition in railroad work.

[The motor arrangement, as has already been explained in MACHINERY, is such that both the rotor and stator can revolve. One of these is geared to the car axle and both rotary elements are connected to an air engine which can act either as an air compressor or as a motor. By throttling one compressor it can be slowed down and as the rotor and stator must always run at the same speed relative to each other, the other compressor, together with its motor connection, will speed up accordingly, provided the demand for power is not above normal. If the demand is above normal, then one or both of the air engines acts as a motor, operated by the compressed air from the tanks. When the demand is below normal, air is compressed in the tanks by the air engines, which then act like compressors, and is thus in readiness for the next call for extra power. By thus manipulating the air engines, a greater or less degree of power is available for driving the car, as required, and the car can be run either faster or slower than the synchronous speed of the motor.

An important feature, due to the compressed air, is the fact that the car can be driven a short distance by compressed air alone, as in switching or through thickly populated districts, where the presence of a high tension current is objectionable. Mr. Arnold's work has been done in the vicinity of Chicago, and unfortunately his experimental car has recently been destroyed by fire; but another one is to be built.—Editor.]

* * *

THE SINGLE-PHASE MOTOR IN EUROPE.

DR. ALFRED GRADENWITZ.

The single-phase motor for electric traction is best developed in European practice in the motors of Dr. Finzi, of Milan, Italy, and of the Union Electric Company, of Berlin, Germany. The series single-phase motor designed by Dr. Finzi works at constant voltage, regulating its speed automatically, according to the load, the speed being inversely proportional to the latter for high values of the torque. It permits of voltage regulation without losses and of the speed being varied within very extensive limits. On the other hand it is not able to use high voltage directly and at present is bound to relatively low frequencies. Compared with continuous current motors it is found to require fewer watt hours per ton in starting, and the characteristic curves for the single-phase motor are very good indeed.

In November, 1903, a description of the Union Electric Company's motor was published in MACHINERY. Since then the results have come to hand of interesting experiments made by the Union Electric Company on the Spindlersfelde-Johannisthal electric line. This line has been in regular operation since the 15th of August, and has been inspected by a great number of German and foreign engineers. At the present time single motor cars, exclusively, are run; it is intended, however, to run trains made up of two motor-cars and trailers later on. The motor-car, including the whole of its equipment, weighs 52 tons, the electric equipment weighing 6 tons. It is fitted with two 125 horse power motors, mounted on the same rotary frame, one exciting system, and one controller at each end of the car. The car is so designed that any desired number may be coupled together and be operated by one guard. The current is collected by two short bows; automatic safety devices and fuses afford protection against excessively high currents. There is in addition a small transformer to supply current for the pneumatic pumps, as well as the controlling and lighting circuits. There are no shunt resistances.

The motors, constructed by the Union Elektricitäts Ges., according to Winter and Eichberg's data, are designed for a tension of 6,000 volts and for 25 cycles. They are permanently connected in series, and though their efficiency with full speed is, as a matter of course, somewhat less than the efficiency of direct-current motors, this advantage of the latter is offset by their great energy consumption in starting.

The trolley wire of the line conveys the electric energy at a tension of 6,000 volts, the running rails serving as a return circuit. The trolley wire shows some novel features, as instead of being supported by transverse wires the working wire is suspended from longitudinal wires in the form of nearly loose catenary curves. From these longitudinal wires, thin vertical wires are suspended at distances of about three meters, to support the working wire. Part of the track is fitted with one bearing wire, whereas the remainder has two such wires; experiment will show which is the better design. This arrangement of the working wire, where the latter has nearly no tension, will materially diminish the danger of breaking it, and as the suspension points are placed at distances not exceeding three meters, the consequences of a break are, at the same time, notably diminished, the end of a broken wire being beyond the reach of the railway *personnel*.

The Lamme and Dr. Finzi motors, being series motors which absorb immediately only tensions below 160 volts, the electric energy has to be reduced to this low tension. The motors designed by the Union Company can operate under any voltage, and are therefore connected directly with the primary circuit, with the exception of a small portion of the circuit, viz., about the sixth part of the energy, which is reduced to low tension. These advantages will result in small weights of the cars and an improvement in the efficiency, the first point being specially important in connection with narrow gage railways. The small gage railway motor of the Union Company is designed for 40 cycles, so that no difficulties will be met with in lighting the cars, as is the case with motors that operate with much lower frequencies. The greater advantage, however, is the fact that alternating current railways, according to the Union system, may be supplied direct from the same machines designed for supply of light and power, special plants and machines thus being unnecessary in the case of small gage railways for light traffic.

From these trial runs great consequences may be anticipated for the electric industry. In fact, in many cases where present systems are not able to afford sufficient saving to justify electrification the Union system is likely to be used advantageously on account of the absence of sub-stations, the lower cost of equipment of the line, and the high efficiency of the power transmission. The scheme will also be especially advantageous in connection with mountain railways, and long tunnel sections, metropolitan, as well as suburban.

* * *

LARGE WESTINGHOUSE-PARSONS TURBINES.

The Westinghouse-Parsons steam turbine was commercially introduced about four years ago in sizes of 600 horse power. Subsequent development has been so rapid that turbines of 5,500 kilowatts or 7,500 horse power, have been designed and are now under construction. A 5,000 kilowatt unit, of the same general type as these largest machines is illustrated herewith, and its distinguishing features are extreme compactness and low rotative speed. Machines of this type will form the initial equipment of the Pennsylvania Railroad Terminal property in New York City, operating the heavy Pullman trains through the tunnel approaches to Manhattan; and similar installations of turbines and generators are to be made in Philadelphia and London for street railway work.

The space occupied by the 7,500 horse power turbine is approximately 27 feet 8 inches by 13 feet 3 inches, and the height to the top of the hand railing is 12 feet. This is equivalent to .049 square foot (less than one-twentieth square foot) per electric horse power capacity, or 20.2 horse power per square foot of floor area required.

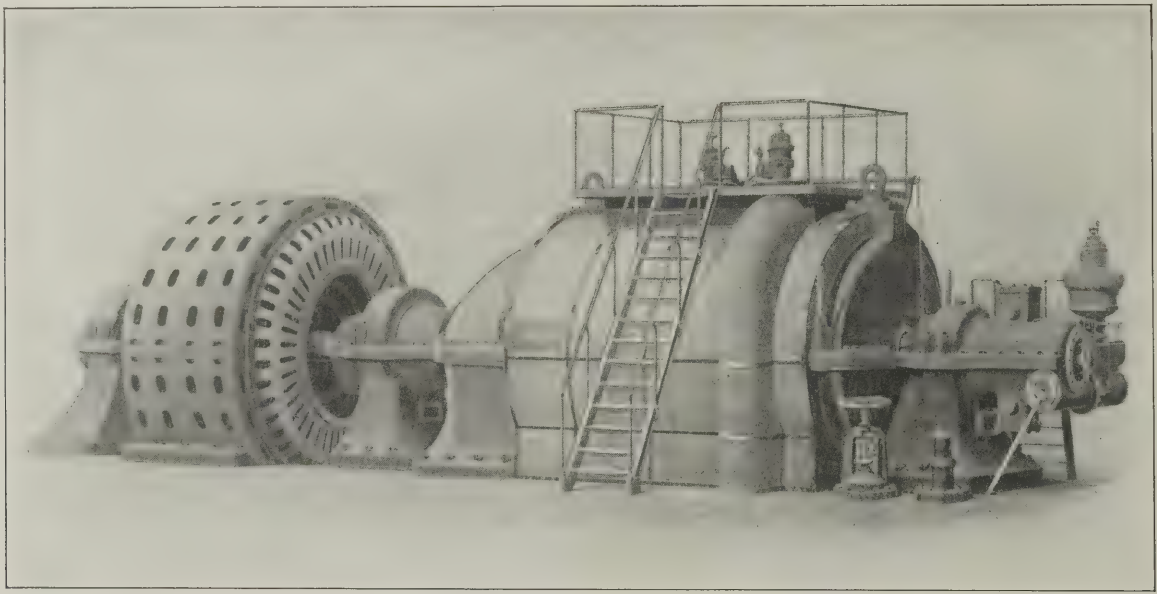
For the complete unit a rectangular area of 47 feet 4 inches in length and 13 feet 0 inches in width is required, which is equivalent to .084 square feet per E. H. P. capacity, or 12 E. H. P. per square foot of floor space. The 5,000 kilowatt units operate at 750 revolutions per minute, the 2,000 kilowatt unit 1,200 to 1,560 revolutions per minute, and the 1,000 kilowatt unit 1,500 to 1,800 revolutions per minute, depending upon the frequency desired.

In the new machines virtually the same general plan of construction and method of using the steam expansively have been retained that were employed in the earlier turbines, and which are very familiar to all readers of technical papers. The single horizontal drum which carries the turbine blades must, however, be supported with unusual rigidity in so large a machine and a novel form of shaft construction has been adopted. A central steel quill carries the entire central rotating parts.

Hollow forged steel ends are forced into the two ends of this quill, under hydraulic pressure, and are in addition secured by arrowhead links. High pressure steam is conveyea to all parts of this quill structure in such a manner as to eliminate stresses and consequent distortion due to highly superheated steam.

The journals in the larger machines are of the solid self-aligning type, similar to that employed in generators and cross-compound engines. The departure from the familiar oil-cushioned journal employed in the small machines is occasioned by the speed reduction secured. The journal shells are babbitt lined and are split horizontally, the two halves being united by bolts with shim adjustment. Oil from a central system is introduced at the center under slight pressure, thoroughly flushing all parts. The diameter of the shaft at the journal of a 5,000 kilowatt machine is 15 inches, strikingly small in comparison to the 34-inch shafts required for a cross-compound reciprocating engine of corresponding capacity.

An important feature of the steam distribution system is the provision of a by-pass valve. This valve admits high pressure steam to the second stage of the turbine on overloads in order to increase its capacity, up to 50 per cent. in excess of full rated load. By properly proportionating the by-pass steam to the overload on the turbine, maximum economy may at all times be secured together with reserve overload capacity. This results in a slight rise in the economy curve on heavy overloads, resembling in some respects the engine economy curve on loads exceeding that of maximum economy. The turbine, however, only suffers in economy at heavy overloads, while the engine economy decreases progressively from 75 to 80 per cent. of full load capacity.



Westinghouse-Parsons 5000 K.W. Generator for Pennsylvania Railroad Terminal, New York.

The main admission valve consists of a double-beat poppet valve operated by a small piston, this in turn being controlled by a small pilot valve directly actuated by the governor mechanism. The valve admits steam to the turbine in puffs, the duration of which is proportioned by the governor to the load upon the turbine. This intermittent method obviates the throttling of steam.

* * *

A writer in *Sparks from the Anvil* refers to the alleged fact that steel will not harden in boiling water and says that the reason for this phenomenon is not apparent since it will harden at higher temperatures as he has proved. He has hardened a chisel in a bath of melted tin, the temperature of which is about 465 degrees F., so that it cannot be the mere heat of the boiling water that prevents steel hardening when dipped in it at the ordinary hardening heat.

NOTES FROM MANCHESTER, ENGLAND.

JAMES VOSE.

Notwithstanding a fairly steady output, the year 1903 has not been characterized by general briskness in the engineering trade of the Manchester district, and the returns of the principal trades unions show an increasing percentage of unemployed amongst their members. Several concerns have, however, been extremely busy. Geo. Richards & Co., Ltd., have double shifts in several departments most of the time. The output during 1903 has been a record one. The pressure of orders is such that important extensions and rearrangements of the shops are under consideration. Boring and turning mills up to 10 feet in diameter have been in great demand, many of them fitted with individual motors—a practice found by Geo. Richards & Co. decidedly on the increase. By means of their patent feed box a large range of positive feeds is instantly obtainable, and their latest improvement is a patent balancing arrangement to the tool bars or slides which entirely dispenses with weights and chains, thus removing what is an objectionable feature in machines as generally built. A recently introduced machine is a duplex turret head boring and turning mill to deal with work up to 24 inches diameter, which has been received with considerable favor, a ready market having been found for the initial machines.

A specialty with this firm is Pearns' pipe facing machine, originally introduced by Mr. Frank Pearns, for facing all descriptions of pipes; but this title is now almost a misnomer, as the machine is so easily adapted to cylinder boring, turning, milling, special facing, etc., that the word "pipe" might well be omitted. A detailed description of this tool might be in order later on. Other lines which have been in good demand are side planers and horizontal boring machines, and the air compressor and sand-blast branches of the firm's business have been continuously engaged on orders throughout the year.

On the other side of Manchester, Bradbury & Co., Ltd., Oldham, are bringing out a turret lathe specially adapted for heavy work. I recently availed myself of an opportunity of seeing it at work, and having its advantages demonstrated, and was very favorably impressed with the solidity and excellent finish of the tool and the ease with which, notwithstanding its massive proportions, it may be manipulated. The hollow spindle has a 4 1-16-inch hole through it, the diameter of the front bearing is 8 inches, and the rear one 5½ inches. A range of 18 speeds in geometrical progression is obtained by friction double and treble back gear in the headstock, and a special countershaft, and by a few quickly-made changes about 60 feeds are available. The tool right through seems a capital blend of the good points of British and American practice. It weighs about 11,000 pounds.

Small turret lathes for the electrical and similar brass-finishing industries have been a strong line with the company for some time, and several important detail improvements were brought to my notice, including a new automatic stock feed motion, dispensing with the objectionable features of the usual wire-feed arrangement.

Mr. S. N. Brayshaw, of Manchester, whose work in the manufacture of milling cutters and analogous fine tools has, during the last few years, attracted considerable attention, has recently made a decided step in advance in the direction of the precisional hardening of cutters, etc., made from carbon steels. As the result of experiments extending over a considerable period, he is now in a position to harden the most intricate cutters, tools, etc., with practically no risk—in fact, the hardening risk has, in his own practice, to all intents and purposes, disappeared. As a result of the fact being made known to the engineering trade he has been almost overwhelmed with hardening orders from outside concerns. In consequence of his researches, he believes he is in a position to prove that in many cases tools may be satisfactorily hardened or ruined within a temperature range of 6 degrees, and can demonstrate a distinct change of appearance in the fracture of a piece with a variation of 1 degree. In the process, which is protected, the articles are partly heated in a gas furnace and then transferred to a special furnace where they are immersed in a bath or melt of salts, the temperature of which can be regulated by means of Bunsen burners and a very delicate electrical pyrometer to within a fraction of 1 degree. After remaining in the melt a length of time varying with its character, the article being dealt with is plunged into water, and the operation is complete. A careful record is kept of every article hardened, and the correct temperature having been found, any number of pieces of the same shape and composition of steel may be hardened with absolute certainty. Mr. Brayshaw prefers hardening customers' own work, but is open to supply furnaces, pyrometers, etc., with the necessary instructions, where such is desired.

Following a prevalent tendency, Meldrum Bros., Ltd., have recently built and equipped a new works on modern lines at Timperley, 7 miles out of Manchester, and are already feeling the benefit of their new facilities for the handling and production of their specialties. Their old shop in Manchester was described in these columns some years ago.

The joint committee of the Manchester Municipal School of Technology and the Manchester Association of Engineers have presented their report on experiments with high-speed tool steels. The report is of an elaborate character. The chief deductions to be drawn from it are, that comparatively moderate speeds and heavy and coarse cuts will remove more metal in a given time than very high speeds and lighter and finer cuts; and that the power required for high-speed cutting does not increase in anything like the same ratio as the speed.

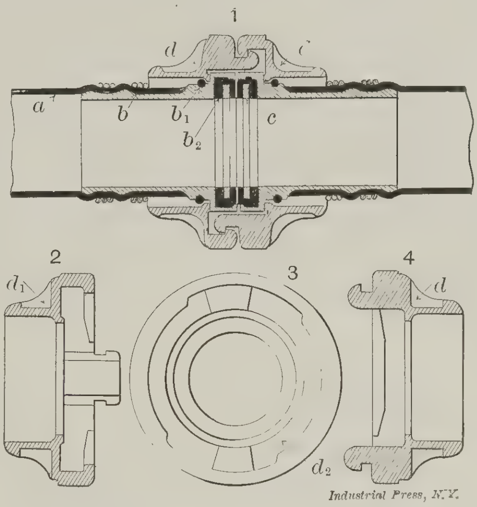
THE STORZ SYSTEM OF PIPE COUPLINGS.

The Storz coupling, like all others of its kind, consists of three principal parts: The lock, the packing and the cover, the latter being entirely independent of the first two. The coupling is formed in two halves, of which the lock and the fastener are exactly alike. The lock takes holds of a groove with a bayonet motion. Since each half, d and d_1, has two hooks, the coupling is held together at four points, two of which are quite sufficient to maintain a perfectly tight joint, so that the other two merely serve to strengthen the connection and act as a reserve. The locking mechanism turns about the binding ring which holds the packing in place, and yet the lock can be turned for coupling or uncoupling without revolving the packing with it, and furthermore, a worn out piece of packing can be removed and replaced without separating the joint. A strong ring protects the bayonet hooks from injury, both when they are opened and closed.

In coupling, the bayonet hooks first slide in the grooves and then enter a decreasing screw surface, so formed that the coupling cannot open of itself, while a slight backward movement of the coupling serves to tighten the packing. The dimensions of the grooves are such that coupling and uncoupling with the dust and dirt that may accumulate in them has no influence whatever. In addition to this there is so much play allowable between the different parts that even when made upon a large scale there is no trouble at all in securing perfect interchangeability.

The construction of the coupling is shown in the illustration; Fig. 1 being a longitudinal section of the whole, while Figs. 2, 3 and 4 are the details. The packing is self-tightening, both by internal as well as external pressure. The rubber-lipped ring, b_2, is pressed more and more tightly into place the higher the water or air pressure in the pipes. These rings are so set in the ends of the pipe castings that they cannot be forced out by any pressure, no matter how high it may be, and further, even when the coupling is opened, the rings are so arranged that they are still protected by an extra outside ring.



Figs. 1 to 4. Storz Pipe Couplings.

In the May, 1903, issue mention was made of the magnesium-aluminum alloy known as magnalium, which has a specific gravity of 2 to 2.5, and other valuable characteristics. Carl Zeiss of Jena has developed two light aluminum alloys called zisium and ziskon which, although heavier than magnalium, have special characteristics that make them also of interest. Zisium has a specific gravity of 2.95 and is somewhat ductile. It makes excellent castings of close texture and rigid structure. The metal works well in the lathe and is handled the same as brass, being turned dry. Tests show that it has a tensile strength of about 11,000 pounds per square inch of section, and an elongation of 0.9 to 1.3 per cent. It takes a high polish and is silvery-white in color. Ziskon is stronger, having a tensile strength of about 25,000 pounds with an elongation of 0.7 per cent. It is heavier than zisium, its specific gravity being 3.35, and is less ductile. It also makes fine castings, works well, and takes a high polish. The unfortunate feature of most such alloys is that the best results can only be produced by an expert who makes his mixtures, etc., with all the accuracy required for a chemical analysis. How it is with these we are not informed, but if they are of the practical everyday nature of, say, brass or bronze mixtures, there should be a considerable field for their use outside that of the manufacture of philosophical and experimental apparatus.

The maximum boiler horse power in central power stations is only attained during a few hours of the day. During the greater part of the day the capacity required is much less than this maximum. On this account it has been found economical and practical to design the boilers and chimneys of ample capacity for this load and to force them above and up to the maximum by means of mechanical draft. This is applied with equal success to old and new plants. In the new power station of the Denver Tramway Power Co., Denver, Colo., mechanical draft is used as an auxiliary to the natural draft provided by a chimney 240 feet high. Artificial draft is furnished by three Sturtevant electrically-driven steel plate fans. The boiler capacity of the plant is approximately 6,000 horse power.

ENGINEERING REVIEW.

CURRENT EVENTS, TECHNICAL AND MECHANICAL—LEADING ARTICLES OF THE MONTH.

The cost of concrete, of course, varies with the locality, but as a general statement it may be said to average one-half the cost of heavy masonry. For piers and abutments the cost of concrete is about $5 per cubic yard as against $12 per cubic for stone. In the vicinity of New York the cost of concrete is estimated at about $6 per cubic yard.

A novel testimonial has been presented to Mr. William E. Corey, president of the United States Steel Corporation, by his associates in the operating department of the Carnegie Steel Company. It is a silver model of a hydraulic forging press such as is used in the manufacture of armor plate, mounted on a base of classic design, the whole being made of silver having a total weight of 535 ounces.

The Girard College for orphan boys in Philadelphia was founded in 1831 by Stephen Girard, who left a bequest of $2,000,000 for that purpose. The chief building is a somewhat remarkable piece of architecture in a number of features. It is an early example of a building heated by the circulation of hot air from furnaces built in the cellar. Flues for ventilation were built in the interior walls which had their apertures in the apex of the arch in each room.
